ABSTRACT
Secure two-party computation allows two untrusting parties to jointly compute an arbitrary function on their respective private inputs while revealing no information beyond the outcome. Existing cryptographic compilers can automatically generate secure computation protocols from high-level specifications, but are often limited in their use and efficiency of generated protocols as they are based on either garbled circuits or (additively) homomorphic encryption only.

In this paper we present TASTY, a novel tool for automating, i.e., describing, generating, executing, benchmarking, and comparing, efficient secure two-party computation protocols. TASTY is a new compiler that can generate protocols based on homomorphic encryption and efficient garbled circuits as well as combinations of both, which often yields the most efficient protocols available today. The user provides a high-level description of the computations to be performed on encrypted data in a domain-specific language. This is automatically transformed into a protocol. TASTY provides most recent techniques and optimizations for practical secure two-party computation with low online latency. Moreover, it allows to efficiently evaluate circuits generated by the well-known Fairplay compiler.

We use TASTY to compare protocols for secure multiplication based on homomorphic encryption with those based on garbled circuits and highly efficient Karatsuba multiplication. Further, we show how TASTY improves the online latency for securely evaluating the AES functionality by an order of magnitude compared to previous software implementations. TASTY allows to automatically generate efficient secure protocols for many privacy-preserving applications where we consider the use cases for private set intersection and face recognition protocols.

1. INTRODUCTION
The design of efficient secure two-party computation protocols is vital for a variety of security-critical applications with sophisticated privacy and security requirements such as electronic auctions [40], data mining [34], remote diagnostics [7], medical data classification [1], or face recognition [15, 50, 44] to name some.

Modern cryptography provides various tools for secure computation. The concept of two-party Secure Function Evaluation (SFE) was introduced in 1982 by Yao [59]. The idea is to let two mutually mistrusting parties compute an arbitrary function (known by both) on their private inputs without revealing any information about their inputs beyond the function’s output. However, the real-world deployment of SFE was believed to be very limited and expensive for a relatively long time. Fortunately, the cost of SFE has been dramatically reduced in the recent years thanks to many algorithmic improvements and automatic tools, as well as faster computing platforms and communication networks.

For several years, two different approaches for secure two-party computation have co-existed. One of them is based on homomorphic encryption (HE). Here one party sends its encrypted inputs to the other party, who then computes the desired function under encryption using the homomorphic properties of the cryptosystem, and sends back the encrypted result. Popular examples are the additively homomorphic cryptosystems of Paillier [45] and Damgård-Jurik [12], and the recent fully homomorphic schemes [17, 13, 55]. The other approach is based on garbled circuits (GC), introduced by Yao [60], that works as follows: one party (con-
I/O, protocols, messages, I/O, computation

Primitives

I/O, enc/dec, computation

Circuit Optimizations: Additionally, TASTY has built-in tools for on-the-fly generation and minimization of boolean circuits (4.3). As new circuit building block we implement fast multiplication circuits based on Karatsuba method [28] that are more efficient than textbook multiplication (used in previous SFE tools), already for 20 bit numbers; for multiplication of 128 bit values, it is more efficient by 45% (5.1.1).

Benchmarking: Using TASTY, we obtain measurements for a detailed performance comparison of multiplication protocols based on GCs with those based on HE. Our experiments show that GC-based multiplication has large communication and time complexity in the setup phase, but results in a more efficient online time than HE-based multiplication for small values (5.1.2). In particular, multiplication of two garbled values with bitlength \( \ell \leq 16 \) bits requires less online communication and time than the multiplication of two homomorphically encrypted values for short-term security.

Applications: We show that TASTY is a usable and useful tool for describing and automatically generating efficient protocols for several privacy-preserving applications. We implemented set intersection and face recognition (5).

The paper is concluded with an overview on future work which could be based on the TASTY framework (6).

1.2 Related Work

While the theoretical foundations of two-party Secure Function Evaluation (SFE) have been laid already in the eighties [59, 60], recent optimizations and prototype implementations show that SFE is ready to be used in practical applications (e.g., [35, 48]). To allow the deployment of SFE in a wide range of privacy-preserving applications it is not only important to maximize the efficiency of SFE protocols, but also to make SFE usable by automatically generating protocols from high-level descriptions. For this, several frameworks for SFE consisting of languages and corresponding tools have been developed in the last years. We review these proposals briefly in the following.

Existing SFE frameworks can be divided into three classes on different abstraction levels as summarized in Table 1.

### 1.1 Our Contribution and Outline

In this paper, we present the following contributions in the respective sections.

**SFE Compiler:** We present TASTY, a tool that allows to automatically generate, benchmark and compare the performance of efficient two-party SFE protocols in the semi-honest model (1.2). We show how TASTY is related to, improves over, and can be combined with existing tools for automatic generation of (two-party) SFE protocols (1.2).

**Specification Language:** TASTYL, the TASTY input Language, allows to describe SFE protocols as sequence of operations on encrypted data based on combinations of Garbled Circuits (GC) and Homomorphic Encryption (HE). We review the underlying theoretical framework for such modularly composed SFE protocols [51] in [2]. TASTY is based on the Python programming language and hides technical cryptographic details from the programmer (1.2).

**Efficient Building Blocks:** TASTY implements efficient building blocks for HE and GC which allow to shift most of the complexity into the less time critical setup phase resulting in SFE protocols with a low-latency online phase (1.4). While the implemented techniques have been known before, their combination and implementation in a single package is unique and useful. We show how the combination of these techniques speeds up the online phase for secure evaluation of AES (a large circuit with more than 30,000 gates) compared to the currently fastest software implementation of GCs [48] from 5 s to only 0.5 s, while the total costs for setup plus online phase stay almost the same (5.2).

Table 1: Abstraction Levels for Automatic Generation of SFE Protocols
described in such languages can then be (formally) analyzed to ensure security of the function (e.g., no information leak to the other party) and are compiled (potentially through lower-level SFE languages) into SFE protocols. Examples are Fairplay’s Secure Function Definition Language (SFDL) \textsuperscript{37} \textsuperscript{3} which can be compiled to boolean circuits (see below), or the Secure Multiparty Computation language (SMCL) \textsuperscript{42} and its Python-based successor PySMCL \textsuperscript{41} which allow compilation into arithmetic circuit-based secure multiparty computation (SMPC) protocols such as the Virtual Ideal Functionality Framework (VIFF) \textsuperscript{11}.

Protocol Description languages allow to specify how the SFE protocol is composed as sequence of basic operations on encrypted (or secret-shared data). Examples (described in more detail below) are VIFF \textsuperscript{11}, the Secure Multiparty Computation language (SMC) \textsuperscript{43, 54}, Sharemind \textsuperscript{5}, and the compiler of MacKenzie et al. \textsuperscript{36}. These languages allow to specify SFE protocols while abstracting away the details of the underlying cryptographic protocols. The language and compiler we present in this paper also fall into this class. However, in contrast to previous works which were restricted to using homomorphic encryption only, our compiler TASTY allows arbitrary combinations of computations under encryption based on garbled circuits and/or homomorphic encryption for highly efficient SFE protocols.

