## Abstract

We consider the problem of constructing protocols for secure computation that achieve strong concurrent and composable notions of security in the plain model. Unfortunately UC-secure secure computation protocols are impossible in this setting, but the Angel-Based Composable Security notion offers a promising alternative. Until now, however, under standard (polynomial-time) assumptions, only protocols with polynomially many rounds were known to exist.

In this work, we give the first  $\tilde{O}(\log n)$ -round secure computation protocol in the plain model that achieves angel-based composable security in the concurrent setting, under standard assumptions. We do so by constructing the first  $\tilde{O}(\log n)$ -round CCA-secure commitment protocol. Our CCA-secure commitment protocol is secure based on the minimal assumption that one-way functions exist.

A central tool in obtaining our result is a new *robust concurrent extraction lemma* that we introduce and prove, based on the minimal assumptions that one-way functions exist. This robust concurrent extraction lemma shows how to build concurrent extraction procedures that work even in the context of an “external” protocol that cannot be rewound by the extractor. We believe this lemma can be used to simplify many existing works on concurrent security, and is of independent interest. In fact, our lemma when used in conjunction with the concurrent-simulation schedule of Pass and Venkatasubramanian (TCC’08), also yields a constant round construction based additionally on the existence of quasi-polynomial time ( $\mathcal{PQT}$ ) secure one-way functions.

## 1 Introduction

The notion of *secure multi-party computation* protocols is central to cryptography. Introduced in the seminal works of [Yao86, GMW87], secure multi-party computation allows a group of (mutually) distrustful parties  $P_1, \dots, P_n$ , with private inputs  $x_1, \dots, x_n$ , to jointly compute any functionality  $f$  in such a manner that the honest parties obtain correct outputs yet no group of malicious parties learn anything beyond their inputs and the prescribed outputs. These early results on secure computation [Yao86, GMW87], along with a rich body of followup works that further refined and developed the concept [GL90, GMW91, Bea91, MR91, Can00, PW01, Can01, Gol04], demonstrated that the delicate task of designing secure protocols can be captured by general secure computation.

Much of the early literature on secure computation only considered the *stand-alone* setting where security holds only if a single execution of the protocol takes place, in isolation with no other cryptographic activity in the system. We call this security *stand-alone security*. While stand-alone

security may be sufficient for basic purposes, it does not suffice in today’s more complex networked environments where other cryptographic protocols might be running in the system simultaneously.

**Concurrent Security.** To deal with more complex systems, the last decade has seen a push towards obtaining protocols that have strong concurrent *composability* properties. For example, we could require concurrent self-composability: the protocol should remain secure even when there are multiple copies executing concurrently. The framework of *universal composability* (UC) was introduced by Canetti [Can01] to capture a more general security requirement for a protocol that may be executed concurrently with not only several copies of itself but also with other protocols in an arbitrary manner.

Unfortunately, strong impossibility results have been shown ruling out the existence of secure protocols in the concurrent setting. UC secure protocols for most functionalities of interest have been ruled out in [CF01, CKL03]. Protocols in even less demanding settings of concurrent security were ruled on in [Lin04, BPS06, AGJ<sup>+</sup>12, Goy12]. We stress that, in fact, the latest sequence of these impossibility results provide an *explicit attack* in the concurrent setting using which the adversary may even fully recover the input of an honest party (see, e.g., the chosen protocol attack in [BPS06]). Hence, designing secure protocols in the concurrent setting is a question of great theoretical interest as well as practical motivation.

To overcome these impossibility results, UC secure protocols were proposed based on various “trusted setup assumptions” such as a common random string that is published by a *trusted party*[CF01, CLOS02, BCNP04, CPS07, Kat07, CGS08]. Nevertheless, a driving goal in cryptographic research is to eliminate the need to trust other parties. The main focus of this paper is to obtain concurrently-secure protocols in the *plain model*.

**Relaxing the Security Notion.** To address the problem of concurrent security for secure computation in the plain model, a few candidate definitions have been proposed, the most well studied one being that of *super-polynomial simulation* [Pas03, PS04, BS05]. The notion of security with *super-polynomial simulators* (SPS) [Pas03, PS04, BS05] is one where the adversary in the ideal world is allowed to run in (fixed) super-polynomial time. Very informally, SPS security guarantees that any polynomial-time attack in the real execution can also be mounted in the ideal world execution, albeit in super-polynomial time. This is directly applicable and meaningful in settings where ideal world security is guaranteed statistically or information-theoretically (which would be the case in most “end-user” functionalities that have been considered, from privacy-preserving data mining to electronic voting).

*Angel-based UC security.* To formalize the notion of SPS security in a way that allows modular analysis and provides composability, Prabhakaran and Sahai [PS04] put forward the notion of *angel-based composable security*. Very roughly, in the angel based security notion, the parties (including the simulator and the adversary) are all polynomial time but have access to an angel which will perform certain *specific* super-polynomial time computations. This angel-based definition is in contrast to the case where the simulator is given direct access to super-polynomial computation power: in this case, the resulting security notion is *not* closed under composition and thus does not permit a modular protocol design in the concurrent setting<sup>1</sup>. A construction for concurrently secure computation in the angel based composable security model were given in [PS04, BS05], but only based on non-standard super-polynomial hardness assumptions.

---

<sup>1</sup>However we note that according to this weaker SPS security notion, concurrently secure protocols in constant rounds are now known [GGJS12].

Very recently, Canetti, Lin, and Pass [CLP10] obtained the first secure computation protocol that achieves angel-based composable security based on *standard polynomial-time assumptions*. Unfortunately, however, the improvement in terms of assumptions comes at the cost of the round complexity of the protocol. Specifically, the protocol of [CLP10] incurs *polynomial-round complexity*. A follow up work of Lin and Pass [LP12] considers the problem of designing *black-box* constructions for secure computation in the concurrent setting. They propose a protocol making only a black-box use of oblivious transfer satisfying the angel-based composable security notion. However the round complexity of their protocol continues to remain polynomial.

We note that the latency of sending messages back and forth has been shown to often be the dominating factor in the running time of cryptographic protocols [MNPS04, BNP08]. Indeed, round complexity has been the subject of a good deal of research in cryptography. For example, in the context of concurrent zero knowledge (ZK) proofs, round complexity was improved in a sequence of works [RK99, KP01, PRS02] from polynomial to slightly super-logarithmic (that nearly matches the lower bound w.r.t. black-box simulation [CKPR01]). The round complexity of non-malleable commitments in the stand-alone and concurrent settings has also been studied in several works [DDN91, Bar02, PR05b, PR05a, LP09, Wee10, Goy11, LP11], improving the round complexity from logarithmic rounds to constant rounds under minimal assumptions. We observe that for the setting of concurrently secure computation protocols with angel-based composable security, the situation is worse since the only known protocols that achieves angel-based composable security based on standard assumptions incurs polynomial-round complexity [CLP10, LP12]. This raises the following natural question:

*“Do there exists round-efficient protocols in the concurrent setting satisfying the angel-based composable notion of security based on standard assumptions?”*

**Our Results.** We answer the above question in the affirmative and provide a  $\tilde{O}(\log n)$  round construction of concurrently secure computation in the plain model. Our construction satisfies the angel-based composable notion of security [PS04, CLP10]. To obtain our result, we construct a “CCA-secure commitment” protocol in  $\tilde{O}(\log n)$  rounds, based only the assumption that one-way functions exist. CCA secure commitments were introduced in [CLP10]; roughly speaking, a commitment protocol is CCA-secure if it remains hiding even when the adversary is given an oracle that can open all commitment values (except the commitment given as a challenge to the adversary). In [CLP10], Canetti et al. show how to construct a protocol that securely realizes any functionality—under the angel-based composable notion of security—given an (appropriate) protocol for CCA secure commitments (see full version of [CLP10]). Prior to our work, the best known construction for CCA secure commitments based on standard (polynomial time) assumptions, required  $n^\epsilon$  rounds [CLP10, LP12]. In contrast, the round complexity of our protocol matches that of the best known constructions for concurrent extractable commitment schemes [PRS02, MOSV06].

**A robust concurrent extraction lemma.** A key technical tool that we introduce is a lemma that allows *robust* extraction of secrets from an adversarial committer  $A^*$  in the *concurrent* setting. We call this lemma, the *robust concurrent extraction lemma*, which is of independent interest. Roughly speaking, the lemma is a strengthening of the concurrent extraction mechanism for the PRS preamble [PRS02] (we shall call this the PRS commitment), and states that concurrent extraction can be performed even in the presence of an external protocol which cannot be rewound by the “simulator.”

More precisely, consider an adversarial committer  $A^*$  who commits to multiple values in *concurrent* sessions of the PRS commitment to honest receivers; let us label these sessions as the **right**

sessions. Simultaneously,  $A^*$  participates in a **left** execution of an arbitrary  $k$ -round protocol, denoted  $\Pi := \langle B, A \rangle$ . Then, the robust concurrent-extraction lemma states that for every  $A^*$  there exists a simulator  $S$  which, *without rewinding the external party  $B$  in its execution of  $\Pi$* , extracts the values committed to by  $A^*$  in every session of the PRS commitment. Furthermore, if  $\ell$  is the round complexity of the PRS preamble, and  $T$  is the running time of  $A^*$ , then  $S$  only fails with probability that is exponentially small in  $\ell - O(k \cdot \log T)$ .

In order to capture correctness of extraction, we formulate our lemma by considering a “real-world” experiment in which  $A^*$  receives the values committed to in every valid PRS commitment from an exponentially powerful party  $\mathcal{E}$ , called the “online extractor.” The extraction of values are provided by  $\mathcal{E}$  as soon as a PRS session ends. Our lemma states, intuitively speaking, that both the adversary  $A^*$  and the exponentially powerful party  $\mathcal{E}$  can be replaced with a polynomial-time simulator, that still interacts with the external party  $B$  in the external protocol  $\Pi$ . We remark that formulating the lemma in a generic way, so that it can handle as general usage of the PRS commitment as we have seen in the literature, is a delicate task. Nevertheless, we show that it is possible to precisely capture the concurrent-extraction property of the PRS commitment in a generic way without referring to any specific protocol that uses it.

An immediate benefit of our formulation is that when the PRS commitment is used inside a larger protocol, the task of “concurrent extraction” can be *formally* isolated from other parts of the protocol. This allows one to design hybrid experiments without having to worry about the extraction. We provide two procedures for this purpose—a simulator  $S$  and an online extraction  $\mathcal{E}$ —and demonstrate their use in the security proof of our protocol.

We also wish to remark that the ability to extract without rewinding  $B$  turns out to be a very useful tool during concurrent security proofs, and we expect this will have significant applications elsewhere. This flexibility simplifies security proofs (of even previous works) to a great extent. For example, a situation similar to our lemma arises in previous works on concurrent non-malleable zero-knowledge [BPS06, LPTV10]. In these works, the problem is solved in an arguably ad-hoc fashion, which stops rewindings after a certain point in the simulation during certain hybrids. This, overall, leads to a rather delicate analysis, and the order of hybrid experiments becomes important.

By using our robust-extraction lemma, this problem can be avoided almost directly. We note however, that in our case, it is crucial that the rewindings not be stopped. This is because, in our situation, one needs to implement the super-polynomial angel from the beginning in each hybrid experiment. Hence, every session in every hybrid requires online extraction—which is possible either by using (all) rewindings or by using super-polynomial simulation.

