# New State Recovery Attack on RC4 

Alexander Maximov and Dmitry Khovratovich<br>Laboratory of Algorithmics, Cryptology and Security<br>University of Luxembourg<br>6, rue Richard Coudenhove-Kalergi, L-1359 Luxembourg<br>Alexander.Maximov@ericsson.com, Dmitry.Khovratovich@uni.lu

#### Abstract

The stream cipher RC4 was designed by R. Rivest in 1987, and it has a very simple and elegant structure. It is probably the most deployed cipher on the Earth.

In this paper we analyse the class RC4- $N$ of RC4-like stream ciphers, where $N$ is the modulus of operations, as well as the length of internal arrays. Our new attack is a state recovery attack which accepts the keystream of a certain length, and recovers the internal state. For the original RC4-256, our attack has total complexity of around $2^{241}$ operations, whereas the best previous attack needs $2^{779}$ of time. Moreover, we show that if the secret key is of length $N$ bits or longer, the new attack works faster than an exhaustive search. The algorithm of the attack was implemented and verified on small cases.

Keywords: RC4, state recovery attack, key recovery attack.

## 1 Introduction

RC 4 [Sch96] is a stream cipher designed by Ron Rivest in 1987, and since then it has been implemented in many various software applications to ensure privacy in communication. It is, perhaps, the most widely deployed stream cipher and its most common application is to protect Internet traffic in the SSL protocol. Moreover, it has been implemented in Microsoft Lotus, Oracle Secure SQL, etc. The design of RC4 was kept secret until 1994 when it was anonymously leaked to the members of the Cypherpunk community. A bit later the correctness of the algorithm was confirmed.

In this paper we study a family RC4- $N$ of RC4 like stream ciphers, where $N$ is the modulus of operations. The internal state of RC 4 is two registers $i, j \in \mathbb{Z}_{N}$ and a permutation $S$ of all elements of $\mathbb{Z}_{N}$. Thus, RC4 has a huge state of $\log _{2}\left(N^{2} N!\right)$ bits. For the original version, when $N=256$, the size of the state is $\approx 1700$ bits. This makes any time-memory trade-off attacks impractical. RC4256 uses a variable length key from 1 to 256 bytes for its initialisation.

The initialisation procedure of RC 4 has been thoroughly analysed in a large number of various papers, see e.g. [MS01,Man01,PP04]. These results show that the initialisation of RC4 is weak, and the secret key can be recovered with a small portion of data/time. Because of these attacks, RC4 can be regarded as broken. However, if one would tweak the initialisation procedure, the cipher becomes secure again.

The simplicity of the keystream generating algorithm of RC4 has attracted many cryptanalysis efforts. In most analyses the scenario assumes that keystream of some length is given, and either a distinguishing ([Gol97,FM00,Max05,Man05]) or a state recovery $\left(\left[\mathrm{KMP}^{+} 98\right]\right)$ attack is of interest. A state recovery attack can be used to determine the actual security level of a cipher, if the initial internal state is considered as a secret key. The first state recovery attack was proposed by Knudsen et al in $1998\left[\mathrm{KMP}^{+} 98\right]$. This had a computational complexity of $2^{779}$. Some minor improvements were found in other literature, e.g. [MT98], but still, there is no attack even close to $2^{700}$. One interesting attempt to improve the analysis was recently done in [Man05]. Although that attack is only a potential one, the pretending time complexity claimed was around $2^{290}$.

In this paper we propose a new state recovery attack on RC4- $N$. For the original design RC4-256 the total time complexity of the attack is less than $2^{241}$, requiring keystream of a similar length. This means that there is no additional gain in using a secret key longer than 30 bytes. We also show that in general if the secret key is of length $N$ bits or longer the new attack is faster than exhaustive key search.

The idea of the new attack is as follows. The algorithm searches for a place in the keystream where the probability of a specific internal state, compliant with a chosen pattern, is high. Afterwards, the new state recovery algorithm is used together with a small portion of data (around $2 N$ output words) in order to recover the internal state of the cipher in an iterative manner. This algorithm has been implemented and verified for small values of $N$, it has determined the correct internal state in every simulation run. The success rate of the full attack is shown to be at least $98 \%$. For large values of $N$, where simulations were impossible, an upper bound for the average complexity of the attack is derived and calculated.

This paper is organized as follows. In Section 2 the new iterative state recovery algorithm is described in detail. Afterwards, Section 3 introduces various properties of a pattern that are needed for the recovering algorithm. An effective searching algorithm to find such patterns is also proposed in Appendix B (due to the page limitation and clarity of presentation). Section 4 describes several techniques to detect specific states by observing the keystream, and also introduces additional properties of a pattern needed for detection purposes. Theoretical analysis of the state recovery algorithm and derivation of its complexity functions are performed in Appendix C. All pieces of the attack are then combined in Section 5. Finally, we perform a set of simulations of the attack, summarize the results and conclude in Section 6. The paper ends with suggestions for further improvements and open problems in Section 7.

### 1.1 Notations

All internal variables of RC 4 are over the ring $\mathbb{Z}_{N}$, where $N$ is the size of the ring. To specify a particular instance of the cipher we denote it by RC4- $N$. Thus, the original design is $\mathrm{RC} 4-256$. Whenever applicable, + and - are performed in modulo $N$. At any time $t$ the notation $a_{t}$ denotes the value of a variable $a$ at time
$t$. The keystream is denoted by $\mathbf{z}=\left(z_{1}, z_{2}, \ldots\right)$, where $z_{i}$ is a value $0 \leq z_{i}<N$. In all tables probabilities and complexities will be given in a logarithmical form with base 2 .

### 1.2 Description of the Keystream Generator RC4- $\boldsymbol{N}$

The new attack targets the keystream generation phase of RC4 and, thus, the initialisation procedure will not be described. We refer to, e.g., [Sch96] for a full description of RC4. After the initialisation procedure, the keystream generation algorithm of RC 4 begins. Its description is given in Figure 1.

```
Internal variables:
i,j - integers in }\mp@subsup{\mathbb{Z}}{N}{
S[0\ldotsN-1] - a permutation of integers 0\ldotsN-1
S[\cdot] is initialised with the secret key
The keystream generator RC4-N
    i=j=0
    Loop until we get enough symbols over }\mp@subsup{\mathbb{Z}}{N}{
        (A) i=i+1
        (B) j=j+S[i]
        (C) swap (S[i],S[j])
        (D) }\mp@subsup{z}{t}{}=S[S[i]+S[j]
```

## 2 New State Recovery Algorithm

### 2.1 Previous Analysis: Knudsen's Attack

In $\left[\mathrm{KMP}^{+} 98\right]$ Knudsen et al. have presented a basic recursive algorithm to recover the internal state of RC 4 . It starts at some point $t$ in the keystream $\mathbf{z}$ given $k$ known cells of the permutation $S_{t}$, which helps the recursion to cancel unlikely branches. The idea of the algorithm is simple. At every time $t$ we have four unknowns:

$$
\begin{equation*}
j_{t}, S_{t}\left[i_{t}\right], S_{t}\left[j_{t}\right], S_{t}^{-1}\left[z_{t}\right] \tag{1}
\end{equation*}
$$

One can simply simulate the pseudo random generation algorithm and, when necessary, guess these unknown values in order to continue the simulation. The recursion steps backward when a contradiction is reached due to previously wrong guesses. Additionally, it can be assumed that some $k$ values are a priori known (guessed, given, or derived somehow), and this may reduce the complexity of the attack significantly. An important note is that the known $k$ values should be located in a short window of the "working area" of the keystream, otherwise they cannot help to cancel hopeless branches.

The precise complexity of the attack was calculated in [KMP ${ }^{+} 98$ ], and several tables for various values of $N$ and $k$ were given in Appendices D. 1 and D. 2 of [Man01]. As an example, the complete state recovery attack on RC4-256 would require time around $2^{779}$.