Protocol Implementation languages allow to describe how exactly the target SFE protocol is composed as sequence of basic cryptographic protocol building blocks. They reside at the lowest level of the abstraction hierarchy and require a substantial amount of expert knowledge in cryptographic protocol design. For example the L1 language \textsuperscript{52} allows to describe secure computation protocols as sequence of basic primitives such as oblivious transfer (OT), homomorphic encryption/decryption, creation and evaluation of garbled circuits, and messages to be exchanged. Qilin \textsuperscript{38} is a Java library for rapid prototyping of cryptographic protocols which currently provides common cryptographic protocols (e.g., OT \textsuperscript{39} and coin flipping) using cryptographic primitives (e.g., Pedersen Commitment \textsuperscript{47} and ElGamal \textsuperscript{14}) implemented with elliptic curves.

Next we describe SFE frameworks which are closely related to ours. In contrast to TASTY, the existing SFE frameworks are based on either garbled circuits (GC) or homomorphic encryption (HE), but not combinations of both.

Garbled Circuits (GC). The most prominent example for automatic generation of SFE protocols is Fairplay \textsuperscript{37} which is based on GCs. Fairplay provides a high-level function description language, SFDL, which allows to specify the function to be computed securely, i.e., the inputs and outputs of the involved parties, and how the outputs are to be computed from the inputs. The language resembles a simplified version of a hardware description language, such as Verilog or VHDL\textsuperscript{4} and supports types, variables, functions, boolean operators ($\land, \lor, \oplus, \ldots$), arithmetic operators ($+$, $-$), comparison ($<$, $>$, $=$, \ldots) and control structures like if-then-else or for-loops with constant range. The Fairplay compiler compiles and optimizes an SFDL program into a boolean circuit which is stored in a file. The circuit can then be evaluated using the Fairplay runtime environment, two Java programs which securely evaluate the circuit using Yao’s garbled circuit protocol, communicating over a TCP socket. Fairplay is supplemented by FairplayMP \textsuperscript{3}, a multi-party version of Fairplay suited for three or more parties with the more powerful SFDL 2 input language (with support for $*$, / and generic functions) and a corresponding circuit compiler. TASTY can serve as efficient runtime environment for the Fairplay compiler suite, i.e., it allows to read in circuits generated by the FairplayMP compiler from SFDL 2 programs\textsuperscript{1} and optimizes these for efficient secure evaluation with state-of-the-art GC evaluation techniques.

Homomorphic Encryption (HE). VIFF \textsuperscript{11}, the Virtual Ideal Functionality Framework, is an open source framework written in Python for specifying secure multi-party computation (SMPC) protocols as a sequence of operations performed on secret-shared (i.e., encrypted) data. While VIFF was mainly designed for secret-sharing based SMPC protocols with three or more parties, it also offers a two-player runtime based on the additively homomorphic Paillier cryptosystem \textsuperscript{48}. Using operator overloading, VIFF allows the programmer to express a desired secure computation directly as standard arithmetic without knowing about the used protocol. Indeed, TASTY, the input language of our compiler, is inspired by the VIFF language, but additionally allows to combine HE with GC-based computations.

In contrast to general-purpose compilers such as Fairplay, VIFF, and TASTY, the compilers described below are built for specific application scenarios, e.g., use specific number representations \textsuperscript{36} \textsuperscript{3} or require $n \geq 3$ parties \textsuperscript{43} \textsuperscript{54} \textsuperscript{6}.

The compiler of MacKenzie et al. \textsuperscript{36} implements secure two-party computations over values which are secret-shared between both parties using \textsuperscript{2} secret-sharing over a prime field. The computations are composed as sequence of basic operations on the shared data (e.g., addition or multiplication). The compiler can be used for specific functions such as cryptographic primitives defined over prime fields, e.g., signatures or encryption schemes, where the secret key is shared between both parties. SMC \textsuperscript{43} \textsuperscript{54}, the Secure Multiparty Computation language, provides a declarative language for describing SMPC based on constraint programming. A program is distributed among the parties in the computation along with an interpreter, each party gives its secret inputs and the interpreter calculates the result. Computations are specified as arithmetic circuits and at least 3 parties are required as the underlying multiplication protocol is based on the BGW protocol \textsuperscript{4}. Sharemind \textsuperscript{5} allows secure computation over the ring of 32-bit integers for three parties and provides an assembly-like programming language. As this setting is fixed and very specific it allows highly efficient protocols.

2. THEORETICAL BACKGROUND

In this section we summarize the framework for modular design of efficient two-party Secure Function Evaluation (SFE) protocols of \textsuperscript{31} on which TASTY is built.

Model. We concentrate on the semi-honest model, where both parties follow the protocol but try to infer additional information from the transcript of messages seen in the protocol. Far from trivial, this model covers many typical practical settings such as protection against insider attacks. Further, designing and evaluating the performance of protocols in the semi-honest model is a first stepping stone to-

\textsuperscript{2}Very high speed integrated circuit Hardware Description Language

\textsuperscript{3}FairplayMP’s compiler can generate circuits for two parties.
wards protocols with stronger security guarantees. Indeed, most protocols and implementations of protocols for practical privacy-preserving applications focus on the semi-honest model. For a detailed discussion on the semi-honest model and its extensions we refer to [31, 32].

**Notation.** We call the two semi-honest SFE participants **client** $C$ and **server** $S$. This naming choice is influenced by the asymmetry in the SFE protocols, which fits into the client-server model. We stress that, while in most real-life two-party SFE scenarios this client-server relationship in fact exists, we do not limit ourself to this setting.

**Function Representations.** Given a function $f$ that should be computed securely, the first task during the design of the corresponding SFE protocol is to find a suitable representation for $f$. Well-established representations which allow efficient SFE protocols are boolean circuits and arithmetic circuits as shown in Fig. 1. The representation determines the size of the function, e.g., multiplication can be expressed as arithmetic circuit with a single multiplication gate while its representation as boolean circuit is substantially larger (cf. [15]). As described in §2.2 the online phase for SFE of boolean circuits is substantially more efficient than SFE of arithmetic circuits, so especially non-linear functions such as comparisons benefit from boolean circuits [30]. The framework of [31] allows to modularly compose functions from building blocks which are compactly represented as boolean or arithmetic circuits and then convert back and forth between the representations under encryption.

![Figure 1: Function Representations](image)

In the following, we summarize efficient methods for SFE of arithmetic and boolean circuits, and conversions between them which are implemented in TASTY. For a comprehensive description we refer to [31] and list the specific primitives implemented in TASTY in §4.3.

### 2.1 Homomorphic Encryption: SFE of Arithmetic Circuits

Additively homomorphic encryption schemes (e.g., [15, 12]) are semantically secure encryption schemes with plaintext space $P$ and ciphertext space $C$ that allow addition under encryption: The operation $+$ can be computed on plaintexts by defining a corresponding operation $\oplus$ on ciphertexts which satisfies $\forall x, y \in P : [x] \oplus [y] = [x + y]$. This naturally allows for multiplication with a plaintext constant $a$ using repeated doubling and adding: $\forall a \in \mathbb{N}, x \in P : a[x] = [ax]$. We write $[x]$ for homomorphic encryption of plaintext $x$.