**Technical Overview.** As mentioned before, the starting point of our construction is the robust extraction lemma. The basic problem encountered in proving the lemma is that given the entire transcript of interaction between  $A^*$  and the honest right parties, there are various “breakpoints” in the transcript (representing messages of the left protocol) which cannot be rewound. In addition, during rewindings (or look-ahead threads), the breakpoints can change their location and can even come earlier than expected (at which point the current thread must be discontinued and another one started). At a high level, we start by considering the necessary modification of the KP/PRS simulator so that when a breakpoint is encountered during the execution of a look-ahead thread, the look-ahead thread is stopped and abandoned.

Our proof shows that even with this modification, the simulation still succeeds. The key observation is that each breakpoint can “spoil” at most a  $d = \log T$  number of “recursive blocks” used in the swapping argument of [PRS02]. Since there are  $k$  breakpoints, this incurs an additional loss of  $k \cdot \log T$  blocks. However, to execute this proof strategy, it becomes crucial to use the informa-

tion learned during a “look-ahead block” in certain special sibling blocks. This new feature of our analysis must be done carefully to maintain the correctness of our swapping argument.

We note that we strive to obtain the best possible bounds for the round complexity  $\ell$  of PRS that is necessary to extract for a given value of  $k$  (rounds of the left protocol). For this reason, we choose to re-analyze the proof presented in [PRS02] (see also [PTV08])<sup>2</sup>.

For the goal of constructing CCA secure commitments, a direct application of the robust extraction lemma will not be sufficient. This is because the number of rounds in the left and the right interaction will be the same, and the robust extraction lemma cannot work with respect to protocols with the same round complexity as the PRScommitment! To construct CCA secure commitments (which is our main technical goal), we instead build upon techniques from prior work on concurrent non-malleable zero-knowledge (CNMZK) [BPS06, GJO10, LPTV10]. At a high level, our protocol is simple: commit to the value using a regular commitment scheme, and then, prove the validity of the commitment using a concurrent zero-knowledge protocol that is also *simulation sound* [Sah99]. We note that we design our own protocol for this task since we strive to achieve a construction based on *one-way functions* only (for CCA secure commitments). Using techniques from [BPS06, LPTV10] is either not possible or results in stronger assumptions such as the existence of collision-resistant hash functions. Our protocol is presented in section 3.

**A Constant Round Protocol from  $\mathcal{PQT}$  One-way Functions.** Our techniques can be seen as a general method which reduce the task of concurrent-extraction to that of concurrent-simulation. The method requires only a constant-factor blow up in the round-complexity (of a given concurrent-simulation method) and a polynomial-factor blow up in the running time of the (given) simulator. By applying our method to the concurrent-simulator of [PV08], we obtain a constant round protocol for CCA-secure commitments based only on the existence of one-way functions secure against adversaries running in time super quasi-polynomial time ( $\mathcal{PQT}$ ) (see [PV08]).

Assuming more complex, and somewhat non-standard assumptions—namely the existence of adaptive one-way functions [PPV08]—a constant round protocol for CCA secure commitments is already known [PPV08]. In addition, our techniques can also be combined with the recent constant round concurrent zero-knowledge protocols of [CLP12, GS12]<sup>3</sup>, to obtain constant round CCA secure commitments from similar (non-standard) assumptions.

**Related Works.** The work of Garg, Goyal, Jain, and Sahai [GGJS12] is closely related to our work, who provide a constant round protocol under the non-composable SPS notion (instead of angel-based composable security). Their work requires the existence of statistically hiding commitment. Independently of [GGJS12], a recent work of Lin, Pass, and Venkatasubramanian [LPV11] also provides a constant round protocol achieving non-composable SPS security, using very different techniques.

Other security notions that deal with concurrent security were presented in [MPR06, GGJS12] who propose the notion of *input indistinguishable computation*, and in [GS09, GJO10] who consid-

---

<sup>2</sup>For example, one can consider the approach of applying a pigeonhole principle argument to argue that  $\omega(\log n)$  slots must occur between some two breakpoints, and then trying to apply the PRS analysis simply to these slots. However, note that even if no breakpoints occur during these slots, *look-ahead threads* that are started during these slots can still encounter breakpoints, since the adversary can choose the scheduling adaptively. Dealing with this analytically would require further loss, and result in a worse asymptotic bound than ours for super-constant values of  $k$ . Our more direct approach shows how to amortize the gains made over all slots, even if only a few slots occur between some breakpoints.

<sup>3</sup>Chung, Lin, and Pass [CLP12] construct a constant-round concurrent zero-knowledge protocol under a new (falsifiable) assumption, namely the *existence of strong  $\mathbf{P}$ -certificate system*. Gupta and Sahai [GS12] also obtain the same result, albeit under a (new) knowledge-type assumption.

ered a modified ideal world that allows the adversary to make more output queries to the ideal functionality (than just one) per session.

## 2 Robust Concurrent Extraction

In this section, we will prove the robust extraction lemma. We use standard notation. In particular,  $A(x; r)$  denotes the process of evaluating (randomized) algorithm  $A$  on input  $x$  with random coins  $r$ , and  $A(x)$  the process of sampling a uniform  $r$  and then evaluating  $A(x; r)$ . We define  $A(x, y; r)$  and  $A(x, y)$  analogously. The set of natural numbers is represented by  $\mathbb{N}$ . Unless specified otherwise,  $n \in \mathbb{N}$  represents the security parameter available as an implicit input, when necessary. All inputs are assumed to be of length at most polynomial in  $n$ .

For two probability distributions  $D_1$  and  $D_2$ , we write  $D_1 \stackrel{c}{\equiv} D_2$  to mean that  $D_1$  and  $D_2$  are computationally indistinguishable. For two interactive Turing machines (ITM)  $A$  and  $B$ , we write  $\text{OUT}_B[A(1^n, x) \leftrightarrow B(1^n, y)]$ , the output of  $B$  after an interaction with  $A$  where their inputs in the interaction are  $y$  and  $x$  respectively, and their random tapes are independent and uniform.

We assume familiarity with commitment schemes. Without loss of generality, we will be using commitment schemes with non-interactive reveal phase—i.e., the committer sends a single message  $(v, d)$  to decommit. For a commitment scheme  $\langle C, R \rangle$ , we denote by  $\text{open}_{\langle C, R \rangle}(c, v, d)$  the decommitment function. That is, the receiver accepts  $v$  as the value committed to in the commitment-transcript  $c$  if  $\text{open}_{\langle C, R \rangle}(c, v, d)$  outputs 1, and rejects otherwise. For statistically binding commitments,  $v$  is uniquely determined given  $c$  with high probability.

### 2.1 The PRS Preamble

The robust extraction lemma deals with the commitment preamble of Prabhakaran, Rosen, and Sahai [PRS02]. This preamble has been used in many prior works, and is often referred to as the PRS preamble. The preamble uses an underlying commitment scheme  $\text{Com}$ . Roughly speaking, the committer first commits to many shares of the value  $v$  to be committed using  $\text{Com}$ . This is followed by a several rounds where in each round, the receiver sends a random challenge, and the committer responds with appropriate decommitments. Each round is called a *slot*.

Essentially, the PRS preamble is an interactive commitment scheme, which is statistically binding (resp. hiding) if the underlying scheme  $\text{Com}$  is statistically binding (resp., hiding). The formal description of the PRS preamble is given in figure 1. As before, we write  $\text{open}_{\text{PRS}}(c, v, \rho) = 1$ , to formally mean that there exists randomness  $\rho$  such that  $c$  is the transcript of the PRS preamble, executed between the honest committer with input  $v$  and randomness  $\rho$  and the honest receiver with randomness (equal to its challenges) appearing in  $c$ .

### 2.2 The Extraction Lemma

In this section, we present the robust extraction lemma. We will consider an adversary  $A^*$  who interacts in many sessions of the PRS preamble; simultaneously,  $A^*$  also participates in a single execution of a two party computation protocol  $\Pi$ . The running time of  $A^*$  is not necessarily polynomial in  $n$ . However, the lemma becomes trivial if the hiding/binding of the underlying commitment  $\text{Com}$  can be broken in  $\text{poly}(n) \cdot T^2$  time, where  $T = T(n)$  is the maximum number of PRS preambles  $A^*$  initiates.

**SIMPLIFYING ASSUMPTION.** We assume, for the clarity of presentation, that the commitment scheme  $\text{Com}$  underlying the PRS preamble is *statistically binding*. Later, we will present the general form

The security parameter is  $n$ , the value to be committed is  $v \in \{0,1\}^n$ , and the round-parameter is  $\ell := \ell(n)$ .

**Commitment.** The committer and the receiver execute the following steps.

1. The committer chooses  $n\ell$  pairs of  $n$ -bit random strings  $(v_{i,j}^0, v_{i,j}^1)$  for  $i \in [n], j \in [\ell]$  such that (for every  $i, j$ ):  $v_{i,j}^0 \oplus v_{i,j}^1 = v$ . It commits to strings  $v$ ,  $v_{i,j}^b$  using the commitment scheme  $\text{Com}$ , for every  $b \in \{0,1\}, i \in [n], j \in [\ell]$ .
2. For  $j = 1$  to  $\ell$ :
  - (a) the receiver sends a  $n$ -bit challenge string  $r_j = r_{1,j}, \dots, r_{n,j}$
  - (b) the committer responds by sending a decommitment to strings  $v_{1,j}^{r_{1,j}}, \dots, v_{n,j}^{r_{n,j}}$

**Decommitment.** The committer decommits to all remaining strings which were not opened in the commit phase.

**Figure 1:** The PRS Preamble based on  $\text{Com}$ .

which deals with both kinds of  $\text{Com}$ , as well as varying round complexity of the preamble.

PROTOCOL II. Let  $\Pi := \langle B, A \rangle$  be an arbitrary two-party computation protocol. We assume w.l.o.g. that both  $B$  and  $A$  receive a parameter  $n \in \mathbb{N}$  as their first input. In addition, for a fixed  $n \in \mathbb{N}$ , let  $\text{dom}_B(n)$  denote the domain of valid (second) input for algorithm  $B$ , and  $k := k(n)$  denote the round complexity of  $\Pi$ .

**The robust-concurrent attack.** Let  $A^*$  be an interactive Turing machine, called the adversary,  $n \in \mathbb{N}$  the security parameter, and  $x \in \text{dom}_B(n)$  an input. In the robust-concurrent attack,  $A^*$  interacts with a special, not necessarily polynomial time, party  $\mathcal{E}$  called the “online extractor.” Party  $\mathcal{E}$  simultaneously participates in one execution of the protocol  $\Pi$ , and several executions of the PRS preamble with  $A^*$ . Party  $\mathcal{E}$  follows the (honest) algorithm  $B(1^n, x)$  in the execution of  $\Pi$  with  $A^*$ . Further, it follows the (honest) receiver algorithm in each execution of the PRS preamble. If  $A^*$  successfully completes a PRS preamble  $s$ ,  $\mathcal{E}$  sends a string  $\alpha_s$  to  $A^*$ , together with a special message  $\text{END}_s$ , to mark the completion of the preamble.

The scheduling of all messages in all sessions— $\Pi$  as well as PRS preambles—is controlled by  $A^*$  including starting new sessions and finishing or aborting existing sessions. We adopt the following conventions [Ros04, PRS02]:

1. When  $A^*$  sends a round  $i$  message of session  $s$ , it immediately receives the next—i.e.,  $(i+1)$ -st message of  $s$ ; this is without loss of generality,<sup>4</sup> and holds for messages of  $\Pi$  as well.
2. If a session  $s$  has been aborted,  $A^*$  does not schedule any further messages of  $s$ .
3. If  $A^*$  starts a PRS preamble  $s$ , it also sends a special message, denoted  $\text{START}_s$ , immediately *after the last message* of step 1 of this preamble is completed (see figure 1). Message  $\text{START}_s$  indicates that the challenge-response phase is about to start.