### 2.2 Our Algorithm for State Recovery

In this section we propose an improved version of the state recovery algorithm. Assume that, at some time $t$ in a window of length $w+1$ of the keystream $\mathbf{z}$, all the values $j_{t}, j_{t+1}, j_{t+2}, \ldots, j_{t+w}$ are known. This means that for $w$ steps the values $S_{t+1}\left[i_{t+1}\right], \ldots, S_{i+w}\left[i_{t+w}\right]$ are known as well, since they are derived as

$$
\begin{equation*}
S_{t+1}\left[i_{t+1}\right]=j_{t+1}-j_{t}, \quad \forall t \tag{2}
\end{equation*}
$$

Consequently, $w$ equations of the following kind can be collected:

$$
\begin{equation*}
S_{k}^{-1}\left[z_{k}\right]=S_{k}\left[i_{k}\right]+S_{k}\left[j_{k}\right], \quad k=t+1, \ldots, t+w \tag{3}
\end{equation*}
$$

where only two variables are unknown,

$$
\begin{equation*}
S_{k}^{-1}\left[z_{k}\right], \quad S_{k}\left[j_{k}\right] \tag{4}
\end{equation*}
$$

instead of four in Knudsen's attack, see (1). Let the set of consecutive $w$ equations of the form (3) be called a window of length $w$.

Since all $j$ s in the window are known, then all swaps done during these $w$ steps are known as well. This makes it possible to map the positions of the internal state $S_{t}$ at any time $t$ to the positions of some chosen ground state $S_{t_{0}}$ at some ground time $t_{0}$ in the window. For simplicity, let us set $t_{0}=0$.

Our new state recovery algorithm is a recursive algorithm, shown in Figure 2. It starts with a collection of $w$ equations, and attempts to solve them. A single equation is called solved or processed if its corresponding unknowns (4) have been explicitly derived or guessed. During the process, the window will dynamically increase and decrease. When the length of the window $w$ is long enough (say, $w=2 N$ ), and all equations are solved, the ground state $S_{0}$ is likely to be fully recovered.

Now we give a more detailed description of the different parts of the algorithm.

Iterative Recovering (IR) Block The Iterative Recovering block receives a number $a$ of active equations (not yet processed) in the window of length $w$ as input, and tries to derive the values of $S_{t}\left[j_{t}\right]$ s and $S_{t}^{-1}\left[z_{t}\right] \mathrm{s}$. To do that, the IR block goes through two steps iteratively, until no more new derivations are possible. If all previous guesses were correct, then all newly derived values (cells of the ground state) will be correct with probability 1 . Otherwise, when the IR block finds a contradiction the recursion steps backward. The two steps are as follows.

Fig. 2. New state recovery algorithm.
A. Assume that, for one of the active equations its output symbol $z_{t}$ is already allocated somewhere in the ground state. I.e., the value $S_{t}^{-1}\left[z_{t}\right]$ is known, and the second unknown $S_{t}\left[j_{t}\right]$ can explicitly be derived using (3).
A contradiction arises if (a) $S_{t}\left[j_{t}\right]$ is already allocated and it is not equal to the derived value; (b) the derived value already exists in some other cell.
B. Already allocated values may give the value of $S_{t}\left[j_{t}\right]$ in another equation. Consequently, a new value $S_{t}^{-1}\left[z_{t}\right]$ can be derived via (3), which might possibly cause a contradiction.

Find and Guess the Maximum Clique (MC) Block If no more active equations can explicitely be solved, $S_{t}^{-1}\left[z_{t}\right]$ for one $t$ has to be guessed. The Find and Guess the Maximum Clique block analyses given active equations, and chooses the element that gives the maximum number of new derivations in consecutive recursive calls of the IR block. This element is then guessed.

The analysis is very simple. Let $a$ active equations be vertices $v_{t}$ in a graph representation. Two vertices $v_{t^{\prime}}$ and $v_{t^{\prime \prime}}$ are connected if $z_{t^{\prime}}=z_{t^{\prime \prime}}$ and/or $S_{t^{\prime}}\left[j_{t^{\prime}}\right]$ and $S_{t^{\prime \prime}}\left[j_{t^{\prime \prime}}\right]$ refer (like pointers) to the same cell of the ground state. Guessing any unknown variable in any connected subgraph solves all equations involved in that subgraph. Therefore, let us call these subgraphs cliques. The MC block searches for a maximum clique, and then guess one $S_{t}^{-1}\left[z_{t}\right]$ for one of the equations belonging to the clique. Afterwards, the IR block is called recursively.

Window Expansion (WE) Block Obviously, the more equations we have the faster the algorithm works. Therefore, a new equation is added to the system as soon as the missing value $S[i]$ in the beginning or in the end of the window is derived. The Window Expansion block checks for this event and dynamically
extends the window. Sometimes several equations are added at once, especially on the leafs of the recursion.

Guess One $\boldsymbol{S}[\boldsymbol{i}]$ (GSi) Block If there are no active equations but the ground state $S_{0}$ is not yet fully determined, the window is then expanded by a direct guess of $S[i]$, in front or in back of the window. Then the WE, IR and MC blocks continue to work as usual. Additional heuristics can be applied for choosing which side of the window to be expanded for a larger success.

Appendix A provides an example that shows the steps of the outlined algorithm.

## 3 Precomputations: Finding Good Patterns

The algorithm presented in the previous section is used in the full state recovery attack as a part of it. Every time when the algorithm is running at some point of the keystream, its effectiveness depends on certain properties of the current internal state. Although these properties are not visible for the intruder, she may have a good guess about places in the keystream where the internal state has good properties (see Section 4), and apply the state recovery algorithm only at those places.

In this section we will define patterns (see Definition 1), they determine huge sets of internal states with common properties. If, for instance, a pattern has a large window then this certainly helps decreasing the complexity of the algorithm. However, the probability that the internal state is compliant with a certain pattern decreases with the number of conditions put on the pattern.

In this section we discuss properties of patterns that influence on the complexity of the attack, and also study their availability. We have also developed an efficient algorithm for finding these paterns, and it is located in Appendix B.

### 3.1 Generative States

Let us start with the following definition
Definition 1 (d-order pattern). A d-order pattern is a tuple

$$
\begin{equation*}
A=\{i, j, P, V\}, \quad i, j \in \mathbb{Z}_{N} \tag{5}
\end{equation*}
$$

where $P$ and $V$ are two vectors from $\mathbb{Z}_{N}^{d}$ with pairwise distinct elements. At a time $t$ the internal state is said to be compliant with $A$ if $i_{t}=i, j_{t}=j$, and $d$ cells of the state $S_{t}$ with indices from $P$ contain corresponding values from $V$.

The example in Figure 4 in Appendix A illustrates how a 5-order pattern allows to receive a window of length 15 . However, the higher the order, the less the probability of such a constraint to happen. Thus, we are interested in finding a low order pattern which generates a long window.

Definition 2 ( $w$-generative pattern). A pattern $A$ is called $w$-generative if for any internal state compliant with $A$ the next $w$ clockings allow to derive $w$ equations of the form (3), i.e., consecutive $w+1$ values of $j$ s are known.

Table 1 demonstrates a 4 -order 7 -generative pattern $A=\{-7,-8,\{-6,-5,-4$, $0\},\{6,-1,2,-2\}\}$, that supports the above definitions. Eight equations involve symbols of the keystream $z_{t+1}, \ldots, z_{t+8}$ associated with a certain time $t$. We say that the keystream is true if the internal state at time $t$ is compliant with the pattern, otherwise we say the keystream is random.