SFE of arithmetic circuits can be naturally based on additively homomorphic encryption as follows: Let $C$ generate a key-pair for the homomorphic cryptosystem and sends the public key together with its inputs encrypted under the public key to server $S$. $S$ uses the homomorphic property to evaluate the arithmetic circuit on the encrypted data. If the cryptosystem is only additively homomorphic, multiplication under encryption requires the help of $C$ in a single round of interaction (details in [31]). Finally, $S$ sends the encrypted outcome of the computation back to $C$ who can decrypt. As often the maximum size of elements in the plaintext space (e.g., $P = \mathbb{Z}_n$ with RSA modulus $n$ for the Paillier cryptosystem [15]) is substantially larger than the size of encrypted values, $S$ can pack multiple values under encryption using Horner’s method before sending them to $C$ to reduce communication and number of decryptions by $C$.

As described in [31], the interactive approach for multiplication currently results in faster SFE protocols than using schemes which also provide one (e.g., [6, 15]) or arbitrary many (e.g., [17, 13, 55]) multiplications under encryption, called fully homomorphic encryption. Such schemes could be integrated in TASTY in future work as described in §6.

### 2.2 Garbled Circuits: SFE of Boolean Circuits

Garbled circuits (GC) are an efficient method for SFE of boolean circuits. The general idea of GCs, going back to Yao [60], is to encrypt (garble) each wire with a symmetric encryption scheme. In contrast to homomorphic encryption (cf. §2.1), the encryptions/garblings here cannot be operated on directly, but require helper information which is generated and sent to $C$ in the setup phase in form of a garbled table for each gate. On the other hand, the online phase of GCs is highly efficient as it requires only symmetric cryptographic operations, e.g., the GC method of [48] implemented in TASTY needs one invocation of SHA-256 per non-XOR gate (cf. §4.3).

On a high-level, Yao’s GC protocol works as follows: In the setup phase, the constructor (server $S$) generates an encrypted version of the function $f$ (represented as boolean circuit), called garbled circuit $\tilde{f}$. For this, he assigns to each wire $W_i$ of $f$ two randomly chosen garbled values $\tilde{w}_i^0, \tilde{w}_i^1$ (symmetric keys) that correspond to the respective values 0 and 1. Note that $\tilde{w}_i^j$ does not reveal any information about its plain value $j$ as both keys look random. Then, for each gate of $f$, the constructor creates helper information in form of a garbled table $\tilde{T}$, that allows to decrypt only the output key from the gate’s input keys. The garbled circuit $\tilde{f}$ consists of the garbled tables of all gates and is sent to $C$ in the setup phase. Later, in the online phase the evaluator (client $C$) obliviously obtains the garbled values $\tilde{z}$ and $\tilde{y}$ corresponding to the plain inputs $x$ and $y$ of $C$ and $S$, respectively (see below). Afterwards, $C$ evaluates the garbled circuit $\tilde{f}$ on $\tilde{x}, \tilde{y}$ by evaluating the garbled gates one-by-one using their garbled tables. Finally, $C$ obtains the corresponding garbled output values $\tilde{y}$ which allow $S$ to decrypt them into the corresponding plain output $z = f(x, y)$.

For converting a plain input bit $y_i$ of $S$ into its garbled equivalent, $S$ simply sends the key $\tilde{y}_i$ to $C$. Similarly, $C$ must obtain the garbled bit $\tilde{x}_i$ corresponding to his input bit $x_i$, but without $S$ learning $x_i$. This can be achieved by running (in parallel for each bit $x_i$ of $x$) a 1-out-of-2 Oblivious Transfer (OT) protocol. OT is a cryptographic protocol into which $C$ inputs his choice bit $b = x_i$ and $S$ inputs two strings $s^0 = \tilde{x}_i^0$ and $s^1 = \tilde{x}_i^1$. The protocol guarantees that $C$ obtains only the chosen string $s^b = \tilde{x}_i^b = \tilde{x}_i^{b_i}$.
\[ \hat{x}_i \] while \( S \) learns no information on \( b = x_i \). We summarize efficient instantiations for parallel OT later in §3. A similar method can be used for converting the encryptions into the respective other type of encryption, which may involve conversion of the encryptions into the respective other type of encryption (see below). Finally, the encrypted output values are revealed and can be decrypted by converting them into their corresponding plain output values. In the following we describe how to efficiently convert between the two types of encryptions.

![Figure 2: Hybrid SFE Protocols](image)

**Conversion between Garbled and Homomorphic Values.** To convert an Homomorphic Value \( \hat{x} \) into a Garbled Value \( \tilde{x} \), \( S \) adds a random mask \( r \) under homomorphic encryption, sends the blinded value \( \tilde{x} = [x] \oplus [r] \) to \( C \) who decrypts and both parties evaluate a garbled subtraction circuit which takes off the random mask under "garbled encryption". A similar method can be used for converting a Garbled Value \( \tilde{x} \) into an Homomorphic Value \( \hat{x} \). For details we refer to §3.

3. SELECTED APPLICATIONS

In this section we show how the TASTY framework can be used to intuitively describe, and automatically generate and measure the performance of two privacy-preserving applications. We consider privacy-preserving set intersection (§3.1) and privacy-preserving face recognition (§3.2). A detailed description of TASTY and its input language TASTYL is given later in §4 further performance results and the specs of the machines used in our performance measurements are given in §4.

3.1 Privacy-Preserving Set Intersection

Privacy-preserving set intersection is a fundamental building block for many privacy-preserving applications such as privacy-preserving checking of no-flight list. We briefly summarize the HE-based set-intersection protocol of [16, 34].

Two parties, client \( C \) and server \( S \), have as inputs a set \( X = \{x_1, \ldots, x_m\} \) respectively \( Y = \{y_1, \ldots, y_n\} \). The protocol should compute the intersection \( X \cap Y \) without revealing any other elements to the other party. The main idea behind this protocol is to encode \( X \) as a polynomial \( p(x) \) whose roots are the \( m \) values \( x_i \), i.e., \( p(x) = (x - x_1)(x - x_2)\ldots(x - x_m) = \sum a_i x^i \). \( C \) computes the coefficients \( a_i \) of \( p(x) \), encrypts them separately using homomorphic encryption and then sends these ciphertexts to \( S \). Then, \( S \) evaluates the polynomial \( p \) homomorphically under homomorphic encryption: \( \tilde{p}(y_i) = [a_0] + [a_1] y_i + \ldots + [a_n] y_i^n \). This is done efficiently with Horner’s method. Now, for each \( y_i \in Y \), \( S \) picks a random value \( r_i \), computes \( \tilde{p}(y_i) = [r_i * p(y_i) + y_i] \), and sends it to \( C \). If \( y_i \) is equal to an element in \( X \), then this is an encryption of \( y_i \) (as \( p(y_i) \) evaluates to 0), and of a random element otherwise. \( C \) finally decrypts \( \tilde{p}(y_i) \) into \( y_i \), and if \( y_i \in X \), \( C \) puts \( y_i \) into the intersection set.