At some point,  $A^*$  halts. We say that  $A^*$  *launches* the robust-concurrent attack.

For  $n \in \mathbb{N}, x \in \text{dom}_B(n), z \in \{0,1\}^*$ , let  $\text{REAL}_{\mathcal{E}, \Pi}^{A^*}(n, x, z)$  denote the output of the following probabilistic experiment: on input  $1^n$  and auxiliary input  $z$ , the experiment starts an execution of

<sup>4</sup>This is because the next message can be stored and delivered whenever needed during the attack.

$A^*$ . Adversary  $A^*$  launches the robust-concurrent attack by interacting with the special party  $\mathcal{E}$  throughout the experiment, as described above. When  $A^*$  halts, the experiment outputs the view of  $A^*$  which includes: all messages sent/received by  $A^*$  to/from  $\mathcal{E}$ , the auxiliary input  $z$ , and the randomness of  $A^*$ .  $\square$

We are now ready to present the robust extraction lemma. Informally speaking, the lemma states that there exists an interactive Turing machine—a.k.a the robust simulator—whose output is statistically close to  $\text{REAL}_{\mathcal{E}, \Pi}^{A^*}(n, x, z)$  even if the final response of  $\mathcal{E}$  at the end of a successful PRS session is actually the value  $A^*$  commits to in that session. Further, the robust simulator does not “rewind”  $B$ , and runs in time polynomial in total sessions opened by  $A^*$ .

**Lemma 1** (Robust Concurrent Extraction). *There exists an interactive Turing machine  $S$  (“robust simulator”), such that for every  $A^*$ , for every  $\Pi := \langle B, A \rangle$ , there exists a party  $\mathcal{E}$  (“online extractor”), such that for every  $n \in \mathbb{N}$ , for every  $x \in \text{dom}_B(n)$ , and every  $z \in \{0, 1\}^*$ , the following conditions hold:*

- 1. Validity constraint.** *For every output  $\nu$  of  $\text{REAL}_{\mathcal{E}, \Pi}^{A^*}(n, x, z)$ , for every PRS preamble  $s$  (appearing in  $\nu$ ) with transcript  $\tau_s$ , if there exists a unique value  $v \in \{0, 1\}^n$  and randomness  $\rho$  such that  $\text{open}_{\text{PRS}}(\tau_s, v, \rho) = 1$ , then:*

$$\alpha_s = v,$$

where  $\alpha_s$  is the value  $\mathcal{E}$  sends at the completion of preamble  $s$ .

- 2. Statistical simulation.** *If  $k = k(n)$  and  $\ell = \ell(n)$  denote the round complexities of  $\Pi$  and the PRS preamble respectively, then the statistical distance between distributions  $\text{REAL}_{\mathcal{E}, \Pi}^{A^*}(n, x, z)$  and  $\text{OUT}_s[B(1^n, x) \leftrightarrow S^{A^*}(1^n, z)]$  is given by:*

$$\Delta(n) \leq 2^{-\Omega(\ell - k \cdot \log T(n))},$$

where  $T(n)$  is the maximum number of total PRS preambles between  $A^*$  and  $\mathcal{E}$ .<sup>5</sup> Further, the running time of  $S$  is  $\text{poly}(n) \cdot T(n)^2$ .

We prove this lemma by presenting an explicit simulator  $S$  and a corresponding party  $\mathcal{E}$ . The explicit constructions appear in subsection 2.3, and the full proof of the lemma appears towards the end of the paper, in section 5. We now make some important remarks about the lemma.

### Remarks.

1. The special party  $\mathcal{E}$  is not completely defined by the lemma. In particular, when a PRS preamble  $s$  does not commit to a *unique and valid* value  $v$ , the value  $\alpha_s$  sent by  $\mathcal{E}$  to  $A^*$  is not defined. This can happen, e.g., when not all shares committed to in step 1 XOR to  $v$ . In such situations,  $\mathcal{E}$  can choose whatever value  $\alpha_s$  it wants. The only requirements on  $\mathcal{E}$  are that it uses honest algorithms during the robust-concurrent attack *and* that for each successfully completed PRS preamble it satisfies the validity constraint. Every  $\mathcal{E}$  satisfying these requirements is called a *valid*  $\mathcal{E}$ .

---

<sup>5</sup>The lemma allows for exponential  $T(n)$  as well. However, if it is too large—e.g.,  $T(n) = 2^{2^n}$ , the PRS preamble should be modified suitably. For example, the value  $v$  as well as the challenges in each slot, must be of length at least  $n + 2 \log T(n)$ .

2. The PRS preamble is used in a variety of complex ways. For example, some protocols require opening the committed PRS-value (e.g., [PRS02, BPS06, OPV10], whereas some others may never open this value (e.g., [LPTV10, GJO10]). To be able to capture such uses generically, we do not enforce any consistency requirements on the PRS preambles. The choice of not fully defining  $\mathcal{E}$  when PRS preamble is not valid provides sufficient flexibility to capture such generic uses of the preamble.
3. When the preamble is used in a larger protocol, a “main” simulator is used to prove the security of the larger protocol. Typically, the main simulator employs the rewinding strategy of [KP01, PRS02] to extract the PRS-values and simultaneously deals with other details of the protocol. Our lemma separates the task of extracting PRS-values from other necessary actions of the main simulator. This makes the overall proofs simpler. Party  $\mathcal{E}$  then only acts as mechanism to transfer the extracted PRS-values back to the main simulator. The main simulator takes upon the role of  $A^*$  to receive extracted values from  $\mathcal{E}$ , while only dealing with other details of the larger protocol.
4. A consequence of the above two remarks is that when a PRS preamble is not consistent, we do not know what value  $\alpha_s$  actually gets extracted. Our choice of the order of quantifiers allows  $\mathcal{E}$  to depend on  $A^*$  as well as  $S$ . This essentially allows  $\mathcal{E}$  to extract and supply the same value  $\alpha_s$  (by running  $S$  internally) that a typical “main” simulator would extract for inconsistent PRS preambles.
5. Requirements 1 and 2 of the lemma imply that if we sample an output of the simulator and consider a PRS preamble  $s$  with transcript  $\tau_s$  which contains a *unique* and *valid* value  $v$ , and receives  $\alpha_s$  as  $\mathcal{E}$ ’s response in the end, then except with probability  $\Delta(n)$ , it holds that  $\alpha_s = v$ .

### 2.3 A Robust Simulator and an Online Extractor

In this section, we present an explicit construction of a robust simulator  $S$ , and the (online extractor) party  $\mathcal{E}$  for which (the robust extraction) lemma 1 holds. The simulator is a slight modification of [KP01, PRS02], to also deal with messages of  $\Pi$ , without rewinding them. We start by defining a few terms first.

**The states of  $A^*$ .** Recall that the scheduling of messages in the robust-concurrent attack is controlled by  $A^*$ , and when  $A^*$  sends the  $i$ -th message of a session  $s$  (either PRS or  $\Pi$ ), it immediately receives the next message of  $s$ , namely the  $(i + 1)$ -st message. The *state* of  $A^*$  at any given point during the attack consists of its *view up to that point*: it includes all messages sent/received by  $A^*$ , its auxiliary input  $z$  and its randomness. The *starting* (or *original*) state of  $A^*$ —denoted throughout by  $\text{st}_0$ —is its state before it receives the first message. If  $\text{st}$  denotes the state of  $A^*$  at some point during the robust-concurrent attack, the set of all PRS preambles which have not completed yet is denote by  $\text{LIVE}(\text{st})$ .

**The robust simulator  $S$ .** The simulator receives as input an auxiliary string  $z \in \{0, 1\}^*$ , and the security parameter  $n$ . The simulator participates with an external party  $B$  of  $\Pi$ . Let  $x \in \text{dom}_B(n)$  and  $\gamma$  denote the input and uniformly chosen randomness of  $B$ . The simulator incorporates the adversary  $A^*$  as a black-box; let  $T = T(n)$  define the maximum number of PRS preambles that  $A^*$  can open during the robust-concurrent attack.

Simulator  $S$  starts by setting  $(1^n, z)$  on  $A^*$ ’s input tape, and a sufficiently long uniform string on its random tape. The simulator then initiates a helper procedure `recurse` as follows:

$$(\text{st}, \mathcal{T}) \leftarrow \text{recurse}(T, \text{st}_0, \emptyset, 1, \emptyset, 0).$$

Throughout its execution, messages of `recurse` are forwarded back and forth to  $B(1^n, x; \gamma)$  and (the black-box)  $A^*$  as appropriate. Finally, the output of  $S$  is the first output of `recurse`, namely `st`; the output `st` is also known as the *main thread*. Procedure `recurse` is given in figure 2, each execution of `recurse` is called a block, and has a unique name denoted by `id`.  $\square$

**The online extractor  $\mathcal{E}$ .** Formally, an execution of  $\mathcal{E}$  begins during a robust-concurrent attack. Let  $(\gamma, \rho)$  denote the random tape of  $\mathcal{E}$ , and  $(n, x, z)$  denote its inputs.  $\mathcal{E}$  incorporates the program of  $A^*$ , and performs the following *internal steps* before it sends out its first message in the robust-concurrent attack,

1.  $\mathcal{E}$  proceeds identically to the robust simulator algorithm  $S$ , using  $\rho$  as its random tape and  $(1^n, z)$  as its inputs. To successfully proceed in this step,  $\mathcal{E}$  uses  $(x, \gamma)$  to simulate the honest algorithm  $B(1^n, x; \gamma)$ , as well as black-box access to  $A^*$ .<sup>6</sup> However,  $\mathcal{E}$  differs from  $S$  in its actions only when a PRS preamble  $s$  completes, in the manner described below.
2. Let  $s$  be a successfully completed PRS preamble; at this point  $S$  either extracts a value  $\mu_s$  or reaches an `ExtractFail`. When this happens,  $\mathcal{E}$  neither sends  $\mu_s$  nor aborts the simulation; instead it proceeds as follows. First,  $\mathcal{E}$  attempts to extract the *actual value* committed to in the preamble by inverting all instances of the underlying commitment `Com`. Then, it decides the value  $\alpha_s$ , to be sent, as follows. If a valid and *unique* value  $v_s$  exists, set  $\alpha_s = v_s$ . Otherwise, it has following cases:
  - (a) If there are more than one valid  $v_s$ , proceed as follows: if  $\mu_s$  equals to any of them, set  $\alpha_s = \mu_s$ , otherwise, set  $\alpha_s$  to be one of them chosen at random.
  - (b) If no valid  $v_s$  exists, then proceed as follows: if  $\mu_s = \text{ExtractFail}$ , set  $\alpha_s$  to be a random value; otherwise, set  $\alpha_s = \mu_s$ .
3. After reaching the end of the simulation,  $\mathcal{E}$  internally stores the randomness  $\rho_s$  and the values  $\alpha_s$  for every PRS preamble  $s$  appearing on the *main thread*.

Having completed the steps above,<sup>7</sup>  $\mathcal{E}$  is now ready to interact with the (outside)  $A^*$  launching the robust-concurrent attack, and proceeds as follows.

- If  $A^*$  sends a message intended for the (only) session of  $\Pi$ ,  $\mathcal{E}$  interacts with  $A^*$  by following actions of  $B(1^n, x; \gamma)$ . Likewise, if  $A^*$  sends a messages for a PRS preamble  $s$ ,  $A^*$  follows the honest receiver algorithm of PRS preamble with *randomness*  $\rho_s$  already computed internally.
- If  $A^*$  successfully completes a PRS preamble  $s$ ,  $\mathcal{E}$  sends the already stored value  $\alpha_s$  to  $A^*$ .  $\square$

### 3 CCA Secure Commitments in $\tilde{O}(\log n)$ Rounds

In this section we apply our robust extraction lemma to construct a  $\tilde{O}(\log n)$ -round protocol for CCA secure commitments. We will need the generalized version of the lemma which allows for *statistically hiding* PRS preamble as well; the general version appears in A. We will also use a

<sup>6</sup>Observe that although  $\mathcal{E}$  depends on  $A^*$  here, it still uses  $A^*$  only as a black-box, as remarked earlier.