Let another pattern $B$ be derived from $A$ as

$$
\begin{equation*}
B=A+\tau=\{i+\tau, j+\tau, P+\tau, V\} \tag{6}
\end{equation*}
$$

for some "shift" $\tau$. The pattern $B$ is likely to be $w$-generative as well. This happens when the properties of $A$ are independent of $N$, which is the usual case.

Table 1. An example of a 4-order 7 -generative pattern.

### 3.2 Availability

We have done a set of simulations in order to find maximum $w$-generative $d$-order patterns, denoted by $M_{d}$. The results are given in Table 7(a) in Appendix D. Searching for a high order pattern is a challenging task since the computational complexity grows exponentially with $d$. The best result achieved in our work is a 14 -order 76 -generative pattern $\mathcal{M}_{4}$.

Table 2. Dependency of the maximum $w$ from $d$, simulated and approximated values.

Table 2 shows the dependency of a maximum achievable generativeness $w_{\max }$ from the order $d$. We can note that this dependency is almost linear, and it converges to $w_{\max }=6 d+\lambda$ as $d \rightarrow \infty$. We make the following conjecture.

Conjecture 1. The rate of $\frac{w_{\max }}{d} \approx 6$ as $d \rightarrow \infty .{ }^{1}$
That conjecture allows us to make a prediction about certain parameters for patterns with large $d$. These could not be found due to a very high precomputation complexity, but they are needed to analyse the attack for large $N$ ( $N=128,256$ in Table 3). However, given those parameters, $d$ and $w$, we can derive theoretical complexities of the attack on average. This has been done in Appendix C.

An efficient search algorithm for patterns with desired properties is given in Appendix B.

## 4 Detection of Patterns in the Keystream

In the previous section we have studied properties of a pattern that are desirable for the state recovery algorithm to work fast and efficient. We have also shown (in Appendix B) how these patterns can be found, and introduced an efficient searching algorithm.

In this section we show how the internal state of RC 4 , compliant to a chosen pattern, can be detected by observing the keystream. If the detection is very good, then the state recovery algorithm might only have to be executed once, at the right location in the keystream.

The detection mechanism itself can be trivial (no detection at all), in which case the algorithm has to be run at every position of the keystream. On the other hand, a good detection may require a deep analysis of the keystream, where specific properties of the pattern can be used efficiently.

### 4.1 First Level of Analysis

The internal state of RC 4 compliant to a $d$-order pattern $A$ can be regarded as an internal event with probability

$$
\begin{equation*}
\operatorname{Pr}\left\{E_{\text {int }}\right\}=N^{-d-1} \tag{7}
\end{equation*}
$$

When the internal event occurs, there could exist an external event $E_{\text {ext }}$ observed in the keystream, and associated with the pattern $A$, i.e., $\operatorname{Pr}\left\{E_{\text {ext }} \mid E_{\text {int }}\right\}=$ 1. Applying Bayes' law we can derive the detection probability $\mathcal{P}_{\text {det }}$ of the pattern $A$ in the keystream as

$$
\begin{equation*}
\mathcal{P}_{\text {det }}=\operatorname{Pr}\left\{E_{\text {int }} \mid E_{\text {ext }}\right\}=\frac{\operatorname{Pr}\left\{E_{\text {int }}\right\}}{\operatorname{Pr}\left\{E_{\text {ext }}\right\}} \tag{8}
\end{equation*}
$$

[^0]Our goal in this section is to study possible external events with high $\mathcal{P}_{\text {det }}$ in order to increase the detection of the pattern.

Definition 3 (l-definitive pattern). A w-generative pattern $A$ is called $l$ definitive if there are exactly $l$ out of $w$ equations with determined $S[j] \mathrm{s}$.

It means that in $l$ equations $S[i]+S[j]$ are known. If, additionally, $z^{\prime}=$ $S[S[i]+S[j]]$ is also known, then the correct value of $z_{t}=z^{\prime}$ at the right position $t$ of the keystream $\mathbf{z}$ detects the case "the state at time $t$ is possibly compliant to the pattern". Otherwise, when $z_{t} \neq z^{\prime}$, it says that "the state at time $t$ cannot be compliant to the pattern".

For detection purposes a large $l$ (up to $d$ ) is important. From our experiments we found that, however, a large $l$ can be achieved via a slight reduction of the parameter $w$. This leads us to one more conjecture.

Conjecture 2. For any $d$ and $w=w_{\max }-\lambda$ there exist a pattern with $l=d$, where $\lambda$ is relatively small ${ }^{2}$.

In the following definition we introduce other properties of a patter that are important for its good detection via the keystream.

Definition 4 ( $b_{\alpha}, b_{\beta}, b_{\gamma^{-}}{ }^{\alpha, \beta, \gamma}$ predictive pattern). Let us have an $l$-definitive pattern $A$ and consider only those equations where $S[j]$ s are determined. Then, the pattern $A$ is called $b_{\alpha}{ }^{-}{ }^{\alpha}$ predictive if for $b_{\alpha}$ of the $l$ equations $S[S[i]+S[j]]$ is determined. For the remaining $l-b_{\alpha}$ equations two additional definitions are as follows. The pattern $A$ is called $b_{\beta}{ }^{-}{ }^{-}$predictive if for $b_{\beta}$ pairs of the $l-b_{\alpha}$ equations the unknowns $S[S[i]+S[j]]$ s must be the same. The set of $b_{\beta}$ pairs must be of full rank. The pattern $A$ is called $b_{\gamma}{ }^{-}$predictive if the $l-b_{\alpha}$ equations contain exactly $b_{\gamma}$ different variables of $S[S[i]+S[j]]$.

These types of predictiveness are other properties of a pattern visible in the keystream. For example, it is not only necessary to search for known $z^{\prime}$ values ( $b_{\alpha}$ of such), but one can also require that certain pairs of the keystream symbols ( $b_{\beta}$ of such) are equal $z_{t^{\prime}}=z_{t^{\prime \prime}}$, which also helps to detect the pattern significantly.

The parameter $b_{\alpha}$ is usually quite moderate and to have it larger than 15 is quite difficult. However, the other criteria are more flexible and can be large. These new parameters follow the constraint

$$
\begin{equation*}
b_{\alpha}+b_{\beta}+b_{\gamma}=l \leq d . \tag{9}
\end{equation*}
$$

Consider the remaining $w-l$ equations of the pattern $A$ where $S[j]$ s are not determined. Let at time instances $t_{1}$ and $t_{2}$ one pair of these equations be such

[^1]that the $S[i]$ values and the $S[j]$ pointers are equal. If the distance $\Delta_{t}=t_{2}-t_{1}$ is small, it is likely that the output $z_{1}$ is the same as $z_{2}$. The probability of this event is
\[

$$
\begin{equation*}
\operatorname{Pr}\left\{z_{1}=z_{2} \mid \Delta_{t}\right\}>\left(1-\frac{\Delta_{t}}{N}\right) \cdot\left(1-\frac{1}{N}\right)^{\Delta_{t}} \approx \exp \left(-\frac{2 \Delta_{t}}{N}\right) \tag{10}
\end{equation*}
$$

\]

Definition 5 ( $b_{\theta-}{ }^{\theta}$ predictive pattern). A pattern $A$ is called $b_{\theta}{ }^{-}{ }^{\theta}$ predictive if the number of such pairs (described above) is $b_{\theta}$. Let the time distances of these pairs be $\Delta_{1}, \ldots, \Delta_{b_{\theta}}$, then the cumulative distance is the sum $\Pi_{\theta}=\Sigma_{i} \Delta_{i}$

These four types of predictiveness are direct external events for a pattern. One should observe the keystream and search for certain $b_{\alpha}$ symbols, check another $b_{\beta}$ and $b_{\theta}$ pairs of symbols that they are equal, and also check that a group of $b_{\gamma}$ symbols are different from the values of $V$ and from each other. Thus, we have

$$
\begin{align*}
& \operatorname{Pr}\left\{E_{\text {ext }}\right\}=N^{-b_{\alpha}-b_{\beta}-b_{\theta}} \cdot\left[\frac{(N-d)!}{N^{b_{\gamma}}\left(N-d-b_{\gamma}\right)!}\right]  \tag{11}\\
& \operatorname{Pr}\left\{E_{\text {int }}\right\} \approx N^{-d-1} \cdot e^{-2 \Pi_{\theta} / N} .
\end{align*}
$$

The example in Table 1 is a 4-definitive $b_{\alpha}=1, b_{\beta}=1, b_{\gamma}=2, b_{\theta}=0$ predictive pattern. For detection one has to test that $z_{t+6}=-2, z_{t+3}=z_{t+4}$, and $z_{t+4}, z_{t+5}$ are different from the initial values at $V$ and $z_{t+4} \neq z_{t+5}$. I.e., when, for example, $N=64$, the detection probability is $64^{-5} \div\left(64^{-2} \cdot 60 \cdot 59 / 64^{2}\right) \approx$ $64^{-2.96}{ }^{3}$.