This protocol can be implemented in TASTYL as listed in Appendix A. The performance for random 32-bit inputs, measured automatically with TASTY, is shown in Table 2.

3.2 Privacy-Preserving Face Recognition

For privacy-preserving face recognition, client \( C \) has a query face which should be searched in a database (DB) of faces held by server \( S \) without disclosing any additional information on the queried face to \( S \) nor any information on the DB to \( C \) (besides the size and the outcome of the computation). At the end, \( C \) obtains either the index of the queried face in the DB, or ‘\( \perp \)’ if no match was found.

We summarize the face recognition protocol of [50] which evaluates the well-known Eigenface algorithm [57] under encryption and can be divided into the following three phases: *Projection*. First, the query face \( \Gamma \) is projected into a low-dimensional eigenspace. This is done under homomorphic encryption as follows: \( C \) encrypts \( \Gamma \) pixelwise and sends \( \tilde{\Gamma} \) to \( S \) who performs the projection under encryption and obtains the encrypted projected query face \( \tilde{\Gamma} \).

*Distance*. Then, the squared Euclidean distance \( ||D|\| = \|(\Omega - \Omega)^2\| \) between the projected face and all faces \( \Omega \) in \( S \)’s DB is computed under homomorphic encryption.

*Minimum*. Finally, the minimum value of \( \{||D||\} \) is computed and, if smaller than a threshold \( \tau \) provided by \( S \), the corresponding index in the DB is revealed to \( C \). Otherwise, \( \perp \) is returned. The protocol of [50] improves over [15] by computing this phase with garbled circuits instead of homomorphic encryption.

The TASTYL code of this protocol is given in Appendix B.
is needed for pre-computing random masks for HE (≈ 20s). The setup phase is less efficient than that of the HE-only protocol of [15] as GCs need to be generated and transferred.

**Online Phase.** When comparing the online time of the protocol generated by TASTY with the hand-optimized implementation of [50] we observe that they mostly differ by a constant overhead. In fact, the online phase is dominated by homomorphically encrypting the vector $\Gamma$ in the projection phase which is not yet optimized in TASTY. For the online communication complexity we observe that data serialization in TASTY, which is also not optimized yet, requires approximately twice as much data as the theoretical lower bound of the protocol of [50]. Still, even without further serialization optimizations, the online communication complexity outperforms that of [15] already for databases with slightly more than 200 faces. We note that the communication complexity of [15] closely matches the theoretical lower bound, i.e., their serialization cannot be optimized further.

### 4. TASTY

In this section we present TASTY, our tool for describing and automatically generating, benchmarking, and evaluating hybrid secure two-party computation protocols.

**Design Goals.** TASTY was designed and developed to meet the following goals:

1. SFE protocols are *programmed* in TASTYL, an intuitive high-level language for describing the protocol as sequence of operations on encrypted data (cf. §4.1).
2. TASTY allows to *test, benchmark and compare* the performance of the generated SFE protocols (cf. §4.2).
3. The generated SFE protocols aim at *minimizing the latency of the online phase*, i.e., the time from providing the inputs until obtaining the outputs. This is achieved by using a combination of highly efficient primitives and pre-computations (cf. §4.3).

**Architecture and Workflow (cf. Fig. 5).** The workflow for using TASTY is as follows:

1. Both users, client $C$ and server $S$, agree on a Protocol Description of the SFE protocol in the TASTY input Language (TASTYL) as described in detail in §4.1.
2. Both users invoke TASTY’s Runtime Environment (details later in §4.3), a program that can automatically analyze, run, test, and benchmark the SFE protocol:
   (a) In the Analysis Phase, the runtime environment checks the syntactical correctness of the protocol description, exchanges a hash of it to ensure that both parties run the same protocol, and analyzes the protocol to automatically determine which parts of the protocol can be pre-computed.
   (b) In the Setup Phase, the parties pre-compute those parts of the protocol which are independent of their inputs, e.g., create/send garbled circuits and oblivious transfers (OT), see §4.3 for details.
   (c) Finally, in the Online Phase, both parties provide their inputs to the computation, and the online part of the SFE protocol is executed (e.g., homomorphic encryptions and decryptions, online OTs, and evaluation of GCs) to jointly compute the respective outputs for both parties.
3. TASTY provides a tool to compare the performance costs of multiple SFE protocols as described in §4.2.
4.1 TASTY input Language (TASTYL)

TASTYL, the input language for TASTY, allows to formulate secure computations as sequences of operations on encrypted data, allowing to abstract away all details of the underlying cryptographic protocols. We start with an overview of the types and operators provided by TASTYL in §4.1.1 and explain the concrete syntax afterwards in §4.1.2.

4.1.1 Types and Operators

The type system of TASTYL and the operators supported by each type are shown in Fig. 6. Each variable in TASTYL is either a scalar Value (cf. top half of Fig. 6) or a Vector (cf. bottom half of Fig. 6) which consists of N Values. They can be either unencrypted Plain Values/Vectors or encrypted Garbled or Homomorphic Values/Vectors.

All Values and Vectors provide the basic operators for (component-wise) addition, subtraction, and multiplication; Vectors also provide dot multiplication: \( \mathbf{v} \cdot \mathbf{w} = \sum_{i=1}^{N} v_i w_i \).

Number Representation. Each Value has a bitlength \( \ell \) that represents the number of bits needed for its representation. Unsigned are unsigned integer values in the range \([0, 2^\ell)\), Signed are signed integers in the range \([-2^{\ell-1}, 2^{\ell-1})\] and Modular are elements in the plaintext space of the homomorphic cryptosystem, i.e., \( \mathbb{Z}_n \) for Paillier.

In addition to the operations of Value/Vector, the plain/encrypted types support further operations and conversions:

Plain Value/Vector. Inputs and outputs of the two parties are Plain Values/Vectors. They can be chosen uniformly at random and provide additional operations (integer) division and comparison.

Homomorphic Value/Vector. Unsigned, Signed and Modular Values/Vectors can be converted into and from homomorphically encrypted Homomorphic Values/Vectors of server \( S \). While Unsigned and Modular values are mapped directly, for Signed values, the positive values are mapped to the elements \( 0, 1, \ldots \) of the plaintext space of the underlying homomorphic cryptosystem, and the negative values to \( n-1, n-2, \ldots \) as described in [31]. Addition of two Homomorphic, and (dot) multiplication of a Homomorphic with a Plain Value/Vector provided by \( S \) is done non-interactively. (Dot) multiplication of two Homomorphic Values/Vectors requires one round of interaction.

Garbled Value/Vector. Unsigned/Signed Plain and Homomorphic Values/Vectors can be converted into and from Garbled Values/Vectors of client \( C \). A Garbled Value can be compared with another one resulting in a Garbled Value of length one bit. This can be used to multiplex (mux) between two Garbled Values. Similarly, the minimum or maximum value and/or index of the components of a Garbled Vector can be determined as Garbled Value(s), e.g., min_value computes the minimum value. For each operation on Garbled Values/Vectors, TASTY automatically infers the underlying garbled circuit.

4.1.2 Syntax and Example

TASTY is a subset of the Python language; we use the following example to explain its syntax and semantics.