<sup>7</sup>We insist that all the steps above are *internal* to  $\mathcal{E}$  and that as of now it has not sent any external message in the robust-concurrent attack. Further, it can successfully complete these steps since it has all the required inputs.

**procedure**  $\text{recurse}(t, \text{st}, \mathcal{T}, f, \text{aux}, \text{id})$ :

1. If  $t = 1$ , **repeat**:

- (a) If the next message is **START**, start a new session  $s$ .
  - send  $r \leftarrow \{0, 1\}^n$  as the challenge of the first slot of  $s$ .
  - add entry  $(s : 1, r, \_)$  to  $\mathcal{T}$ .
- (b) If the next message is the slot- $i$  challenge of an existing session  $s$ .
  - send  $r \leftarrow \{0, 1\}^n$  as the slot- $i$  challenge of  $s$ .
  - add entry  $(s : i, r, \_)$  to  $\mathcal{T}$ .
- (c) If the next message is the slot- $i$  *response*, say  $\beta$ , of an existing session  $s$ .
  - If  $\beta$  is a valid message:
    - update entry  $(s : i, r_i, \_)$  to  $(s : i, r_i, \beta)$ .
    - if  $i = \ell$ , i.e., it is the last slot, send  $(\text{END}, \text{extract}(s, \text{id}, \mathcal{T}, \text{aux}))$ .
  - Otherwise, if  $\beta = \perp$ , abort session  $s$ , and add  $(s : \perp, \perp, \perp)$  to  $\mathcal{T}$ .
  - Update  $\text{st}$  to be the current state of  $A^*$
  - **return**  $(\text{st}, \mathcal{T})$ .
- (d) If the next message is a *response* from  $A^*$  for the external protocol  $\Pi$ .
  - If  $f = 0$ , i.e., it is a look-ahead block, then **return**  $(\text{st}, \mathcal{T})$ ;
  - If  $f = 1$ , i.e., it is the *main thread*, do the following:
    - send  $A^*$ 's message to the external party of  $\Pi$ , return the response to  $A^*$ .
    - Update  $\text{st}$  to be the current state of  $A^*$
    - For every live session  $s \in \text{LIVE}(\text{st})$ , do the following:
      - $\times_{s, \text{id}} = \text{true}$ ,
      - for every block  $\text{id}'$  that contains the block  $\text{id}$ , set:  $\times_{s, \text{id}'} = \text{true}$ .

2. If  $t > 1$ ,

# Rewind the first half twice:

- (a)  $(\text{st}_1, \mathcal{T}_1) \leftarrow \text{recurse}(t/2, \text{st}, \mathcal{T}, 0, \text{aux}, \text{id} \circ 1)$  [look-ahead block  $C'$ ]
- (b) Let  $\text{aux}_2 = (\text{aux}, \mathcal{T}_1 \setminus \mathcal{T})$ ,  
 $(\text{st}_2, \mathcal{T}_2) \leftarrow \text{recurse}(t/2, \text{st}, \mathcal{T}, f, \text{aux}_2, \text{id} \circ 2)$  [main block  $C'$ ]

# Rewind the second half twice:

- (c)  $(\text{st}_3, \mathcal{T}_3) \leftarrow \text{recurse}(t/2, \text{st}, \mathcal{T}^*, 0, \text{aux}, \text{id} \circ 3)$  [look-ahead block  $D'$ ]
- (d) Let  $\mathcal{T}^* = \mathcal{T}_1 \cup \mathcal{T}_2$  and  $\text{aux}_4 = (\text{aux}, \mathcal{T}_3 \setminus \mathcal{T}^*)$ ,  
 $(\text{st}_4, \mathcal{T}_4) \leftarrow \text{recurse}(t/2, \text{st}, \mathcal{T}^*, f, \text{aux}_4, \text{id} \circ 4)$  [main block  $D'$ ]

(e) **return**  $(\text{st}_4, \mathcal{T}_3 \cup \mathcal{T}_4)$ .

**procedure**  $\text{extract}(s, \text{id}, \mathcal{T}, \text{aux})$ :

1. Attempt to extract a value for  $s$  from  $\mathcal{T}$ .
2. If extraction fails, consider every block  $\text{id}_1$  for which  $\times_{s, \text{id}_1} = \text{true}$ .
  - Let  $\text{id}'_1$  be the sibling of  $\text{id}_1$ , with input/output tables  $\mathcal{T}_{\text{in}}, \mathcal{T}_{\text{out}}$  respectively.
  - Attempt to extract from  $\text{aux}_{\text{id}'_1} := \mathcal{T}_{\text{out}} \setminus \mathcal{T}_{\text{in}}$ ; (included in  $\text{aux}$ ).
3. If all attempts fail, abort the simulation and **return** **ExtractFail**.  
 Otherwise **return** the extracted value.

**Figure 2:** Procedures  $\text{recurse}$  and  $\text{extract}$  used by the robust simulator  $S$ .

non-malleable commitment scheme, denoted  $\text{NMCom}$ , that is *robust* w.r.t. constant round protocols [LP09]. Constant round constructions for such protocols are now known, see section C for details and definitions.

The protocol has a very intuitive “commit-and-prove” structure where the committer commits to the value  $v$  using a PRS preamble, and then proves its consistency using what resembles a “concurrent simulation-sound” protocol. We start by recalling the notion of CCA secure commitments from [CLP10].

### 3.1 CCA Secure Commitments

Let  $\langle C, R \rangle$  denote a statistically binding and computationally hiding commitment scheme. We assume w.l.o.g. that  $\langle C, R \rangle$  has a non-interactive reveal phase—i.e., the committer simply sends  $(v, d)$ . The decommitment is verified using a function  $\text{open}(c, v, d)$ ; that is, the receiver accepts  $v$  as the value committed in the commitment-transcript  $c$  if  $\text{open}(c, v, d)$  outputs 1, and rejects otherwise. A tag-based commitment scheme with  $l(n)$ -bit identities [PR05b, DDN91] is a commitment-scheme where in addition to  $1^n$ ,  $C$  and  $R$  also receive a “tag” (or *identity*) of length  $l(n)$  as common input. We will consider schemes which are *efficiently checkable*: meaning that if  $R$  *accepts* in the interaction (with transcript  $c$ ) then there exists a decommitment pair  $(v, d)$  such that  $\text{open}(c, v, d) = 1$ .

In CCA-secure commitments, we consider an adversarial receiver  $A$ , who has access to an oracle  $\mathcal{O}$ , called the “decommitment oracle.” The oracle participates with  $A$  in many *concurrent* sessions of (the commit phase of)  $\langle C, R \rangle$ , using tags of length  $l(n)$ , chosen adaptively by  $A$ . At the end of each session, if the session is accepting, the oracle returns the (unique) value committed by  $A$  in that session; otherwise it returns  $\perp$ . (In case there is more than one possible decommitment,  $\mathcal{O}$  returns any one of them.)<sup>8</sup>

Roughly speaking, we say that a tag-based scheme  $\langle C, R \rangle$  is CCA-secure if there exists a decommitment oracle  $\mathcal{O}$  for  $\langle C, R \rangle$ , such that the hiding property of the scheme holds even for adversaries  $A$  with access to  $\mathcal{O}$ . Formally, let  $\text{IND}_b(\langle C, R \rangle, \mathcal{O}, A, n, z)$  denote the output of the following probabilistic experiment: on common input  $1^n$  and auxiliary input  $z$ , the PPT adversary  $A^{\mathcal{O}}$  (adaptively) chooses a pair of challenge values  $(v_0, v_1) \in \{0, 1\}^n$  and a tag  $\text{id} \in \{0, 1\}^{l(n)}$ , and receives a commitment to  $v_b$  using the tag  $\text{id}$  (note that  $A$  interacts with  $\mathcal{O}$  throughout the experiment as described before); finally, when  $A^{\mathcal{O}}$  halts, the experiment returns the output  $y$  of  $A^{\mathcal{O}}$ ;  $y$  is replaced by  $\perp$  if during the experiment,  $A$  sends  $\mathcal{O}$  any commitment using the tag  $\text{id}$ .

**Definition 1** (CCA-secure Commitments, [CLP10]). *Let  $\langle C, R \rangle$  be a tag-based commitment scheme with tag-length  $l(n)$ , and  $\mathcal{O}$  be a decommitment oracle for it. We say that  $\langle C, R \rangle$  is CCA-secure w.r.t.  $\mathcal{O}$ , if for every PPT ITM  $A$ , every  $z \in \{0, 1\}^*$ , and every sufficiently large  $n$ , it holds that:*

$$\text{IND}_0(\langle C, R \rangle, \mathcal{O}, A, n, z) \stackrel{c}{\equiv} \text{IND}_1(\langle C, R \rangle, \mathcal{O}, A, n, z).$$

*We say that  $\langle C, R \rangle$  is CCA-secure if there exists a decommitment oracle  $\mathcal{O}'$  such that  $\langle C, R \rangle$  is CCA-secure w.r.t.  $\mathcal{O}'$ .*

An analogous version of the definition which considers many concurrent executions on left (instead of just one), is known to be equivalent to the current definition (via a simple hybrid argument). Also note that, for this reason, this definition implies concurrent non-malleable security for commitments [PR05a].

---

<sup>8</sup>Note that since  $\langle C, R \rangle$  is efficiently checkable, and the session is accepting, such a valid decommitment always exists. In addition, note that since we only have statistical binding, this value is unique except with negligible probability.

### 3.2 Our Protocol for CCA Secure Commitments

We are now ready to present our CCA secure commitment protocol, denoted CCA-Com. The protocol employs the PRS preamble in *both* directions (similar to [GJO10, LPTV10]). However, our protocol is much simpler, and admits an easier security proof.

We now provide a quick overview of our protocol. Our protocol will also use a constant-round non-malleable commitment scheme—NMCom—that is robust w.r.t. 4 rounds. The formal description of our protocol appears in figure 3.

Let  $v \in \{0, 1\}^n$  be the value to be committed. Our commitment protocol, CCA-Com, consists of five phases. In the first phase, the committer  $C$  commits to  $v$  using a statistically-binding PRS preamble. We denote this instance of the preamble by  $\text{PRS}_1$ . In phase 2, the receiver  $R$  uses a statistically-*hiding* PRS preamble to commit to a random value  $\sigma \in \{0, 1\}^n$ ; we denote this instance of the PRS preamble by  $\text{PRS}_2$ .

In phase 3,  $C$  commits to  $0^n$  using the *robust* NMCom scheme. In phase 4,  $R$  decommits to the value  $\sigma$  (of phase  $\text{PRS}_2$ ). Finally, in phase 5,  $C$  uses a witness-indistinguishable (WI) *proof* system to prove that: “either there exists a valid value  $v$  in phase 1 or the value committed in NMCom is  $\sigma$ .” It can use, for example, Blum’s 3-round protocol repeated in parallel  $n$  times [Blu87]. We remark that it is necessary to use a proof system which ensures soundness against unbounded provers.

To decommit,  $C$  sends decommitments corresponding to the first phase, namely  $\text{PRS}_1$ . The round-complexity of both PRS preambles is  $\ell \in \omega(\log n)$ . We have the following theorem, whose proof appears in section 4.