### 4.2 Second Level of Analysis

In fact, the first level of analysis allows to detect a pattern with probability at most $N^{-1}$ (because $j$ is not detectable), whereas with the second level of analysis it can be 1 . Let us introduce a technique that we call a chain of patterns.

Definition 6 (chain of patterns $A \rightarrow B$, distance, intersection). Let us have two patterns $A=\left\{i_{a}, j_{a}, P_{a}, V_{a}\right\}$ and $B=\left\{i_{b}, j_{b}, P_{b}, V_{b}\right\}$. An event when two patterns appear in the keystream within the shortest possible time distance $\sigma$ is called chain of patterns, and is denoted as $A \rightarrow B$ if $B$ appears after $A$.

The chain distance $\sigma$ between two patterns $A$ and $B$ is the shortest possible time between $A$ 's ending and $B$ 's beginning of their windows, i.e.,

$$
\begin{equation*}
\sigma=i_{b}-\left(i_{a}+w_{a}\right) \quad \bmod N \tag{12}
\end{equation*}
$$

The intersection of $A$ and $B$ is the number $\xi$ of positions in $A$ that are reused in $B$. These positions must not appear as $S[i]$ during $\sigma$ clockings while the chain distance between $A$ and $B$ is approached.

[^2]For example, let $A=\{0,0,\{1,3,5,6,7,8,22,23\},\{2,8,-3,-2,1,7,4,-9\}\}$ and $B=\{34,34,\{35,36,37,38,39,44,48,52\},\{8,-2,1,2,4,-5,5,3\}\}$. After $w_{a}=$ 30 clockings the first pattern becomes $A^{\prime}=\{30,28,\{15,28,30,35,36,37,38,39\}$, $\{-3,-9,7,8,-2,1,2,4\}\}$. Obviously, the last $\xi=5$ positions can be reused in $B$, and after $\sigma=4$ clockings a new pattern $B\left(w_{b}=34\right)$ can appear if $j_{t+34}=j_{b}$. The probability that the chain $A \rightarrow B$ appears is $N^{-9} \cdot N^{-4}$, multiplied by the probability that 5 elements from $A^{\prime}$ stay at the same locations during the next 4 clockings. This is much larger than the trivial $N^{-9} \cdot N^{-9}$. Thus, a more general theorem can be stated.

Theorem 1 (chain probability). The probability of a chain $A \rightarrow B$ to appear is

$$
\begin{equation*}
\mathcal{P}_{A \rightarrow B}=\operatorname{Pr}\left\{E_{\text {int }}\right\} \approx N^{-\left(d_{a}+d_{b}+2-\xi\right)} \cdot e^{-2\left(\Pi_{\theta a}+\Pi_{\theta b}\right) / N} \cdot e^{-\xi} \tag{13}
\end{equation*}
$$

Proof. In [Man01] it has been shown that $\xi$ elements stay in place during $N$ clockings with an approximate probability $e^{-\xi}$. The remaining part comes from an assumption that the internal state is random, from where the proof follows.

Obviously, the probability of the external event for the chain is

$$
\begin{equation*}
\operatorname{Pr}\left\{E_{\text {ext }}\right\}=N^{-\left(b_{\alpha a}+b_{\beta a}+b_{\theta a}\right)-\left(b_{\alpha b}+b_{\beta b}+b_{\theta b}\right)} \tag{14}
\end{equation*}
$$

which can be smaller than $\operatorname{Pr}\left\{E_{\text {int }}\right\}$ (see $\mathcal{Y}_{4}$ in Table 6 in Appendix D), confusing the equation (8). This happens since $\operatorname{Pr}\left\{E_{\text {ext }}\right\}$ is calculated assuming that the keystream is random. However, in RC4 only a portion of the observed external probability space can appear (which is another source for a distinguishing attack, but it is out of scope of this paper). Therefore, in the case when $\operatorname{Pr}\left\{E_{\text {ext }}\right\}<$ $\operatorname{Pr}\left\{E_{\text {int }}\right\}$ we simply assume that the detection probability is 1 .

Table 6 in Appendix D presents a few examples with a good trade-off (based on our intuition) between $w$ and detectability for various $d$. Since the computation time for searching such patterns with multiple desired properties is really huge, only a few examples for small $d$ were given. However, we believe that for large $d$ it is possible to detect such patterns with a high probability, up to 1 , applying the two proposed levels of analysis.

## 5 Complete State Recovery Attack on RC4

### 5.1 Attack Scenario and Total Complexity

Recall pattern detection techniques from Section 4. In the attack scenario an adversary analyses the keystream at every time $t$, and applies the state recovery algorithm if the desired internal event (pattern) is detected. In all cases except one the recovering algorithm deals with a random keystream.

Proposition 1 (Total Attack Complexities). Let the detection probability be $\mathcal{P}_{\text {det }}$, then the total time $C_{T}$ and data $C_{D}$ complexities of the attack are

$$
\begin{align*}
& C_{T}=\operatorname{Pr}\left\{E_{\text {int }}\right\}^{-1}+\left(\mathcal{P}_{\operatorname{det}}^{-1}-1\right) \cdot C_{\text {Rand }}+1 \cdot C_{\text {True }} \\
& C_{D}=\operatorname{Pr}\left\{E_{\text {int }}\right\}^{-1} \tag{15}
\end{align*}
$$

### 5.2 Success Rate of the Attack

The complexities $C_{\text {True }}$ and $C_{\text {Random }}$ are upper bounds for the average time the algorithm requires. It means that for some cases it could take more time than these bounds. In order to guarantee the upper bound of the total (not average) time complexity one can terminate the algorithm after, for example, $C_{\mathrm{thr}}$ operations. In this case the success rate of the attack can be determined.

Fig. 3. Probability density (left) and cumulative (right) functions of the time $C_{\text {True }}$ in logarithmical form ( $k=\log _{2} C_{\text {True }}$ ). The scenario is $N=64, M_{8}$ and 2000 samples.

Figure 3 shows density and cumulative functions for the time complexity of an example attack scenario. It shows that around $98 \%$ of all simulations of the attack have time smaller than the average $2^{29.28}$ (vertical line). When the keystream is random the termination makes the average time bound $C_{\text {Random }}$ even smaller, since the random case is likely to be repeated very many times and the second term in (15) can only decrease.

The plots in Figure 3 also show that even if the termination of the algorithm is done on the level $C_{\mathrm{thr}}=\sqrt{C_{\text {True }}}\left(\approx 2^{15}\right)$, the success rate of the attack is still very high. I.e., the state recovery algorithm on RC4-64 can be done in time $2^{15}$ with success probability $35 \%$ ! If a similar situation happens for large $N$ (e.g., $N=256$ ), then the full time complexity can be significantly decreased (perhaps, down to a square root of the estimated average complexity), and the success probability can still be very large.