Example (cf. Fig. 7). Client \( C \) and server \( S \) have vectors \( \mathbf{v} \) and \( \mathbf{w} \) of \( N = 4 \) unsigned 32-bit values as inputs. As output, \( C \) obtains \( \min_{i=1}^{N} v_i w_i \). The products \( v_i w_i \) are computed with homomorphic encryption (HE) and the minimum with garbled circuits (GC).

This protocol can be directly formulated in TASTYL as shown in Fig. 7 and described in the following: The protocol gets two parties client and server as inputs to whom the variables used throughout the protocol are bound (details below). At the beginning, two constants \( N = 4 \) and \( L = 32 \) are defined. Then, the input of \( C \), client.v, is defined as an unsigned vector of bitlength \( L \) and dimension \( N \), and read from standard input. Similarly, the input of \( S \), server.w, is
The underlying conversion protocols are described in defined and read. Then, C’s input vector client.v is converted into a homomorphic vector server hv for S who multiplies this component-wise with his input vector server.w resulting in the homomorphic vector server hv. This homomorphic vector is converted into a garbled vector client.gx and its minimum value client.gmin is computed. Finally, C obtains the intended output by decrypting (converting) client.gmin into the unsigned value client.min.

Type Conversions. Types can be naturally converted into each other by providing them as input to the constructor of the target type, e.g., in Fig. 7, the unsigned vector client.v is converted into the homomorphic vector client hv via client hv=HomomorphicVec(val=client.v).

Garbled Bit Manipulations. To allow manipulation of single bits, a Garbled Value gv can be converted back and forth into a list of Garbled Bits (= Garbled 1-bit Values): gv[i] yields the i-th garbled bit of gv (i = 0 is the least significant bit). Vice versa, a (unsigned) garbled m-bit value gv can be constructed from a list of m garbled bits, e.g.,
gv = Garbled(val=[gb0,gb1]).

Send Operator. The send operator transfer variables between the parties, e.g., in Fig. 7 hv is sent from C to S with server hv. When combined with a type conversion, the send operator invokes the corresponding conversion protocol, e.g., in Fig. 7 homomorphic vector hx held by S is converted into garbled vector gx held by C with client gx=GarbledVec(val=server hx).

Binding of Variables. While constants can be declared globally (e.g., N and L in Fig. 7), each variable has to be assigned to one of the parties as an attribute.

Inferring Type and Length Automatically. For each operator, TASTY automatically infers the bitlength and type of the output variables from those of the input variables s.t. no overflow occurs. Homomorphic variables raise an exception if the result does not fit into the plaintext space of the homomorphic cryptosystem. For example, in Fig. 7, the component-wise product of two vectors with N components of unsigned L-bit values results in the homomorphic vector server hv with N components of unsigned 2L-bit values.

Multiple Outputs. Garbled circuits can also have multiple garbled output values written as comma separated list on the left side of the assignment operator, e.g., the garbled minimum value gv and its index gi can be computed as (client.gv, client.gi)=client.gx.min_value_index().

Circuits from File. TASTY allows secure evaluation of boolean circuits read from an external file, e.g., circuits generated by the FairplayMP compiler. For this, the labels of the input- and output wires of the circuit are mapped to Garbled Values of corresponding bitlength. An example TASTYL file with the concrete syntax for evaluating a garbled file circuit is available at.

4.2 Tools

The TASTY framework provides the following tools to initialize, execute, and post-process TASTYL programs:

tasty_init <path> creates a new directory which contains a file protocol.py with a template for the TASTYL program (the example program shown in Fig. 7) and a file protocol.ini which contains default configuration parameters such as the intended security level (cf. Table 4), or the IP address and port of the server.

tasty <options> <path> is the runtime environment of TASTY as explained in (cf. Fig. 5); it analyzes the TASTYL program in path, establishes a TCP/IP socket between server S and client C, and runs the setup phase and online phase of the SFE protocol. The option flags allow to overwrite the default parameters and to specify if run as server (-s) or as client (-c).

Testing and Benchmarking. When invoked with the -d option, tasty runs in driver mode. Here, the TASTYL program is instrumented by a driver, an additional class written in protocol.py. The driver can invoke the protocol multiple times with varying static parameters (e.g., different bitlengths) and inputs to the TASTYL program; the outputs of the TASTYL program are sent back to the driver which allows to write functional test cases. The costs of each protocol run, i.e., detailed information on the transferred data and timings of the sub-tasks of the protocol phases, are written into a file which can be post-processed as described next.

tasty_post <analyze_script> <cost_files> can post-process the costs measured in one or more driver runs with an analyze script, e.g., average, print, or plot graphs. All graphs in this paper were plotted with tasty_post.

A concrete example for how to use TASTY’s benchmarking capability is given in Appendix 3.

4.3 Primitives and Optimizations

In TASTY we implemented the following efficient primitives and automatic optimizations that allow to move expensive operations as pre-computations into the setup phase (cf. Fig. 5) in order to achieve an online phase with low latency. The modular architecture of TASTY allows easy extension with other primitives as well. Due to the lack of space we mention the key-features of the used primitives and refer to the description in and the original papers for details.

Pre-Defined Security Levels. TASTY has pre-defined security levels following standard recommendations of NIST.

```python
# coding: utf-8

def protocol(client, server):
    N = 4
    L = 32
    client.v = UnsignedVec(bitlen=L, dim=N)
    client.v.input(desc="enter values for v")

    server.w = UnsignedVec(bitlen=L, dim=N)
    server.w.input(desc="enter values for w")

    gv = GarbledVec(val=[gb0,gb1])

    client.gv = HomomorphicVec(val=client.v)
    server.hv = server hv

    multiple vectors (component-wise)
    client.gx <<= GarbledVec(val=server hv)

    convert homomorphic to garbled vector
    client.gmin = client.gx.min_value()
    client.gmin.output(desc="minimum value")

    convert unsigned to homomorphic vector
    server.hx = server hv * server.w

    # convert to unsigned value
    server.min = UnsignedVec(bitlen=L, dim=N)

    # compute minimum value
    client.gmin = client.gx.min_value()
    client.min.output(desc="minimum value")
```

**Homomorphic Encryption (HE).** We use the additively homomorphic cryptosystem of Paillier [45]. As key generation for Paillier (an RSA modulus $n$) is computationally expensive and can be used over multiple protocol runs, the public key is generated and exchanged in the analysis phase. For efficient encryption we use the extensions of [42, Sect. 6] for pre-computing expensive modular exponentiations of the form $r^n \mod n^2$ in the setup phase and only two modular multiplications per encryption in the online phase. As $\mathbb{C}$ knows the factorization $p, q$ of $n$, he uses Chinese remaining modulo $p$ and $q$ for pre-computing $r^n \mod n^2$ and efficient decryption. Paillier ciphertexts have twice the length of the asymmetric security parameter as the ciphertext space is twice the length of the asymmetric security parameter.

**Garbled Circuits (GC).** We use the GC construction with free XORs and garbled row reduction of [48] secure in the random-oracle model. This GC construction provides free XOR gates (no garbled table and negligible computation). For non-XOR $d$-input gates, the garbled table consists of $2^d - 1$ entries (of size $t + 1$ bit each with symmetric security parameter $t$), creation requires $2^d$ and evaluation 1 invocation of SHA-256 modeled as random oracle.