**Theorem 1.** *Assuming the existence of collision-resistant hash functions, protocol CCA-Com presented in figure 3 is a  $\tilde{O}(\log n)$ -round CCA secure commitment scheme for identities of length  $n$ .*

### 3.3 Construction based on One-way Functions

Protocol CCA-Com of the previous section requires the use of a statistically-hiding phase  $\text{PRS}_2$ . If we change the protocol so that  $\text{PRS}_2$  is statistically-binding, we will not be able to prove that the right sessions of CCA-Com remain statistically binding. This is because of the presence of the super-polynomial time oracle  $\mathcal{O}$ . Indeed, without the oracle we can make  $\text{PRS}_2$  statistically-binding and have a protocol based on one-way functions; but in the presence of oracle, it may happen that  $A^*$  is able to ensure that for some right session  $s$ ,  $\tilde{u}_s = \tilde{\sigma}_s$ .

To avoid this problem, we must somehow remove  $\text{PRS}_2$  yet still be able to later modify the left PRS slot-by-slot. The key observation is that in case of commitments, there is only one left session. Therefore, we can use a different simulation strategy which guarantees “soundness” w.r.t. unbounded committers as well.

Based on this observation, our one-way functions based protocol does not use  $\text{PRS}_2$ . Instead it uses a CoinFlip protocol in which no unbounded prover can succeed in “setting up a trapdoor” but a rewinding party can. Our new protocol, denoted CCA-Com\*, appears in figure 4.

**Theorem 2.** *Assuming the existence of one way functions, protocol CCA-Com\* presented in figure 4 is a  $\tilde{O}(\log n)$ -round CCA secure commitment scheme for identities of length  $n$ .*

For the proof of this theorem see appendix B. Although the proof is very similar to that of theorem 1, one crucial point is that we need to re-use the idea of robust-simulation, and be careful about how we apply it.

**Protocol CCA-Com.** The committing algorithm is denoted by  $C$ . The receiver algorithm is denoted by  $R$ . The common input is the security parameter  $n$  and an identity  $\text{id}$  of length  $n$ . The private input of  $C$  is the value  $v \in \{0,1\}^n$  to be committed. The protocol proceeds in following five phases:

- *Phase 1:*  $C$  commits to  $v$  using a statistically-binding PRS preamble. This instance of the preamble is denoted by  $\text{PRS}_1$ , and let  $\tau_1$  be the commitment-transcript.
- *Phase 2:*  $R$  commits to random  $\sigma \leftarrow \{0,1\}^n$  using a statistically-hiding PRS preamble. This instance of the preamble is denoted by  $\text{PRS}_2$ .
- *Phase 3:*  $C$  commits to the all-zero string  $0^n$  using  $\text{NMCom}$ , with common identity  $\text{id}$ . Let  $\tau_3$  be the commitment-transcript.
- *Phase 4:*  $R$  decommits to  $\sigma$ , by sending the appropriate decommitment strings.
- *Phase 5:*  $C$  proves to  $R$ , using a public coin, constant round WI *proof* system (e.g.,  $n$  parallel repetitions of Blum’s protocol), that either:
  - (a)  $\exists v \in \{0,1\}^n$  s.t.  $\tau_1$  is a valid PRS-commitment to  $v$ ; OR
  - (b)  $\tau_3$  is a valid commitment to  $\sigma$  as per  $\text{NMCom}$ .

**Decommitment oracle  $\mathcal{O}$ .** The oracle extracts the value committed to in transcript  $\tau_1$  of the first phase, and returns it.

**Figure 3:** Protocol CCA-Com.

## 4 Proof of Security for CCA-Com

We start by noting that the scheme is statistically-binding even against an unbounded cheating committer algorithm  $C^*$ . This is because of the following.  $\text{PRS}_2$  is statistically-hiding for  $\sigma$ , and therefore except with negligible probability, the value committed to in  $\text{NMCom}$  (which is statistically-binding) does not equal  $\sigma$ . Then, from the soundness of the WI *proof*, it follows that  $C^*$  can succeed only when the  $\text{PRS}_1$  is consistent. It will be important to have statistical-binding w.r.t. unbounded  $C^*$  since we will be dealing with the super-polynomial time oracle  $\mathcal{O}$  in various hybrid experiments.

We now proceed to demonstrate the CCA security of our scheme. To do so, we will directly construct a PPT simulator  $\text{SIM}$ , which simulates the view of any CCA adversary  $A^{*\mathcal{O}}$ .  $\text{SIM}$  will not have access to the decommitment oracle  $\mathcal{O}$ , and uses  $A^*$  only as a black-box. Recall that  $\mathcal{O}$  extracts the value from the transcript of  $\text{PRS}_1$ .  $\text{SIM}$  only receives  $1^n$  and auxiliary-input  $z$  for  $A^*$ , as its own inputs.

**Lemma 2.** *There exists a strict polynomial time machine  $\text{SIM}$  such that for every PPT ITM machine  $A^*$ , every  $z \in \{0,1\}^*$ , every sufficiently large  $n$ , and every  $b \in \{0,1\}$ , it holds that:*

$$\text{SIM}^A(1^n, z) \stackrel{c}{\equiv} \text{IND}_b(\langle C, R \rangle, \mathcal{O}, A, n, z).$$

**Proof.**

**Protocol CCA-Com\***. The committing algorithm is denoted by  $C$ . The receiver algorithm is denoted by  $R$ . The common input is the security parameter  $n$  and an identity  $\text{id}$  of length  $n$ . The private input of  $C$  is the value  $v \in \{0, 1\}^n$  to be committed.  $\text{Com}$  is a statistically-binding scheme.

**Round parameters.** Let  $q := q(n)$  be a fixed function in  $\omega(1)$ , and let  $\ell := \ell(n) = q(n) \cdot \log n \cdot \omega(1)$ . Let  $k \in O(1)$  be the round complexity of  $\text{NMCom}$ .

- *Phase 1:*  $C$  commits to  $v$  using the PRS preamble with parameter  $\ell \in \omega(\log n)$ . This instance of the preamble is denoted by  $\text{PRS}_1$ , and let  $\tau_1$  be the commitment-transcript.
- *Phase 2:*  $C$  and  $R$  execute the following  $\text{CoinFlip}$  protocol. In round  $i \in [q]$ :
  - (a)  $C$  commits a “short” string  $u_i \in \{0, 1\}^{\log n}$  using  $\text{Com}$ ,  
Let  $c_i$  be the commitment-transcript, and  $d_i$  a decommitment-string.
  - (b)  $R$  sends a “short” random string  $\sigma_i \in \{0, 1\}^{\log n}$
 Define  $u = (u_1, \dots, u_q)$ ,  $\sigma = (\sigma_1, \dots, \sigma_q)$ , and  $d = (d_1, \dots, d_q)$ .
- *Phase 3:*  $C$  commits to string  $(u, d)$  using  $\text{NMCom}$  and identity  $\text{id}$ . Let  $\tau_3$  be the commitment-transcript.
- *Phase 4:*  $C$  proves to  $R$ , using a public coin, constant round WI *proof*—e.g.,  $n$  parallel repetitions of Blum’s protocol—that either:
  - (a)  $\exists v \in \{0, 1\}^n$  s.t.  $\tau_1$  is a valid PRS-commitment to  $v$ ; OR
  - (b)  $\tau_3$  is a valid commitment to  $(u, d)$  as per  $\text{NMCom}$ , such that  $\forall i \in [q]$ :
    - (i)  $\text{open}_{\text{Com}}(c_i, u_i, d_i) = 1$ , and
    - (ii)  $u_i = \sigma_i$ .

**Decommitment oracle  $\mathcal{O}$ .** The oracle extracts the value committed to in transcript  $\tau_1$  of the first phase, and returns it.

**Figure 4:** Protocol CCA-Com\* based on one-way functions.

Recall that during its execution  $A^*$  opens one session of  $\text{CCA-Com} := \langle C, R \rangle$  on left, while simultaneously interacting in multiple concurrent sessions of  $\text{CCA-Com}$  with  $\mathcal{O}$ , called the right sessions. Let  $T = T(n)$  be a polynomial upper-bounding the number of right sessions of  $A^*$ .

Algorithm **SIM** will use the robust simulator  $S$  guaranteed by the (general version of) the robust-extraction lemma (see sections 2 and A), allowing it to extract the values committed to by  $A^*$  in all PRS preambles. It then uses these values to simulate the answers of  $\mathcal{O}$ , as well as to succeed in WI proof (by committing the extracted value in  $\text{NMCom}$  of the left session).

**SIM** uses two helper procedures: the robust simulator  $S$  and an “interface” algorithm  $I$  to be described shortly. Procedure  $I$  essentially “decouples” the PRS preambles from the rest of the  $\text{CCA-Com}$  protocol. It incorporates  $A^*$  as a black-box, and handles all messages of all sessions of  $\text{CCA-Com}$  internally and honestly, *except* for all the PRS preambles in which  $A^*$  acts as the *committer*. All these preambles are forwarded to outside PRS-receivers. That is,  $I$  participates in a robust-concurrent attack, interacting with the party  $\mathcal{E}$ . It executes PRS preambles with  $\mathcal{E}$ , and at the end of each PRS preamble  $s$ ,  $I$  expects to receive a value  $\alpha_s$  from  $\mathcal{E}$ . This value will be used internally.

**SIM** is a polynomial time machine without access to any super-polynomial time helper. Therefore, to run  $I$ , it runs the robust-simulator  $S$  providing it black-box access to the “adversary” procedure  $I$ . **SIM** outputs whatever  $S$  outputs. Formal descriptions follow.

**Algorithm  $\text{SIM}(1^n, z)$ .** Return the output of  $S^I(1^n, z)$ , where procedure  $I$ —which has black-box access to adversary  $A^*$ —is described below.

**Procedure  $I(1^n, z)$ .** Procedure  $I$  launches the robust-concurrent attack, by committing in several PRS sessions to external receivers denoted  $R_1, \dots, R_T$ . At the end of each preamble, it expects to receive a string  $\alpha_s$ .  $I$  incorporates the  $\text{CCA}$  adversary  $A^*$  internally, as a black-box.  $I$  initiates an execution of  $A^*$ , simulating various sessions of  $\text{CCA-Com}$  that  $A^*$  opens as follows.

1. If  $A^*$  starts a new session  $s$  of  $\text{CCA-Com}$  on *right*,  $I$  starts by initiating a new session of the statistically-binding  $\text{PRS}_1$  with an external receiver  $R_s$ . Then, messages of phase-1 of  $s$  are relayed between  $A^*$  and  $R_s$ .  $I$  simulates all other phases of  $s$  internally by following the honest algorithm for each phase.
2. If  $A^*$  starts a new session  $s$  of  $\text{CCA-Com}$  on *left*,  $I$  initiates a new session of the statistically-*hiding* preamble to be used as  $\text{PRS}_2$  of  $s$  with an external receiver  $R'_s$ .  $I$  completes various phases of  $s$  as enumerated below.
  - (a) *Phase 1:*  $I$  commits to an all zero string to  $A^*$ .
  - (b) *Phase 2:*  $I$  simply relays messages between  $A^*$  and  $R'_s$ .
  - (c) *Phase 3:*  $I$  commits to value  $\alpha_s$  using  $\text{NMCom}$  (instead of  $0^n$ ). Value  $\alpha_s$  was received from outside at the end of  $\text{PRS}_2$  of sessions  $s$ .
  - (d) *Phase 4:* If  $A^*$  correctly opens the value in  $\text{PRS}_2$  of session  $s$ ,  $I$  checks that the opened value is equal to the “fake witness”  $\alpha_s$ . If not, it outputs a special symbol `ExtractFail`, and halts. Otherwise it continues the execution.
  - (e) *Phase 5:*  $I$  uses  $\alpha_s$  and the randomness used in phase 3 ( $\text{NMCom}$ ) to complete the WI proof in phase 5.<sup>9</sup>

---

<sup>9</sup>Note that, technically,  $I$  can use the valid witness corresponding to the  $\text{PRS}_1$  phase  $s$ . This is since it committed to a valid value, namely  $0^n$ . However, we choose to use  $\alpha_s$  so that **SIM** will in fact be a valid simulator even for our concurrent non-malleable zero-knowledge protocols.