## 6 Simulation Results and Conclusions

We have selected a set of test cases with various parameters and patters, and derived total data and time complexities of the new attack. Table 3 presents the results of this work. For example, when $N=64$, the total complexity of the new attack is upper bounded by $2^{60}$, if the pattern $\chi_{9}$ is used. This is much faster than, for example, Knudsen's attack, which complexity for this case is $2^{132.6}$. Even if $d=9$ elements of the state are known, Knudsen's attack needs $2^{98.1}$ of time, which is still much higher. The complexity of a potential attack recently discussed by I. Mantin in [Man05] ${ }^{4}$ is also higher. As it was shown in Section 5.2, the success rate of the new attack is at least $98 \%$.

Table 3. Simulation results and comparisons with previous attacks.

[^3]Table 3 also contains intermediate probabilities and complexities for the attack, including theoretical $(\Delta=0)$ and attuned $(\Delta=2)$ values for $C_{\text {Rand }}$ and $C_{\text {True }}$. When it was possible, the real attack on a true keystream was simulated (real complexities for $C_{\text {True }}$ are shown in italic). In these simulations the complete state of RC4 was successfully recovered for every randomly generated keystream compliant with the corresponding pattern.

For larger $N$, patterns of a high order are needed to receive an attack of low complexity. The largest pattern that we could find in this work is $\mathcal{M}_{4}$, and this was applied to attack RC4- $N$ with $N=128,160,200,256$. These attack scenarios are those that we have in our hands already. However, the complexities received are not optimal, but they are still lower than in Knudsen's attack. Conjecture 1 and also discussions in Section 4 make it possible to approximate the parameters of a hypothetical pattern that is likely to exist ( $\star$ - patterns). To be secure, we relate $d$ and $w$ as $w=6 d-6$, with a confidence gap of 6 positions. The remaining parameters were chosen moderate as well. As the result, we obtained an attack on RC4-256 with the (upper bounded) total complexity of $2^{241.7}$, and this is the best state recovery attack known at the moment.

In general, we have noted the following tendency. For RC4- $N$ with a secret key of length $N$ bits or longer, the new attack can recover the internal state much faster than an exhaustive search. This observation can also be seen from the results in Table 3.

As the last point of the discussions we note that the key recovery attack can be easily converted from a state recovery attack. There are several papers dealing with recovering the secret key from a known internal state [MS01,Man01,PM07]. However, this part works much faster than currently known state recovery attacks, and, therefore, we just refer to these papers without giving details.

## 7 Further Improvements and Open Problems

Pattern detection improvements. With a chain of patterns described in Section 4 one could reach a good detection. However, not only forward direction of chaining can be considered, but also backward one. Additionally, there is a possibility to analyse longer sequences of patterns in order to have a good detectability. Another idea is to use unusual recyclable patterns in a similar manner as in [Man05]. The difference is that these patterns are both recyclable and have a long window. For example, $A=\{0,-4,\{6,4,1,5,3\},\{0,1,7,-2,-1\}\}$.

State recovery algorithm improvement. The GSi block can choose the corner (left or right) of the window to be extended by an additional heuristic analysis of the current situation during the process. Another improvement is achieved if the MC block could speculatively run the recursion for additional 1-3 extra forward steps for every possible guess, and, afterwards, make such a guess for which the number of sub branches is the minimum. The average time of the attack for this strategy is reduced.

Derivation and statistics. Our investigation showed that the derived theoretical upper bound gives a much larger complexity than the one received from the
real simulations of the attack. Obviously, a better analysis of the algorithm's complexity is needed. This would allow a more accurate estimation of the total complexity, and it might improve the complexities in Table 3 significantly. Another interesting problem is to determine the density function of the recovering algorithm, likewise in Figure 3. This may allow us to decrease the complexity in square root times, maintaining a high success rate.

Other open problems. The search for patterns of a higher order with long windows is another challenging open question. We have shown that there are chains of patterns with short distances. The first pattern is used for the recovering algorithm, and the second one is for detection. However, another interesting question is whether or not the second pattern can also be used in the recovering algorithm.

We believe that the outlined open problems have a huge potential for reducing the complexity of the attack on RC4. Perhaps, very soon we will be witnessing an attack of complexity lower than $2^{128}$ on the full RC4-256.

## A Example Support for the State Recovery Algorithm

Figure 4 illustrates an example of the process of the IR block. In the example we start with specific values of $i$ and $j$, and also $d=5$ cells of the state $S$ are filled with certain values, whereas the remaining cells are unknown. This constraint allows to collect $w=15$ equations of the form (3). The keystream is given in the rightmost column of the table.

The first iteration, in Figure 4(b), finds that $z_{6}=4$ and $z_{8}=-2$ are already allocated, thus solving equations 6 and $8\left(s_{4}=10, s_{9}=5\right)$. Afterwards, given $s_{9}=5$, the IR block solves the equation 14 and successfully checks for a contradiction, in Figure 4(c). Finally, after the step (e) four additional cells of the state $S$ were derived with probability 1.

When the IR block is processed, the input to the MC block is the maximum clique of size 4 equations with 5 unknowns, shown in Figure 4(f). It means that guessing only one unknown determines four other ones. Furthermore, the space of possible guesses is significantly reduced due to the higher probability of a contradiction to occur.

## B Searching Technique

Since the search space for a $d$-order pattern grows exponentially with $d$, only patterns of order $d \leq 6$ were analysed before in various literature, e.g., in [Man05]. In this section we suggest a few techniques that accelerate this search significantly, and allow to search and analyse patterns of order up to $d \leq 15$, approximately, on a usual desktop PC.

First, we need to make some observations on the construction of patterns. Afterwards, several ideas based on the observation for improving the algorithm follow.

Fig．4．Example of the iterative reconstruction process．

As can be seen from Table 7 in Appendix D，all＂good＂patterns found have $V \mathrm{~S}$ with values from a short interval $I_{\delta}=[-\delta \ldots+\delta]$ ，where $\delta \approx 10 \ldots 25$ is quite

Fig. 5. Dependency of the maximum $w$ from $\delta$ for various $d$.
conservative. Figure 5 illustrates the dependency of the maximum achievable $w$ from $\delta$. From this we make the following conjecture.

Conjecture 3. A pattern with the largest $w$ is likely found among all possible combinations for $i=0, j \in I_{\delta}, V \in I_{\delta}^{d}$, with a moderate value of $\delta \ll N$.

This conjecture will be used as the basis for a significant improvement in the searching technique of such patterns.

Table 4 provides the number of patterns for $\delta=15$, and various values of $d$ and $w$. When $d$ and $\delta$ are fixed, the amount of desired patterns can be exponentially increased by letting $w$ be slightly less than $w_{\max }$. This approach can help finding patterns with additional properties which are introduced in Section 4.

| $\begin{array}{lr} \hline d & \\ \downarrow & w \\ 4 & \#\left\{A_{4}\right\} \end{array}$ | The number of patterns $A_{d}$ when $\delta=15$. |  |  |  |  |  |

Table 4. The number of different constraints for specific $d$ and $w$, when $\delta=15$.

The first idea is to set $i=0$ due to (6), and for the remaining variables only a small set of values $I_{\delta}$ for some $\delta$ should be tested due to Conjecture 3.

A straightforward approach would be to allocate $d$ values in a vector $S$ and then to check the desired properties of the pattern. The time complexity of this
approach is $O\left(\binom{N}{d}\binom{\left|I_{\delta}\right|}{d}\left|I_{\delta}\right|\right)$, which is still very large. Our second idea is to allocate a new element in $S$ only when it is necessary. This will significantly decrease the time complexity.

Fig. 6. Recursive algorithm for searching patterns with large $w$.