**Circuits.** For computations on Garbled Values/Vectors, TASTY dynamically generates circuits using the efficient circuit constructions of [39] which are optimized for a low number of non-XOR gates (cf. [5.1.1] for multiplication circuits). Alternatively, circuits can be generated externally, e.g., using the Fairplay compiler [37], and read from a file (cf. [5.1.2]). TASTY optimizes the circuits to a low number of non-XOR gates using the optimization of [48] which replaces 3-input gates with a low number of 2-input non-XOR gates. XOR gates are replaced by an XOR gate and an inversion gate which is propagated into successor gates [46]. Generating, reading, and optimizing circuits is mostly pipelined to allow processing of large circuits with low memory footprint.

**Oblivious Transfer (OT).** All OTs are pre-computed in the setup phase (cf. Fig. 5) using the construction of [2]; the resulting online phase for OT is highly efficient (transfer and XOR of bitstrings) and depends mostly on the network latency for two messages. To minimize the computation complexity of the setup phase, we use the efficient OT extension of [24] to reduce the usually large number of OTs needed in the protocol down to at most $t$ real OTs and some invocations of SHA-256 modeled as random oracle, where $t$ is the symmetric (computational) security parameter. The remaining real OTs (at most $t$) are implemented with the OT protocol of [39, Sect. 3.1] using elliptic curves and SHA-256 as random oracle. The elliptic curve implementation provides (optional) point compression to reduce communication at the cost of a negligibly larger computation overhead.

**Compiler Optimizations.** TASTY parses the TASTYL program and performs several optimizations on the resulting abstract syntax tree (AST): constant propagation, dead code elimination, partial code evaluation, and loop unrolling.

### 5. PERFORMANCE MEASUREMENTS

We measure the performance of primitives implemented in TASTY and compare different protocols against each other and with existing SFE implementations: multiplication circuits and protocols based on GC or HE ([5.1]), SFE of an AES circuit generated by the Fairplay compiler ([45.2]), and SFE of large GCs ([5.3]).

**System Setup.** All performance measurements are performed on two desktop PCs with Intel Core 2 Duo CPU (E8650) running at 3.00GHz and 4GB RAM connected via Gigabit Ethernet. The system runs on 64 bit Gentoo Linux with Python version 2.6.5, gmpy version 1.11 and GMP version 4.3.2. Unless stated otherwise, all measurements were performed for short-term security (cf. Table 4) and using point compression for elliptic curves (cf. [4.1.3]).

#### 5.1 Multiplication Circuits and Protocols

As arithmetic circuits can express arbitrary computations as sequence of additions and multiplications, multiplication is a fundamental basic operation. Indeed, the main difference between SFE protocols based on arithmetic and boolean circuits is the cost for multiplications. We present efficient multiplication circuits in [5.1.1] and compare the performance of secure multiplication protocols in [5.1.2].

##### 5.1.1 Multiplication Circuits

**Textbook Multiplication.** The usual way of multiplying two unsigned $\ell$-bit integers $x$ and $y$, called "Textbook Method", multiplies $x$ with each bit of $y$ and adds up all the properly shifted results according to the formula $x \cdot y = \sum_{i=0}^{\ell} x_i y_i 2^i$. This results in a circuit with $2\ell^2 - \ell$ non-XOR 2-input gates [30].

**Karatsuba Multiplication.** As observed by Karatsuba [28], multiplication can be performed more efficiently using the following recursive method (details in Algorithm 1): $x$ and $y$ are split into two halves as $x = x_h 2^{\ell/2} + x_i$ and $y = y_h 2^{\ell/2} + y_i$. Then, the product can be computed as $xy = (x_h y_h 2^{\ell/2} + x_i y_i 2^{\ell/2} + y_h 2^{\ell/2} + y_i 2^{\ell/2}) + z_i$. After computing $z_h = x_h y_h$, and $z_i = x_i y_i$, $z_d$ can be computed with only one multiplication as $z_d = (x_h + x_i)(y_h + y_i) - z_h - z_i$. This process is continued recursively until the numbers are sufficiently small ($\ell = 19$ in our case as described below) and multiplied with the classical school method. Overall, multiplying two $\ell$ bit numbers with Karatsuba's method requires three multiplications of $\ell/2$ bit numbers and some additions and subtractions with linear bit complexity resulting in costs $T_{Karatsuba}(\ell) = 3T_{Karatsuba}(\ell/2) + c\ell + d$ for constants $c$ and $d$. The master theorem [8] §4.3f yields asymptotic complexity $T_{Karatsuba}(\ell) \in O(\ell \log_2 3) \approx O(\ell^{1.585})$.

**Circuit Complexity.** In TASTY we have implemented both methods for multiplication based on efficient addition and subtraction circuits of [39]. As shown in Fig. 8 and Table 5 Karatsuba multiplication is more efficient, i.e., results
consider the case where both inputs are provided by one party (S for GC1 and C for HE1), or one by each of the parties (GC2 and HE2). The inputs are Unsigned \( \ell \)-bit values and the output, a \( 2\ell \)-bit Unsigned value is converted into a Plain output for \( C \). In the following, we compare the communication- and the computation complexity of the setup- and online phase of the protocols.

**Algorithm 1** Karatsuba multiplication

1: function \( \text{KARATSUBA}(x, y) \) \( \triangleright x, y \) are \( \ell \)-bit integers
2: if \( \ell \leq 19 \) then
3:     return \( \text{TEXTBOOK}(x, y) \)
4: end if
5: \( x_h||x_l \leftarrow x \) \( \triangleright x = x_h 2^{\lfloor \ell/2 \rfloor} + x_l \)
6: \( y_h||y_l \leftarrow y \) \( \triangleright y = y_h 2^{\lfloor \ell/2 \rfloor} + y_l \)
7: \( P_h \leftarrow \text{KARATSUBA}(x_h, y_h) \)
8: \( P_l \leftarrow \text{KARATSUBA}(y_l, y_l) \)
9: \( x_s \leftarrow x_h + x_l \)
10: \( y_s \leftarrow y_h + y_l \)
11: \( P_s \leftarrow \text{KARATSUBA}(x_s, y_s) \)
12: \( P_d \leftarrow P_s - P_h - P_l \)
13: return \( (P_h 2^{\lceil \ell/2 \rceil}) + P_d 2^{\lceil \ell/2 \rceil} + P_l \)
14: end function

in circuits with less non-XOR gates, than Textbook multiplication already for multiplication of 20 bit operands. By interpolating through the points for bitlength \( \ell \in \{32, 64, 128\} \) and solving the resulting system of linear equations we obtain as approximation for the number of non-XOR gates

\[
T_{\text{Kara}}(\ell) \approx 9.0165\ell^{1.585} - 13.375\ell - 34.
\]

**Table 5:** Size of Multiplication Circuits (in number of 2-input non-XOR gates)

5.1.2 **Multiplication Protocols**

Using TASTY we compare the performance of different secure multiplication protocols based on homomorphic encryption (HE) and garbled circuits (GC). For this we constructed four basic test cases. For each SFE paradigm, we

\[
\text{Karatsuba} - \text{Input non-XOR gates})
\]

**Figure 9:** Multiplication Protocols: Communication

**Communication (cf. Fig. 9).** Our experiments show that GC-based multiplication requires a substantial amount of setup communication (for transfer of GCs) whereas the online communication of GC is better than HE for multiplication of small values. The online communication for multiplying with HE is independent of the bitlength \( \ell \) as a constant number of ciphertexts (2 for HE1 and 5 for HE2) is exchanged. For multiplying with GC, the setup communication grows rapidly due to the large size of the GCs, whereas the online communication complexity grows much slower.