3. *Oracle answers:* If  $A^*$  successfully finishes a session  $s$  of CCA-Com on right,  $I$  sends the (already extracted) value  $\alpha_s$  to  $A^*$ .

When  $A^*$  halts,  $I$  outputs the view of  $A^*$ , and halts.  $\square$

**Proving Indistinguishability.** We are now ready to prove our lemma. We will prove this by using a series of hybrid experiments. Our hybrid experiments will be designed by making step-by-step changes to how  $I$  communicates with  $A^*$  internally in various phases of the protocol. For  $i \in [7]$ , we denote by  $\nu^i$  the output of hybrid  $H_i$ .

**Hybrid  $H_0$ :** This hybrid is identical to the experiment  $\text{IND}_b(\langle C, R \rangle, \mathcal{O}, A, n, z)$ . Recall that in this experiment,  $A^{*\mathcal{O}}$  receives a commitment to value  $v_b \in \{0, 1\}^n$  from the honest committer  $C$ , while interacting with the oracle  $\mathcal{O}$ . The output of the experiment consists of the view of  $A^*$ , which is also the output of  $H_0$ .

**Hybrid  $H_1$ :** This hybrid is identical to  $H_0$ , except for the following differences:

- (a)  $H_1$  does not forward the right sessions to  $\mathcal{O}$ . Instead, it executes all right sessions on its own, by playing the honest receiver strategy  $R$ . Denote by  $R_s$  the instance of  $R$  executed in session  $s$ .
- (b) When  $A^*$  successfully completes the session  $R_s$ ,  $H_1$  queries a different oracle  $\mathcal{O}'$ , which acts as follows. The query to  $\mathcal{O}'$  consists of only part of the commitment-transcript  $\text{PRS}_1$  that belongs for the value to be committed. All other messages (e.g., commitments of shares and slot-messages) are not part of the query. In particular, if Com is non-interactive, the query will be commitment of the value  $\tilde{v}_s$ . If there is a unique value defined by the query,  $\mathcal{O}'$  extracts that value, and returns it as the answer. In all other cases, it behaves exactly as  $\mathcal{O}$ .

**Hybrid  $H_2$ :** This hybrid is identical to  $H_1$ ; we use it to set up some notation. Define a procedure  $I_2$ , which is identical to procedure  $I$  (defined above), except that it executes (all internal phases of) the left session honestly and that it uses the oracle  $\mathcal{O}'$  as in  $H_1$ . That is, it only forwards the PRS preambles received from  $A^*$  outside, but executes all other phases internally and honestly. Formally,  $I_2$  is identical to  $I$  except:

- (a)  $I_2$  receives the value  $v_b$  to be committed in left sessions of CCA-Com, as an input. Furthermore,  $I_2$  commits to value  $v_b$  in  $\text{PRS}_1$  of the left session (instead of  $0^n$ , step 2(a)).
- (b) When a session  $s$  of  $\text{PRS}_1$  ends,  $I_2$  expects to receive a value  $\alpha_s$  from outside. If  $s$  is a statistically-binding session, then  $I_2$  gives  $\alpha_s$  to  $A^*$ . If  $s$  is statistically-hiding, it *ignores* the value  $s$ —there is only one such session corresponding to the left session.
- (c)  $I_2$  uses the valid witness,  $v_b$  and the randomness of  $\text{PRS}_1$  to complete its WI proof in the left session (step 2(e)).  $I_2$  does not check the validity of the “fake witness” (step 2(d)).

Observe that  $I_2$  is essentially launching a robust-concurrent attack. It does not perform any rewinds. Hybrid  $H_2$  simply runs the procedure  $I_2^{A^*}$ , and simulates PRS-receivers for it exactly as  $H_1$  does; furthermore, when a statistically-binding session  $s$  finishes,  $H_2$  forwards its commitment to  $\mathcal{O}'$  and returns the oracle's answer, denoted  $\alpha_s$ , to  $I$ . On the other hand, if the statistically-hiding session of PRS ends,  $H_2$  sends a random string  $\alpha_s$  (which, by construction, is ignored by  $I_2$ , see point (b)). The output of  $H_2$  is the view of  $I_2$  (which in turn is the view of  $A^*$ ).

**Hybrid  $H_3$ :** For procedure  $I_2$ , let  $\mathcal{E}$  be our online extractor as defined in section 2.3 (with addendum from section A to deal with statistically-hiding PRS as well). Recall that  $\mathcal{E}$  is a super-polynomial time machine, which facilitates the robust-concurrent attack. In particular, it acts honest receivers in all PRS preambles, as well as provides extractions for each one of them when they finish.

On input  $(1^n, v_b, z)$ , hybrid  $H_3$  starts an execution of  $I_2(1^n, v_b, z)$ , making it interact with party  $\mathcal{E}$ . The output of  $H_3$  is the output of the robust-concurrent attack, which in turn consists of the view of  $I_2$  (and hence  $A^*$ ). Therefore,  $H_3$  differs significantly from  $H_2$ : it does not run PRS receivers and does not have access to  $\mathcal{O}'$ , since these are automatically done by  $\mathcal{E}$  for  $H_3$ .

From hereon, we will only be making changes to the interface procedure  $I_2$ . All future hybrids, except for the last one, differ from  $H_2$  in only that they use a modified version of  $I_2$ . Furthermore, changes are made to the phases of the *left session* only, of which there is only one.

**Hybrid  $H_4$ :** This hybrid is identical to  $H_3$  except that instead of using  $I_2$ , it uses procedure  $I_4$ . Let  $\alpha_s$  be the value that  $I_2$  receives from  $\mathcal{E}$  at the end of statistically-hiding PRS<sub>2</sub> of the *left session*. Furthermore, let  $\sigma_s$  be the value opened by  $A^*$  which appears internally, in the *left session* of CCA-Com (simulated for  $A^*$  by  $I_2$ ).

Procedure  $I_4$  is identical to  $I_2$  except that when  $A^*$  sends  $\sigma_s$  along with valid openings,  $I_4$  tests that  $\alpha_s = \sigma_s$ ; it aborts the entire simulation if this test fails, and outputs `BindingFail`. Recall that  $I_2$  simply ignores  $\alpha_s$ .

**Hybrid  $H_5$ :** This hybrid is identical to  $H_4$  except that instead of using  $I_4$ , it uses a modified procedure  $I_5$ . Procedure  $I_5$  is identical to  $I_4$  except that instead of committing to  $0^n$ , it commits to  $\alpha_s$  in protocol NMCom of the *left session*  $s$ .

**Hybrid  $H_6$ :** Identical to  $H_5$  except that instead of using  $I_5$ , it uses a modified procedure  $I_6$ . Procedure  $I_6$  is identical to  $I_5$  except that it uses the “fake witness” in the WI proof of the left session  $s$ . Recall that the “fake witness” consists of the value  $\alpha_s$  and the randomness used in NMCom.

**Hybrid  $H_7$ :** Identical to  $H_6$  except that instead of using  $I_6$ , it uses a modified procedure  $I_7$ . Procedure  $I_7$  is identical to  $I_6$  except it does not receive the input  $v_b$ , and commits to  $0^n$  in the first phase PRS<sub>1</sub> of the left session. Observe that  $I_7$  is in fact identical to  $I$ .

**Hybrid  $H_8$ :** This hybrid differs from  $H_7$  in two crucial places. First, it does not receive the value  $v_b$  as input. Therefore, its only inputs are  $(1^n, z)$ . In addition, it does not use the party  $\mathcal{E}$ . Instead,  $H_8$  simply runs the robust simulator  $S$  with inputs  $(1^n, z)$  and black-box  $I_7$ . It outputs whatever  $S$  outputs. Observe that  $H_8$  is in fact our original simulator SIM, presented earlier.  $\square$

**Notation.** Let  $\nu^0$  denote the output of  $H_0$ . Let  $u^0$  be the variable denoting the value committed by  $C$  in NMCom in the left session, and let  $\sigma^0$  be the variable denoting PRS-value opened by  $A^*$  in (phase-4 of) the left session. Since there is only one left session, we will not use any subscripts. Analogously, define variables  $\tilde{u}_s^0$  and  $\tilde{\sigma}_s^0$  for the  $s$ -th right session in hybrid  $H_0$ . Finally, we denote by  $\tilde{v}_s^0$  the value  $A^*$  commits in PRS<sub>1</sub> of the  $s$ -th right session in  $H_0$ . For  $i \in \{0, \dots, 8\}$  define values  $\nu^i, \tilde{u}_s^i, \tilde{\sigma}_s^i$  and  $\tilde{v}_s^i$  w.r.t. the hybrid  $H_i$  analogously. Identity of the left session is referred to by `id`, and that of the  $s$ -th right sessions by `ids` without mention of the hybrid. Further, unless specified

otherwise, index  $s$  is in  $[T]$ , and  $\widetilde{\text{id}}_s$  is not equal to  $\text{id}$ , and the probability is taken over the randomness of the hybrid in consideration.

We start by noting that  $\nu^0$  is identical to  $\text{IND}_b(\langle C, R \rangle, \mathcal{O}, A, n, z)$ . Next, we claim the following.

**Claim 1.** *For every hybrid  $i \in \{0, \dots, 4\}$  and for every right session  $s \in [T]$ ,*

$$\nu^0 \stackrel{s}{\equiv} \nu^1 \equiv \nu^2 \stackrel{s}{\equiv} \nu^3 \stackrel{s}{\equiv} \nu^4 \quad (1)$$

$$\Pr [\widetilde{u}_s^i = \widetilde{\sigma}_s^i] \leq \text{negl}(n) \quad (2)$$

PROOF. It is seen by way of construction of hybrids  $H_1$  and  $H_2$ , that  $\nu^0 \stackrel{s}{\equiv} \nu^1 \equiv \nu^2$ .<sup>10</sup> In case of hybrid  $H_3$  party  $\mathcal{E}$ , which also simulates PRS sessions exactly as  $H_2$  does (since  $\mathcal{E}$  is valid). Furthermore,  $\mathcal{E}$  extracts the values  $\alpha_s$  in the (first message) of the PRS preamble exactly as  $\mathcal{O}'$  does in  $H_2$ . If a unique and valid  $\alpha_s$  exists, the value  $\alpha_s$  returned to  $I_2$  is the same in both hybrids. However, when the value is not unique,  $\mathcal{E}$  uses a different decision procedure to decide the value of  $\alpha_s$ . Nevertheless, statistical-binding of PRS ensures that this happens with only negligible probability. It follows that the distribution of answers  $\alpha_s$  in both hybrids is statistically close, and hence  $\nu^2 \stackrel{s}{\equiv} \nu^3$ .

Finally, in  $H_4$  the only difference is that  $I_4$  verifies that  $\alpha_s = \sigma_s$  (i.e., the fake witness is correct). From the validity constraint 1(b) on  $\mathcal{E}$  (see lemma 6, section A) this condition fails with only negligible probability. Therefore,  $\nu^3 \stackrel{s}{\equiv} \nu^4$ .