The diagram of a recursive algorithm exploiting the first two ideas is shown in Figure 6, but it can be improved with the following heuristic. The third idea is to start searching for a desired pattern somewhere in the middle of its future window. Let us split $d$ as $d=d_{\mathrm{fwd}}+d_{\text {back }}$ and then start the algorithm in Figure 6 allowing to allocate exactly $d_{\text {fwd }}$ cells of $S$. At the point $(*)$ the current length of the window $w$ is compared with some threshold $w_{\text {thr }}$. If $w \geq w_{\text {thr }}$, then a similar recursive algorithm starts, but it goes backward and allocates remaining $d_{\text {back }}$ cells of $S$. This double-recursion results in a pattern with $w$ likely to be close to the maximum possible length of the window.

## C Complexity Analysis of the Recovering Attack

Since for large inputs it is not always possible to make real simulations of the new recovering attack, we are interested in a theoretical upper bound of its complexity. In this section we explain how this complexity can be derived, verified and used.

## C. 1 Tool for Simulations and Analysis

The new recovering algorithm is a recursion as shown in Figure 7(a). The nodes are IR and WE blocks, whereas each branch is initiated by MC or GSi blocks.

A branch is terminated when a contradiction occurs, and only one path leads to the correct solution, where the internal state is successfully recovered.

We measure the complexity of the attack as the number of branches, i.e., the number of guesses in the MC and GSi blocks done.

Fig. 7. (a) Attack as a recursion; (b) Three parts of the tool for simulations.

Let us introduce a three-part tool, shown in Figure 7(b), in order to calculate the complexity of the attack when a certain pattern is given. We give a description of each of the three parts.

In the first part the simulation of the attack with a certain pattern is launched (all four blocks, IR, WE, MC, GSi, are working), and the number of branches is counted. Whenever the depth of the recursion reaches $\Delta_{\mathrm{thr}}$, some precomputed function for the complexity of the remaining subtree is called, and the recursion makes a backward step.

The second part is a precomputed pattern-independent upper bound of the average complexity, when the status of the recursion can be described as the number of already allocated cells $L$ and the number of active equations $a$.

The third part is Knudsen's attack complexity accepted as an upper bound for the algorithm on the leafs of the recursion, in order to avoid analysis of WE.

To receive theoretical complexity using this tool one should run the simulations a sufficient number of times, and then take an average of the results. The exact complexity is received when $\Delta_{\text {thr }}=\infty$, in this case the tool requres the same computational time as the targeting complexity. On the other hand,
when $\Delta_{\text {thr }}=0$, the upper bound of the complexity is received immediately. The reason to introduce $\Delta_{\mathrm{thr}}$ and the three parts of the tool will be explained later.

## C. 2 Assumptions

We will derive the precomputed pattern-independent upper bound of the average complexity under the following assumptions.

Assume that the algorithm first processes all given $w$ equations of the kind (3) with two unknowns in each, and then Knudsen's attack is applied to the remaining part of the recursion (see table on the right, in the columns with WE on and off).

Assume that in all given $w$ equations the values $S_{t}\left[j_{t}\right]$ refer to different unknowns. This makes the attack slower since in the MC block the maximum clique can then only be constructed via keystream symbols. The table on the right shows that for this assumption the complexity of the attack is higher.

Assume that the keystream is random, which is reasonable since the real internal state is unknown to an attacker. We have selected several patterns with similar properties, $d=$ $4, w=9$ ( $凡$ s and $\mathfrak{O}$ s from Table 7). One half of them have different $S_{t}\left[j_{t}\right] \mathrm{s}$, and the other half contains pairs of equal $S_{t}\left[j_{t}\right] \mathrm{s}$. Afterwards, the complexities of the attack are estimated $\left(\Delta_{\mathrm{thr}}=\right.$ $\infty, N=25$ ) when the keystream is random/true, and WE is on/off. The results clearly show that the complexities under our assumptions are upper bounds.

## C. 3 Average Complexity Derivations

In this section a precomputed pattern-independent upper bound of the average complexity is derived under the assumptions proposed above. In all formulas the following meaning of variables is accepted: $a$ is the number of active (not yet processed) equations of the form (3); $L$ is the number of known and previously assigned cells of the state, and no single $z_{t}$ from the active equations can be one of the $L$ values; $l$ is the number of already (the most recently) assigned cells of the state, and $z_{t}$ s from active equations could possibly be one of the $l$ values; $q_{\max }$ is the size of the maximum possible clique that can be found in the MC block.

Fig. 8. Four cases supporting derivations of the attack complexity.

Every step of the recursion has a complexity to which we will refer as: $C_{\mathrm{K}}(L)$ is the complexity of Knudsen's attack, given that $L$ cells of the internal state are known, and it can be precomputed as in $\left[\mathrm{KMP}^{+} 98\right] ; C_{\mathrm{MC}}\left(L ; a ; q_{\max }\right)$ is the complexity of the MC block; $C_{\mathrm{IR}}^{\mathrm{AO}}\left(L ; l ; a ; q_{\max }\right)$ is the complexity of one iteration of the IR block that starts with $L$ known and $l$ new values, and ends with another set of new values of some size $\delta ; C_{\mathrm{IR}}^{\mathrm{A} 1}\left(L ; l ; a ; q_{\max }\right)$ is the same as $C_{\mathrm{IR}}^{\mathrm{AO}}$, but for one of the equations the value of $S[j]$ is known; $C_{\mathrm{IR}}^{\mathrm{B}}\left(L ; a ; q_{\max }\right)$ is the complexity of the case when IR returns no new assignments, but for one equation $S[j]$ is known, i.e., the IR block makes an iteration of a different sort in this case.

Supplementary Formulas When $L$ cells of $S_{0}$ are already known and $\delta$ new assignments are performed one by one, the probability of no contradiction is

$$
\begin{equation*}
\mathcal{P}_{c}(L ; \delta)=\frac{(N-L)!}{(N-L-\delta)!N^{\delta}}, \quad \text { when } \quad 0 \leq L+\delta \leq N \tag{16}
\end{equation*}
$$

Let $M(r ; a ; q)$ be the number of possible keystream sequences of length $a$, where each symbol can have one out of $r$ values, and the maximum possible size
of a clique is $q$. The value of $M$ can recursively be calculated as ${ }^{5}$

$$
\begin{align*}
& M(r ; a ; q)=\sum_{i=0}^{q}\binom{a}{i} M(r-1 ; a-i ; q), \quad \text { where } \quad\left\{\begin{array}{l}
1 \leq a, t \leq N \\
q \leq a
\end{array}\right.  \tag{17}\\
& M(r ; 0 ; 0)=1, \quad \text { where } 1 \leq t \leq N
\end{align*}
$$

Complexity $\boldsymbol{C}_{\mathrm{IR}}^{\mathrm{AO}}\left(\boldsymbol{L} ; \boldsymbol{l} ; \boldsymbol{a} ; \boldsymbol{q}_{\max }\right)$ The probability that, in one iteration, $\delta$ out of $a$ equations will be solved is

$$
\begin{align*}
\mathcal{P}_{\mathrm{A} 0}\left(L ; l ; a ; \delta ; q_{\max }\right)= & \binom{a}{\delta} \frac{M\left(l ; \delta ; q_{\max }\right) \cdot M\left(N-L-l ; a-\delta ; q_{\max }\right)}{M\left(N-L ; a ; q_{\max }\right)}, \\
& \text { when }\left\{\begin{array}{l}
0 \leq L+l+a \leq N, \\
0 \leq \delta \leq a
\end{array}\right. \tag{18}
\end{align*}
$$