**Setup Time (cf. Fig. 10(a)).** The time of the setup phase for GC-based multiplication protocols depends on the bitlength \( \ell \) as GCs need to be computed; for better visualization we do not plot GC setup times for \( S \) in Fig. 10(a) as they are similar to those of \( C \). For HE-based multiplication, the setup time is independent of \( \ell \) as a constant number of encryptions is pre-computed.

**Online Time (cf. Fig. 10(b)).** For GC-based multiplication, the time needed by \( C \) depends on the size of the evaluated GC which grows with the bitlength \( \ell \); GC’s online time for \( S \) is negligible. For HE-based multiplication, the time in the online phase is almost independent of \( \ell \) for small bitlengths.

**Conclusion.** The setup phase for GC-based multiplication is substantially more expensive than that of HE-based multiplication. However, for small values, GC-based multiplication can result in a faster online time than HE-based multiplication. Furthermore, GC-based multiplication, in contrast to HE-based multiplication, needs no (when composed with other GC-based computations) or negligible online interaction and workload for \( S \).

**Parallel Multiplications.** When \( N \) multiplications are done in parallel, e.g., component-wise multiplication of two vectors of \( N \) components, time and data complexity of GC-based multiplication grows linearly in \( N \). HE-based parallel multiplication increases slower as multiple homomorphic values can be packed before sending from \( S \) to \( C \) (cf. 4.4).

**Security Level.** We note that when the security level is
increased to medium- or even long-term security, the performance of HE-based multiplication decreases rapidly while the performance of GC-based multiplication is affected only moderately, as the asymmetric security parameter grows substantially faster than the symmetric one (cf. Table 1).

### 5.2 Evaluation of Fairplay Circuits and AES

As described in §4.1.2, TASTY can evaluate externally generated file circuits. Using this feature, we compare the performance of TASTY for evaluation of the AES functionality with the state of the art software implementation of GCs reported in [48, Table 2] which is implemented in C++ and measured on two machines also with Intel Core 2 Duo’s running at 3.0 GHz and 4GB of RAM connected by gigabit ethernet. We use the AES circuit of [48] which has 128 bit input bits provided by each party, 128 output bits for ethernet. We use the AES circuit of [48] which has 128 bit input bits provided by each party, 128 output bits for ethernet. We use the AES circuit of [48] which has 128 bit input bits provided by each party, 128 output bits for ethernet. We use the AES circuit of [48] which has 128 bit input bits provided by each party, 128 output bits for ethernet. We use the AES circuit of [48] which has 128 bit input bits provided by each party, 128 output bits for ethernet.

The performance of different GC implementations for evaluating the AES functionality is compared in Table 6.

Table 6: GC Evaluation of AES. Times in seconds.

than that of [48] by an order of magnitude. Recall, a short online phase, i.e., latency from providing the inputs until obtaining the outputs, is important for many real-world applications. To minimize this, TASTY shifts most computations into the less time-critical setup phase (cf. §5.2). Also TASTY has a slightly shorter total time than [48], whereas the data complexity is slightly larger due to less optimal data serialization in Python. More detailed, the setup time of [48] is 1s for GC creation and 1s for data transfer, and the online time is 3s for OT and 2s for GC evaluation. In TASTY, the setup time is dominated by 1.1s for OT and 1.8s for GC creation, and the online time is dominated by 0.4s for GC evaluation.

### 5.3 Evaluation of Large GCs

As AES, compared in §5.2, is the only non-trivial circuit for which performance results are reported in [48] and the code is not available yet, we compare the performance of TASTY for evaluation of large GCs with the original Fairplay system [37] implemented in Java.

Our test circuits have 10 unsigned 8-bit input values provided by C, |C| non-XOR 2-input gates and one output bit for S. For our measurements we use ultra-short term security parameters which provide the same security as Fairplay. Our measurement results are shown in Table 7.

Comparison. Memory. With 4GB memory, Fairplay was not able to evaluate circuits with 2²² gates and raised an OutOfMemoryError, while TASTY ran out of memory for circuits with 2²³ gates. In both cases, the huge blowup in memory is due to allocation of intermediate objects for each gate.

Communication. As expected, TASTY needs less communication than Fairplay as the chosen GC technique needs 3 instead of 4 entries per garbled 2-input non-XOR gate. Further, as GC is transferred in the setup phase, TASTY’s online communication is independent of the circuit size.

Time. TASTY’s setup time is slower than Fairplay’s total time by approximately a factor of 2 which we assume is due to less efficient internal data structures and nested function calls in the completely interpreted Python language compared to bytecode-compiled Java. On the other hand, TASTY’s online time is faster than the total time of Fairplay by factor 2 as we shifted complexity into the setup phase.

Conclusion. From the performance measurements with previous GC implementations in §5.2 and §5.3 we conclude that choosing more efficient primitives has large impact on the communication complexity whereas the memory and time complexity are dominated by non-cryptographic factors.

As OT seemed not to be the performance bottleneck in [48], they implemented a less efficient, UC secure OT protocol.

This yields the maximum number of 80 OTs before the OT extension kicks in which is not provided by Fairplay.
Table 7: Evaluation of Large GCs

| $|C|$ | Time [s] | Communication [MB] | | | |
|---|---|---|---|---|---|---|
| | TASTY | | TASTY | | | |
| | Setup | Online | Setup | Online | | |
| $2^{23}$ | 2 | 0.8 | 0.3 | 0.155 | 0.07 | 0.003 |
| $2^{18}$ | 4 | 6 | 1 | 3.67 | 1.7 | 0.003 |
| $2^{10}$ | 17 | 44 | 8 | 28.8 | 13.5 | 0.003 |
| $2^{20}$ | 80 | 177 | 32 | 113 | 54.2 | 0.003 |
| $2^{21}$ | 175 | 368 | 65 | 226 | 109 | 0.003 |
| $2^{22}$ | - | 787 | 132 | - | 217 | 0.003 |

such as optimizing data structures and flow for the selected programming language.

6. FUTURE WORK

To facilitate future work, TASTY is available for download at [56]. It is ready for being used as a tool for describing, implementing, benchmarking, and comparing protocols for many privacy-preserving applications. It could also be extended into a platform for comparing cryptographic primitives, e.g., rapidly emerging (fully) homomorphic encryption schemes.