We first prove the second equation for hybrid  $H_0$ . Fix any right-session  $s$  of  $H_0$ . Observe that  $\text{PRS}_2$  of  $s$  is statistically-hiding. Therefore, except with negligible probability, we have that value  $\widetilde{\sigma}_s^0$  is not defined until after the completion of  $\text{NMCom}$  of session  $s$ . Since  $\text{NMCom}$  is statistically-binding, and there are exponentially many possible values for  $\widetilde{\sigma}_s^0$ , the claim follows (for hybrid  $H_0$ ). Now, observe that the same argument applies for hybrids  $H_1$  and  $H_2$  as well. In case of  $H_3$  and  $H_4$ , since  $\mathcal{E}$  simulates PRS receivers honestly, the same argument applies to these hybrids as well.  $\square$

A corollary of the second equation is that in each of these hybrids, for every right session  $s$  that is accepting, there exists a *unique* and *valid*<sup>11</sup> value  $\widetilde{v}_s^i$  to which  $A^*$  is committed to (except with negligible probability). This is because if the second equation holds, from the soundness of WI proof against unbounded adversaries,<sup>12</sup> phase  $\text{PRS}_1$  must be consistent defining a unique and valid value. Therefore, in all future hybrids, we will continue to maintain the second equation as an invariant.

**Claim 2.** *We have that,  $\nu^4 \stackrel{c}{\equiv} \nu^5$ ; and  $\forall s : \Pr [\widetilde{u}_s^5 = \widetilde{\sigma}_s^5] \leq \text{negl}(n)$ .*

PROOF. Both hybrids  $H_4$  and  $H_5$  use party  $\mathcal{E}$  which is super-polynomial time. Therefore, to prove the claim, we need to first need to eliminate the use of  $\mathcal{E}$ . Observe that this can be done by employing the robust simulator  $S$ . However, since we aim to reduce the claim to the non-malleability of  $\text{NMCom}$ , we would like one left execution and one right execution of  $\text{NMCom}$  that the robust-simulator  $S$  does not rewind.

Recall that the only difference between  $H_4$  and  $H_5$  is that they use different procedures:  $I_4$  and  $I_5$  respectively. The only difference between  $I_4$  and  $I_5$  is that the first one commits to  $x = 0^n$

<sup>10</sup>First two hybrids are not identical since the oracle changes:  $\mathcal{O}$  extracts from the full PRS transcript (and therefore always checks for consistency), whereas  $\mathcal{O}'$  simply extracts from the (first) committing message of PRS. Statistical-binding ensures that this difference happens only in negligible cases.

<sup>11</sup>Recall that  $v$  is valid if all shares XOR to  $v$ ; formally, there exists randomness  $\rho$  such that  $\text{open}_{\text{PRS}}(\tau_1, v_s, \rho) = 1$  where  $\tau_1$  is the commitment-transcript of  $\text{PRS}_1$  of  $s$ .

<sup>12</sup>We need this since  $A^*$  does have access to super-polynomial computations via  $\mathcal{O}$ , and we do not know what he might be learning.

whereas the second one commits to  $x = \alpha_s$  in phase NMCom of the left session. Recall that  $\alpha_s$  is the value sent by  $\mathcal{E}$  at the conclusion of PRS<sub>2</sub> of the left session.

We design an intermediate procedure  $I_*$ , which is identical to  $I_4$  except for the following differences:

1. When the NMCom phase of the left session is about to begin,  $I_*$  sends  $(0^n, \alpha_s)$  to an external committer.
2.  $I_*$  does not execute the NMCom of the left session internally. Instead, it expects to receive it from an external honest committer, denoted  $C_{\text{NM}}$ , who either commits to  $0^n$  or  $\alpha_s$ .
3. For a randomly chosen right session  $j$ ,  $I_*$  does not execute the the NMCom of session  $s$  internally. Instead, it forwards the messages of this NMCom to an external honest receiver, denoted  $R_{\text{NM}}^j$ .

Therefore,  $I_*$  is executed several PRS preambles, and at the same time acting as a man-in-the-middle for protocol NMCom by receiving a commitment and making a commitment at the same time. Let  $B$  denote the party who runs algorithm  $C_{\text{NM}}$  as well as  $R_{\text{NM}}^j$  for  $I_*$ , both *honestly*. Observe that the number of rounds of interaction between  $B$  and  $I_*$  are  $2k$  where  $k$  is the round-complexity of NMCom. The input  $x$  to  $B$  consists of the value to be committed by  $C_{\text{NM}}$ .

Viewed this way,  $I_*$  is an adversary who launches the robust-concurrent attack with respect to party  $B$ , and the party  $\mathcal{E}$ . Furthermore, if  $B$  commits to  $x = 0^n$  then the execution is identical to that of  $H_4$  with  $I_4$ ; on the other hand, if  $x = \alpha_s$ , the execution is identical to that of  $H_5$  with procedure  $I_5$ . That is,

$$\begin{aligned}\nu^4 &\equiv \text{REAL}_{\mathcal{E}, \Pi}^{I_*}(n, 0^n, z), \\ \nu^5 &\equiv \text{REAL}_{\mathcal{E}, \Pi}^{I_*}(n, \alpha_s, z).\end{aligned}$$

where protocol  $\Pi = (B, P_2)$ , and  $P_2$  is “converse of  $B$ —that is  $P_2$  acts as a receiver in one NMCom in which  $B$  is acting as a committer and vice-versa in the other.

Now, we can remove  $\mathcal{E}$  and instead use the robust-simulator  $S$  to sample statistically close views. That is, suppose that we run  $S$  with  $I_*$  and consider the output  $\text{OUT}_s(x) := \text{OUT}_s[B(1^n, 0^n) \leftrightarrow S^{I_*}(1^n, z)]$ . By applying the robust concurrent extraction lemma, we have that statistical distance between  $\text{OUT}_s(x)$  and  $\text{REAL}_{\mathcal{E}, \Pi}^{I_*}(n, x, z)$  is at most:

$$\Delta(n) \leq 2^{-\Omega(\ell - 2k \cdot \log T)} \leq \text{negl}(n),$$

for every  $x \in \{0^n, \alpha_s\}$  since  $\ell \in \omega(\log n)$ ,  $k$  is a constant, and  $T$  is at most a polynomial. Using this with the equations above, we get:

$$\nu^4 \stackrel{s}{\equiv} \text{OUT}_s(0^n) \tag{3}$$

$$\nu^5 \stackrel{s}{\equiv} \text{OUT}_s(\alpha_s) \tag{4}$$

By construction,  $\text{OUT}_s(x)$  is the output of  $S^{I_*}$  in an interaction with  $B$  on input  $x$ . Algorithm  $S^{I_*}$  is a PPT man-in-the-middle adversary for NMCom who receives a commitment to  $x$  from  $C_{\text{NM}}$ , and commits a value, say  $\tilde{u}_j(x)$ , to  $R_{\text{NM}}^j$ . From non-malleability of NMCom w.r.t. to itself, we have that:

$$(\tilde{u}_j(0^n), \text{OUT}_s(0^n)) \stackrel{c}{\equiv} (\tilde{u}_j(\alpha_s), \text{OUT}_s(\alpha_s)) \tag{5}$$

It immediately follows from (3), (4), and (5), that  $\nu^4 \stackrel{c}{=} \nu^5$ . Furthermore, suppose that the other part of the claim is false, so that for some session  $s \in [T]$  value  $\tilde{u}_s^5 = \tilde{\sigma}_s^5$  with noticeable probability  $p$ . Define this to be event  $\mathbf{bad}_5$  for hybrid  $H_5$ , and analogously define  $\mathbf{bad}_4$  for  $H_4$ .

Now observe that since  $j$  was chosen uniformly from  $T$  sessions,  $j = s$  with probability  $1/T$ . Therefore, value  $\tilde{u}_s^5$  appears as the variable  $\tilde{u}_j(\alpha_s)$  with probability  $1/T$ . In addition, value  $\tilde{\sigma}_j(\alpha_s)$  is a part of  $\text{OUT}_s(\alpha_s)$ , and therefore, event  $\mathbf{bad}_5$  is efficiently observable given both  $(\tilde{u}_j(\alpha_s), \text{OUT}_s(\alpha_s))$ ; and it occurs with probability  $p/T$  which is noticeable. By an analogous argument, event  $\mathbf{bad}_4$  is also efficiently observable; furthermore  $\mathbf{bad}_4$  must occur with noticeable probability as well due to equation (5). This contradicts equation (2). Hence the claim.  $\square$

**Claim 3.** *We have that,  $\nu^5 \stackrel{c}{=} \nu^6$ ; and  $\forall s : \Pr [\tilde{u}_s^6 = \tilde{\sigma}_s^6] \leq \text{negl}(n)$ .*

PROOF. The proof of this claim is almost identical to the proof of claim 2. The only difference is that instead of using non-malleability w.r.t. itself property of  $\text{NMCom}$ , we use the fact that  $\text{NMCom}$  is robust w.r.t. every *interesting* 3-round protocol (i.e., one that “hides” its input, see section C). Since the only difference between  $H_5$  and  $H_6$  is in the WI part, the proof follows; we omit the details.  $\square$

**Claim 4.** *We have that,  $\nu^6 \stackrel{c}{=} \nu^7$ ; and  $\forall s : \Pr [\tilde{u}_s^7 = \tilde{\sigma}_s^7] \leq \text{negl}(n)$ .*

PROOF. Observe that in  $H_6$ , since the “fake witness” is being used in the WI part, the  $\text{PRS}_1$  phase of the left session (which commits to input value  $v_b$ ) does not have to be consistent. Therefore, we proceed as follows:

1. Design  $\ell + 1$  intermediate hybrids  $H_{6:i}$  for  $i = \{0, \dots, \ell - 1\}$  where  $H_{6:0} = H_6$ ,  $H_{6:\ell} = H_7$ .
2. Hybrid  $H_{6:i}$  is the same as  $H_{6:i+1}$  except that in slot- $i$  of  $\text{PRS}_1$  phase of the left session,  $H_{6:i+1}$  commits to shares of an all-zero string.
3. Now, following the proof of claim 4 and by using the robustness of  $\text{NMCom}$  w.r.t. the 3-round protocols, we conclude that  $\nu^{6:i} \stackrel{c}{=} \nu^{6:i+1}$  and that  $\forall s : \Pr [\tilde{u}_s^{6:i} = \tilde{\sigma}_s^{6:i+1}] \leq \text{negl}(n)$ , where variables are analogously defined. The details of this part are repetitive, and omitted.

The claim now follows.  $\square$

**Completing the proof.** Note that the output of  $H_8$ , is statistically-close to  $\nu^7$  due to the robust-concurrent-extraction lemma. Therefore, combining all the equations we have that  $\nu^0 \stackrel{c}{=} \nu^8$ . Since  $H_8$  is identical to the simulator, the lemma follows.  $\blacksquare$

## 5 Proof of the Robust Extraction Lemma

We organize this section in two parts. The first part introduces important terminology used throughout the proof. The terminology is mostly consistent with previous literature [KP01, PRS02, Ros04, PTV08], and can be skipped by experts at first reading—except, for the notion of *breakpoints* (paragraph 2) and *unmarked view* of a block. In the second part, we present the actual proof of the lemma.

## 5.1 Terminology

We now introduce some terminology about the recursive structure of `recurse`. An execution of `recurse` is called a *block*. The six inputs of a block  $B$ , namely  $(t, \text{st}, \mathcal{T}, f, \text{aux}, \text{id})$  are referred to as follows. Input  $t$  is called the *length*,  $\text{st}$  the *starting state*, and  $\mathcal{T}$  the *starting solutions*. Input  $f$  is used as an identifier whose only purpose is to formally identify if  $B$  “lies on the main thread” (defined later); it does if  $f = 1$ . Input  $\text{aux}$  is called the *auxiliary table* (or auxiliary solutions), used only in special cases. Finally,  $\text{id}$  is the *identity* of the block  $B$ , used to uniquely specify  $B$  in the full recursive structure of `recurse`.