In these $\delta$ equations $z_{t}$ must be one of the $l$ values and they must give $\delta$ new values $S_{t}\left[j_{t}\right]$, since, otherwise, they would have been found before. For each of the $\delta$ equations, $S_{t}\left[z_{t}\right]$ is allocated somewhere. Thus, a new value $S_{t}\left[j_{t}\right]=$ $S_{t}^{-1}\left[z_{t}\right]-S_{t}\left[i_{t}\right]$ can be derived. The number of active equations is evidently reduced by $\delta$. The total complexity of $C_{\mathrm{IR}}^{\mathrm{AO}}$ is recursively expressed as

$$
\begin{align*}
& C_{\mathrm{IR}}^{\mathrm{AO}}\left(L ; l ; a ; q_{\max }\right)=\sum_{\delta=1}^{a-1} \mathcal{P}_{\mathrm{A} 0}\left(L ; l ; a ; \delta ; q_{\max }\right) \cdot \mathcal{P}_{c}(L+l ; \delta) \cdot C_{\mathrm{IR}}^{\mathrm{AO}}\left(L+l ; \delta ; a-\delta ; q_{\max }\right) \\
& \quad+\mathcal{P}_{\mathrm{AO}}\left(L ; l ; a ; a ; q_{\max }\right) \cdot \mathcal{P}_{c}(L+l ; a) \cdot C_{\mathrm{K}}(L+l+a) \\
& \quad+\mathcal{P}_{\mathrm{AO}}\left(L ; l ; a ; 0 ; q_{\max }\right) \cdot C_{\mathrm{MC}}(L+l ; a), \quad \text { when }\left\{\begin{array}{l}
0 \leq L+l+a \leq N, \\
1 \leq q_{\max } \leq a,
\end{array}\right. \\
& C_{\mathrm{IR}}(L ; l ; 0 ; 0)=C_{\mathrm{K}}(L+l), \quad \text { when } \quad L+l \leq N . \tag{19}
\end{align*}
$$

Complexity $\boldsymbol{C}_{\mathrm{MC}}\left(\boldsymbol{L} ; \boldsymbol{a} ; \boldsymbol{q}_{\max }\right)$ The probability of a maximum clique of size $q$ to appear is

$$
\begin{align*}
& \mathcal{P}_{\mathrm{MC}}\left(L ; a ; q_{\max } ; q\right)= \\
& \quad \frac{M(N-L ; a ; q)-M(N-L ; a ; q-1)}{M\left(N-L ; a ; q_{\max }\right)}, \quad \text { where }\left\{\begin{array}{l}
1 \leq L+a \leq N \\
1 \leq q \leq q_{\max } \leq a
\end{array}\right. \tag{20}
\end{align*}
$$

with a boundary case $\mathcal{P}_{\mathrm{MC}}(L ; 0 ; 0 ; 0)=1$. The parameter $q_{\text {max }}$ tells us that in the remaining active equations no cliques of size more than $q_{\text {max }}$ exist, since, otherwise, it would have been found on a previous call of the MC block.

Consider the unknown $x=S_{t}^{-1}\left[z_{t}\right]$ from the clique that has to be guessed as one of the $N-L$ remaining values. The choice of $x$ is in principal one of the

[^4]following three options. (a) $x$ is one of the $j_{t} \mathrm{~s}$ and the equation associated with time $t$ belongs to the clique. This happens in $q$ choices and results in $q-1$ new values. An additional contradiction test should be included: $S_{t}\left[i_{t}\right]+z_{t}$ must be equal to $S_{t}^{-1}\left[z_{t}\right](=x)$. (b) $x$ is one of the $j_{t} \mathrm{~s}$ and the equation associated with time $t$ does not belong to the clique. This happens in $a-q$ choices and results in $q+1$ new values. (c) In the remaining $N-L-a$ choices $q$ new values of the state are obtained.

Finally, the MC block is the only block where the complexity is summarized. Thus, its total complexity is

$$
\begin{align*}
& C_{\mathrm{MC}}\left(L ; a ; q_{\max }\right)=\underbrace{(N-L)}_{\text {complexity }}+\sum_{q=1}^{q_{\max }} \mathcal{P}_{\mathrm{MC}}\left(L ; a ; q_{\max } ; q\right) \cdot[ \\
& \quad+\underbrace{q}_{q \text { branches }} \cdot \underbrace{\frac{1}{N}}_{z_{t}=j_{t-1}} \cdot \mathcal{P}_{c}(L+1 ; q-1) \cdot C_{\mathrm{IR}}^{\mathrm{AO}}(L+1 ; q-1 ; a-q ; q)  \tag{21}\\
& \quad+\underbrace{a-q \text { branches }}(a-q) \\
& \\
& \quad+\underbrace{(N-L-a)}_{\text {remaining branches }} \cdot \mathcal{P}_{c}(L+1 ; q) \cdot C_{\mathrm{IR}}^{\mathrm{A} 1}(L+1 ; q ; a-q ; q) \\
& \quad \\
& \text { when } 1 \leq L+a \leq N, \text { and } 1 \leq q_{\max } \leq a .
\end{align*}
$$

Complexity $\boldsymbol{C}_{\mathrm{IR}}^{\mathrm{A} 1}\left(\boldsymbol{L} ; \boldsymbol{l} ; \boldsymbol{a} ; \boldsymbol{q}_{\max }\right)$ This case is similar to that of $C_{\mathrm{IR}}^{\mathrm{AD}}$, although this case is divided into two subcases with respect to the number of processed equations.

$$
\left.\begin{array}{rl}
C_{\mathrm{IR}}^{\mathrm{A} 1}\left(L ; l ; a ; q_{\max }\right)= & \sum_{\delta=0}^{a-1} \underbrace{\binom{a-1}{\delta} \frac{M\left(l ; \delta ; q_{\max }\right) \cdot M\left(N-L-l ; a-\delta ; q_{\max }\right)}{M\left(N-L ; a ; q_{\max }\right) \cdot}}_{\text {probability of processing } \delta \text { equations, except "special" one }} \\
& \times \mathcal{P}_{c}(L+l ; \delta) \cdot\left\{\begin{array}{ll}
C_{\mathrm{IR}}^{\mathrm{B}}\left(L+l+\delta ; a-\delta ; q_{\max }\right), & \delta=0, a-1 \\
C_{\mathrm{IR}}^{\mathrm{A} 1}\left(L+l ; \delta ; a-\delta ; q_{\max }\right), & \text { otherwise }
\end{array}\right\}
\end{array}\right\} \begin{aligned}
& \quad+\sum_{\delta=0}^{a-1} \underbrace{\binom{a-1}{\delta} \frac{M\left(l ; \delta+1 ; q_{\max }\right) \cdot M\left(N-L-l ; a-\delta-1 ; q_{\max }\right)}{M\left(N-L ; a ; q_{\max }\right) \cdot}}_{\text {probability of processing } \delta+1 \text { equations, including "special" one }} \\
& \quad \times \frac{1}{N} \cdot \mathcal{P}_{c}(L+l ; \delta) \cdot\left\{\begin{array}{ll}
C_{\mathrm{MC}}\left(L+l ; a-1 ; q_{\max }\right), & \delta=0 \\
C_{\mathrm{K}}(L+l+a-1), & \delta=a-1 \\
C_{\mathrm{IR}}^{\mathrm{AO}}\left(L+l ; \delta ; a-\delta-1 ; q_{\max }\right), & \text { otherwise }
\end{array}\right\}
\end{aligned}
$$

where by "special" equation we refer to the one for which the value of $S[j]$ is known.