Further Primitives. By adding 1-out-of-n OT as a further primitive, TASTY could be used for Hamming distance based computations [25] (based on HE and 1-out-of-n OT) with application to secure face identification [44]. Also other additively homomorphic encryption schemes for large [12] or small [9, 10] ciphertext space, or the schemes of [6, 18] which allow arbitrary many additions and one multiplication might be useful for some protocols. If applications require multiplication of very large numbers within a circuit one might consider implementation of multiplication circuits which are asymptotically faster than Karatsuba multiplication, e.g., Toom-3 [29, Sect. 4.3.3.A] splits each factor into 3 parts and performs 5 instead of 9 sub-multiplications resulting in complexity $\Theta(n^{\log_2 5}) \approx \Theta(n^{1.47})$.

Compilation to TASTYL. As a long-term goal it would be beneficial to automatically generate TASTYL programs from a high-level description of the algorithm to be computed securely in a function description language such as Fairplay’s SFDL language (cf. §4.2). Using TASTY’s capabilities for measuring the costs of the generated protocols the compilation process could automatically choose between circuits or homomorphic encryption (with one out of multiple homomorphic encryption schemes) for specific sub-tasks to generate highly efficient protocols.

Streaming vs. Pre-Computation. As discussed in §4 a crucial design goal of TASTY is to shift as many operations as possible into the setup phase resulting in a highly efficient online phase. This paradigm is justified when the two parties have a long-term relation where the function is known in advance and pre-computations can be performed ahead of time; this leads to a quick response time once the parties provide their inputs in the online phase. In some application scenarios where parties make ad-hoc decision when and what to compute securely, such pre-computations are not possible. HE-based SFE protocols naturally allow to change the evaluated functionality on-the-fly and stream data as soon as it is ready to keep CPUs and network busy simultaneously (e.g., as implemented in VIFF [11]). Also GC-based SFE protocols can be adapted to this streaming scenario as described in [26, 27]. In contrast to the compilation paradigm used in Fairplay [37, 38], TASTY already generates the circuits on-the-fly gate-by-gate. Foreach gate, the garbled table can be generated on-the-fly [29] and sent over the network and evaluated directly [27]. Also OT can be extended on-the-fly as mentioned in [24].

7. ACKNOWLEDGEMENTS

We thank anonymous reviewers of ACM CCS’10 for their helpful comments and Benny Pinkas for his suggestions on an early version of this paper. This work was funded by EU FP7 project CACE and ECRYPT II.

APPENDIX

A. SET INTERSECTION (§3.1) IN TASTYL

```python
# coding: utf-8

from tasty.crypt.math import getPolyCoefficients

def protocol(c, s):
    M = 100  # size of client's set
    N = 100  # size of server's set

    c.X = ModularVec(dim=M).input(desc="X")
    s.Y = ModularVec(dim=N).input(desc="Y")

    # interpolate coeffs of poly with roots c.X
    s.a = getPolyCoefficients()(c.X)

    # encrypt and send coefficients to server
    s.ha = HomomorphicVec(val=s.a)

    # evaluate and rerandomize p(y, i) under enc
    s.hbarY = HomomorphicVec(dim=N)
    for i in xrange(N): # 0, ..., N-1
        s.hbarY[i] = s.ha * s.Y[i] + s.ha[rand()]

    # send hbarY to client and decrypt
    c.hbarY = HomomorphicVec(val=c.hbarY)

    # compute intersection of c.X and c.barY
    for e in c.X:
        c.output(e, desc="in output set")
```

B. FACE RECOGNITION (§3.2) IN TASTYL

```python
# coding: utf-8

def protocol(c, s):
    K = 12  # dimension of eigenspace
    N = 10304  # number of pixels
    M = 42  # size of database

    # Declarations
    s.homegarbar = HomomorphicVec(dim=K)
    s.lgamma = HomomorphicVec(dim=N)
    s.hD = HomomorphicVec(dim=M)
    c.bot = UnsignedVec(bitlen=M, dim=(M+1))
    c.gbot = GarbledVec(val=c.bot)

    # Client inputs
    c.gamma = UnsignedVec(bitlen=8, dim=N).input()
    c.psi = UnsignedVec(bitlen=8, dim=N).input()

    # Server inputs
    s.omega = UnsignedVec(bitlen=32, dim=(M, K)).input()
    s.psi = UnsignedVec(bitlen=8, dim=N).input()
```
C. EXAMPLE: AUTOMATIC BENCHMARKING WITH TASTY

In this section we give a basic example how TASTY can be used to easily and automatically benchmark a TASTYL program for different parameter lengths. A high-level overview of TASTY's benchmarking capabilities is given in §4.2.

First, we create a new TASTYL project folder by invoking

```bash
tasty_init -d our_example
```

Afterwards, we adapt the benchmarking driver and the TASTYL program to our needs as shown in Fig. [11]. The benchmarking driver's `next_params` method yields the bitlengths for which the protocol should be run: `l = 1, 2, ..., 80`. The TASTYL program whose performance we would like to benchmark is a protocol which chooses two random `l`-bit inputs and multiplies them using homomorphic encryption.

We copy the TASTY project folder (our_example/) to client and server and invoke TASTY on both machines (client connects to server on TCP port 9000):

```bash
server> tasty -sd our_example
client> tasty -cd -H server:9000 our_example
```

TASTY automatically iterates over all bitlengths returned by the benchmarking driver, invokes the TASTYL program for this bitlength and stores the measured performance benchmarks into a file (results/costs.bin) on the client.

Finally, we adapt the post-processing script (analyze.py) as shown in Fig. [12] to select the costs to be drawn into the graph and run it with the measured costs:

```bash
client:our_example/> tasty_post analyze.py \ results/costs.bin
```

The resulting graph is shown in Fig. [13]. As expected, the costs are similar to HE2 in Fig. [10(b)].

To see a list of all costs which were measured use tasty_post -i our_example/results/costs.bin.

---

### Example: Automatic Benchmarking with TASTY

In this section we give a basic example how TASTY can be used to easily and automatically benchmark a TASTYL program for different parameter lengths. A high-level overview of TASTY’s benchmarking capabilities is given in §4.2.

First, we create a new TASTYL project folder by invoking

```bash
tasty_init -d our_example

Afterwards, we adapt the benchmarking driver and the TASTYL program to our needs as shown in Fig. [11]. The benchmarking driver’s `next_params` method yields the bitlengths for which the protocol should be run: `l = 1, 2, ..., 80`. The TASTYL program whose performance we would like to benchmark is a protocol which chooses two random `l`-bit inputs and multiplies them using homomorphic encryption.

We copy the TASTY project folder (`our_example/`) to client and server and invoke TASTY on both machines (client connects to server on TCP port 9000):

TASTY automatically iterates over all bitlengths returned by the benchmarking driver, invokes the TASTYL program for this bitlength and stores the measured performance benchmarks into a file (`results/costs.bin`) on the client.

Finally, we adapt the post-processing script (`analyze.py`) as shown in Fig. [12] to select the costs to be drawn into the graph and run it with the measured costs:

```bash
client:our_example/> tasty_post analyze.py \ results/costs.bin

The resulting graph is shown in Fig. [13]. As expected, the costs are similar to HE2 in Fig. [10(b)].

To see a list of all costs which were measured use `tasty_post -i our_example/results/costs.bin`.