Complexity $\boldsymbol{C}_{\mathrm{IR}}^{\mathrm{B}}\left(\boldsymbol{L} ; \boldsymbol{a} ; \boldsymbol{q}_{\max }\right)$ This is the IR block where one equation (associated with time $t$ ) has $S_{t}\left[j_{t}\right]$ known. There could be three cases similar to $C_{\mathrm{Mc}}$. However, these cases are not chosen by us as in MC, but instead one of them appears with some probability. The probability that the value $z_{t}$ is in the clique of size $q+1$ is

$$
\begin{equation*}
\mathcal{P}_{\mathrm{A} 1}\left(L ; a ; q_{\max } ; q\right)=\binom{a-1}{q} \frac{(N-L) \cdot M\left(N-L-1 ; a-q-1 ; q_{\max }\right)}{M\left(N-L ; a ; q_{\max }\right)} \tag{23}
\end{equation*}
$$

and the target complexity is

$$
\begin{align*}
C_{\mathrm{IR}}^{\mathrm{B}}\left(L ; a ; q_{\max }\right) & =\sum_{q=0}^{q_{\max }-1} \mathcal{P}_{\mathrm{A} 1}\left(L ; a ; q_{\max } ; q\right) \times[ \\
& \underbrace{\frac{q}{N}}_{\begin{array}{c}
S^{-1}[z] \\
\text { is one } \\
\text { of the } q
\end{array}} \cdot \underbrace{\frac{1}{N}}_{\begin{array}{c}
\text { No contra- } \\
\text { diction in } \\
\text { the clique } \\
\text { of size } q
\end{array}} \cdot \mathcal{P}_{c}(L+1 ; q-1) \cdot C_{\mathrm{IR}}^{\mathrm{A} \mathrm{O}}\left(L+1, q-1, a-q-1, q_{\max }\right) \\
& +\frac{a-q-1}{N} \cdot \mathcal{P}_{c}(L+1 ; q) \cdot C_{\mathrm{IR}}^{\mathrm{A} 1}\left(L+1 ; q ; a-q-1 ; q_{\max }\right) \\
& \left.+\frac{N-L-a+1}{N} \cdot \mathcal{P}_{c}(L+1 ; q) \cdot C_{\mathrm{IR}}^{\mathrm{AO}}\left(L+1 ; q ; a-q-1 ; q_{\max }\right)\right] . \tag{24}
\end{align*}
$$

## C. 4 How to Apply the Complexities?

When the pattern is known and $\Delta_{\mathrm{thr}} \neq 0$, the complexity function should be applied at the point where the MC block is called. In this case $C_{\text {MC }}\left(L ; a ; q_{\max }\right)$ is added to the total complexity counter, where $L$ and $a$ are known, and $q_{\max }$ is the size of the maximum clique that had been previously found during the simulation.

When the pattern is unknown $\left(\Delta_{\mathrm{thr}}=0\right)$ but its parameters $d, w, l, b_{\alpha}, b_{\beta}, b_{\gamma}, b_{\theta}$ are given, the upper bound of the total complexity is calculated as
$C_{\text {Rand }}<\mathcal{P}_{c}\left(d, b_{\gamma}\right) \cdot C_{\mathrm{IR}}^{\mathrm{AO}}\left(0 ; d+b_{\gamma} ; w-l-b_{\theta} ; w-l-b_{\theta}\right)$, for random keystream, $C_{\text {True }}<C_{\mathrm{IR}}^{\mathrm{AO} *}\left(b_{\gamma} ; d ; w-l ; 1\right), \quad$ for true keystream,
where $C_{\mathrm{IR}}^{\mathrm{A} 0 *}$ is the same as $C_{\mathrm{IR}}^{\mathrm{AO}}$ except that the first call of the IR block may not have contradictions ${ }^{6}$.

## C. 5 Restricted Verification Tests on Random Keystream

A set of patterns for restricted verification tests were chosen such that practical simulations of the attack would have as close conditions to the assumptions in Section C. 2 as possible. We set $\Delta_{\mathrm{thr}}=0, C_{\mathrm{K}}(L)=0$, switch off the WE and GSi blocks, take patterns with $b_{\alpha}=b_{\beta}=0$, and test them on a random keystream.

Table 5. Results of restricted verification tests.

The results of the tests are given in Table 5. The first group of tests shows that the theoretical complexities are close to the complexities achieved through simulations. The second group of tests shows that the actual complexity of the attack depends on a certain pattern, and it may vary.

## C. 6 Why Is Part-1 Needed?

Consider the pattern $A=\{0,0,\{3,1\},\{1,2\}\}$ and $N=28, q_{\max }=1$. The length of the window is $w=5$. The probability of exactly one equation to be solved during the first iteration of the IR block is 0.3042 , then a new value of $S[j]$ is received. In theory the probability that no contradiction would occur is ( $N-L-$ $l) / N \approx 0.928$, whereas in practice it is around 0.6 , and this is a large deviation.

This simple example shows that no assumptions could cover all peculiarities of an actual pattern used. Therefore, when a precise pattern is given, it would be advised to run partial simulations of the attack in order to test top level branches of the recursion with the depth $1-3$, since the case of the remaining subtrees becomes well compliant with the assumptions. This solution can attune theoretical complexity significantly in some cases.

## C. 7 Full Verification Tests on True Keystream

In order to verify reliability of complexity functions a set of full verification tests for three attack scenarios were carried out. For all scenarios $N=64$, the patterns are $\mathcal{M}_{8}, \mathcal{M}_{9}$, and $\mathcal{M}_{1}$, and a true keystream is generated randomly. The four blocks in practice and the part with Knudsen's attack in theory are switched on.

Figure 9 shows the results of the tests for the three scenarios. Real complexities received via simulations of the state recovery algorithm are horisontal lines, wherease the curves are corresponding theoretical upper bounds of average complexities for various $\Delta_{\mathrm{thr}}$, respectively. When $\Delta_{\mathrm{thr}}=0$, points on the curves are pattern independent upper bounds.

Fig. 9. Three patterns, true keystream, full attack, $N=64$. The results of full verification tests of complexity functions of the new state recovery attack.

Table 7. Various patterns that were achieved by our simulations (part II).

[^0]:    ${ }^{1}$ Indeed, the "jump" of $w_{\max }$ as $d$ increments by one is the sequence $\Gamma=\{4,5,6,6,4$, $6,5,8,5,6,7,8, \ldots\}$. Obviously, for small $d$ this "jump" is small, and it is notable that the "jump" increases for larger $d$. In our simulations heuristics were used (see Section B) when searching patterns for $d \geq 6$. This means that our "jumps" in the sequence $\Gamma$ could possibly be larger if an optimal searching technique is applied, since our heuristic cannot guarantee that we get a pattern with the longest window. This suggests that the ratio $w \rightarrow 6 d$ as $d \rightarrow \infty$ seems quite a fair conjecture.

[^1]:    ${ }^{2}$ Table 6(a) in Appendix D contains patterns $\mathcal{X}_{\text {s }}$ with $l=d$ where $w$ is still large, which supports the above conjecture. Indeed, Table 4 in Appendix B shows how the number of available patterns grows when relaxing the condition put on $w$. I.e., a slight reduction of $w$ increases the chance of finding a pattern with $d=l$. This makes the conjecture fair.

[^2]:    ${ }^{3}$ Since ${ }^{\gamma}$-predictiveness has a minor influence on detection, we skip this parameter in future calculations.

[^3]:    ${ }^{4}$ Mantin detects a large number of bytes of the state, and then applies Knudsen's attack given those bytes. However, to make these knowns to reduce the complexity of Knudsen's attack they must be located in a short window all together, and this is not the case. This fact is confirmed in [Man05] (Section "State Recovery Attack").

[^4]:    ${ }^{5}$ One should start with a loop for $t=1 \rightarrow N$, then a loop for $a=1 \rightarrow N$, and then calculate the corresponding subtable.

[^5]:    ${ }^{6}$ Brief boundings that need only $d$ and $w$ are $C_{\mathrm{IR}}^{\mathrm{AO}}(0 ; d ; w ; w)$ and $C_{\mathrm{IR}}^{\mathrm{AO} *}(0 ; d ; w ; 1)$.