Blocks of length  $t = 1$  are called the *atomic* blocks. The output  $(\text{st}', \mathcal{T}')$  of a block consists of the *final* (or output) state and the *final* (or output) solutions. Each message of protocol  $\Pi$  is called a *breakpoint*, often denoted by a cross mark  $\times$ . If  $B$  is an atomic block, and a message of  $\Pi$  is scheduled during its execution, we say that  $B$  contains a breakpoint;  $B$  may contain one or several breakpoints.

Let  $B$  be a block that is not atomic.  $B$  executes four blocks during its own execution, in the following order:  $C'$ ,  $C$ ,  $D'$  and  $D$ . Blocks  $C'$ ,  $D'$  are called the *look-ahead blocks*; and  $C$ ,  $D$  the *main blocks* (see steps 2(a) to 2(d) of procedure `recurse`). Furthermore, blocks  $C$  and  $C'$  (resp.,  $D$  and  $D'$ ) are called *siblings*; they are the *children* of the same *parent* block  $B$ . We say that  $B$  contains its children blocks.

We say that blocks  $B_1$  and  $B_2$  are *consecutive*, denoted  $B_1 \rightarrow B_2$ , if the final state of  $B_1$  is the starting state of  $B_2$ . We say that  $B_1$  and  $B_2$  are *connected* if  $B_1 \rightarrow B_2$  or  $B_2 \rightarrow B_1$ . A thread  $h$  is represented by a sequence of consecutive blocks  $(B_1, \dots, B_m)$ , i.e.,  $B_i \rightarrow B_{i+1}$  for every  $i \in \{1, \dots, m-1\}$ . Further, if it holds that for every  $i \in [m]$ , block  $B_i$  in the sequence is an *atomic* block, then we say that the sequence is the *primitive sequence* of  $h$ . Note that a primitive sequence *uniquely* identifies a thread. That is, a thread  $h$  can be uniquely referred to by specifying the *identity* of each atomic block  $B_i$  in the sequence. Note that identities, by construction, are indeed unique for every block, including blocks that are not atomic. We say that threads  $h_1$  and  $h_2$  are the *same* if their primitive sequences are equal. We say that a thread  $h$  is an *internal thread* of a block  $B$  if every block  $B_i$  in the primitive sequence of  $h$  is contained in  $B$ . If  $B$  is not an atomic block, it contains many internal threads. The *base thread*  $h$  of a block  $B$  is an internal thread of  $B$  whose primitive sequence consists of only *main blocks*. That is every atomic block appearing in the primitive sequence of the base-thread is actually a *main* block of its parent block. By construction, the base thread of a block  $B$  is unique. Finally, we say that a block  $B$  *lies* on a thread  $h$  if there exists a sequence  $h'$  of blocks containing  $B$  such that the primitive sequence of both  $h$  and  $h'$  is identical.

We note that the terminology so far is exclusively about the recursive structure of `recurse`. In particular, it allows us to refer to various blocks and threads without considering any specific execution with any given random tape or inputs. Fixing the length  $t$  of a block, completely fixes the flow chart of all recursive calls inside that block and hence its internal structure.

**Main Thread:** A thread  $h$  is called the *main thread*, if every sequence of blocks  $\{B_i\}_i$  specifying  $h$ , is a *main block*. Equivalently,  $h$  is a main thread if every (atomic) block in the primitive sequence of  $h$  has receives the flag  $f = 1$ . Observe that, by construction, there exists a *unique* main thread. All other threads are called *look-ahead* threads.

Recall that the *original* state of  $A^*$  is denoted by  $\text{st}_0$ , and consists of its auxiliary input  $z$  and its randomness. Also recall that the execution of  $A^*$  proceeds in rounds, where in round  $i$  of the interaction, adversary  $A^*$ —who is participating in many PRS preambles as well as one session of

$\Pi$ —sends its next message and immediately receives a response. The state of  $A^*$  at the beginning of the round  $i$ , consists of its original state  $\text{st}_0$ , and all messages that it sends or receives. This terminology allows us to refer to the state of  $A^*$  even within an atomic block  $B$ .

We say that a state  $\text{st}$  of  $A^*$  lies on a thread  $h$  if there exists an atomic block  $B_i$  in the primitive sequence of  $h$  such that the state of  $A^*$  is  $\text{st}$  at some point during the execution of  $B_i$ . Let  $\text{st}_1$  and  $\text{st}_2$  be two states of  $A^*$  that lie on  $h$  such that  $\text{st}_2$  appears before  $\text{st}_1$ ; then we denote by  $\text{st}_1 \rightarrow \text{st}_2$ , all messages that lie on  $h$  between  $\text{st}_1$  and  $\text{st}_2$ , and call it a *segment* of a *part* of the thread  $h$ . We say that a block  $B$  *contains* a message  $v$  if  $v$  appears on an internal thread of  $B$ . A session  $s$  is said to lie on a thread  $h$  if all messages of  $s$  appear on  $h$ . Finally, we say that a block  $B$  contains the  $j$ -th slot of session  $s$  if  $B$  contains both  $(r_j, \beta_j)$ , where  $r_j$  is the receiver-challenge in round  $j$  of  $s$ , and  $\beta_j$  the corresponding openings sent by  $A^*$ . Recall that  $(r_j, \beta_j)$  is a convincing slot if  $\beta_j$  consists of valid openings of commitments chosen by  $r_j$ .

**Unmarked view/execution of a block.** Consider all internal threads of a block  $B$ , which contain a breakpoint  $\times$  (i.e., a message of  $\Pi$ ). By construction, if a  $\times$  appears on a look-ahead thread, the execution of the look-ahead thread stops as soon as  $\times$  occurs—that is, there are no further messages scheduled after  $\times$ . However, if  $\times$  occurs on the base-thread of  $B$ , *and* the base-thread is a part of the main-thread, the execution does not stop after  $\times$ , and continues. The unmarked view (or execution) of  $B$  consists of executing the part of each internal-thread  $h$  of  $B$  executed *only* up to the point where a  $\times$  occurs on  $h$ . Therefore, if base-thread of  $B$  contains a  $\times$  then the unmarked-execution will continue the base thread after the  $\times$ . We note that all threads and breakpoints  $\times$  considered are internal to  $B$ , and that any breakpoint not contained in  $B$  does not affect unmarked view of  $B$ .

Now, we say that a message  $v$  is contained in the unmarked view of  $B$  if  $v$  appears on an internal thread of  $B$  in the unmarked execution of  $B$ . This means that  $v$  appears on internal thread of  $B$  before an breakpoint  $\times$  appears on that thread. We define the term “slot- $j$  of a session appears in the unmarked view of  $B$ ” analogously.

## 5.2 Proof of Successful Simulation

Let us fix a *target* thread  $h$  and a *target* session  $s$  that lies on  $h$ . Formally, define a random tape  $\rho$  of the simulator to be *bad* if all slots of session  $s$  that lie on  $h$  are convincing, whereas all slots of  $s$  that lie on look-ahead threads are not convincing. We now define notion of *robust blocks*, and an ordering relation (adapted from [PRS02, Ros04, PTV08]).

**Definition 2** (Robust Block). *Let  $\rho$  be a fixed random tape. Let  $h$  be an arbitrary thread, and  $B$  an arbitrary block, all defined by the execution of `recurse` with random tape  $\rho$ . Further, let  $s$  be an arbitrary session of the PRS preamble that lies on  $h$ . We say that  $B$  is a robust block with respect to  $h$  and  $s$  if it satisfies the following conditions:*

- (a) (Main block:)  $B$  lies on  $h$  and does not contain the `START` message of session  $s$ .
- (b) (Full slot:)  $B$  contains a convincing slot of  $s$  (not necessarily on  $h$ ) in the unmarked execution. That is, a convincing slot appears on an internal thread of  $B$ , prior to any breakpoint  $\times$  on that thread.
- (c) (Good sibling:)  $B'$  does not contain an `END` of session  $s$ .
- (d) (Blocked `END`:)  $B$  does not contain any `END` of  $s$  in the unmarked view.

(e) (*Locatable:*) Every slot of  $s$  that lies on  $h$  and appears before  $B$  is convincing, and all other threads (that complete) before  $B$ , do not contain any convincing slot of  $s$ .

Let us first establish the following claim:

**Claim 5.** *If  $B$  is a robust block, then it is a main block (of its parent).*

PROOF. Suppose that  $B$  is not a main block. Then it is a look-ahead block, and therefore, there does not exist any block  $C$  for which  $B \rightarrow C$ . Since  $s$  completes on  $h$ ,  $h$  contains the END of  $s$ , denoted  $\text{END}_s$ . Since  $\text{END}_s$  occurs after all slots of  $s$ , and  $B$  contains a full slot of  $s$ , we have that  $\text{END}_s$  cannot occur before  $B$ . Further, since there is no  $C$  such that  $B \rightarrow C$ ,  $\text{END}_s$  cannot occur after  $B$  either. Therefore,  $\text{END}_s$  must occur in  $B$ . Consider the internal thread of  $B$  on which  $\text{END}_s$  occurs, say  $h'$ . By requirement (d),  $\text{END}_s$  cannot occur in the unmarked view of  $B$ . However, since  $B$  is a look-ahead block, by construction, the unmarked view is the entire view of  $B$ , and hence  $B$  cannot contain  $\text{END}_s$ . This is a contradiction.  $\square$

Recall that a block  $B$  contains all its children blocks, as well as all blocks that are contained by its children. If a block  $B_1$  contains another block  $B_2$ , then  $B_2$  does not contain  $B_1$ . We say that  $B_1, B_2$  are *disjoint*, if  $B_1$  does not contain  $B_2$  and vice versa.

The following order relation will provide a correct order to swap blocks (unchanged from [PTV08]).

**Definition 3.** *Let  $C$  and  $B$  be two blocks on a common thread. We write  $C > B$  iff*

- $C$  and  $B$  are disjoint, and  $C$  occurs before  $B$ , or
- $C$  and  $B$  are not disjoint, and  $C$  is a larger block that contains  $B$ .

Since these are the only two possible cases, relation  $>$  defines a total order on any set of blocks that lie on the *same* thread. Now, let us formally define the *swap* operation. The swap operation takes as input a random tape  $\rho$ , and the identity of a block  $B$ . Let  $B'$  be the sibling of  $B$ . The swap operation exchanges part of  $\rho$  used to executed  $B$  with that used to execute  $B'$ , and outputs the resulting tape.

Finally we define the *undo* function on any given random tape  $\rho'$ . The *undo* function is defined with respect to the target thread  $h$  and the target session  $s$ . Since we are dealing with an external party of protocol  $\Pi$  as well, we define *undo* also with respect to a fixed input  $x$  and randomness  $\gamma$  of the external party. The output of  $\text{undo}(\rho') := \text{undo}_{x,\gamma,h,s}(\rho')$  is defined as follows:

1. Execute the simulation using *recurse*, with random tape  $\rho'$  and  $(x, \gamma)$  as (input, randomness) of the external party of  $\Pi$ . Call a block special if it *does not* lie on the target thread and contains a convincing slot of the target session. That is the block lies on a look ahead thread with a convincing slot of  $s$ .
2. Locate the first special block,  $D$ , after the START; that is, any other special block  $E$  after START satisfies  $D > E$ .
3. Swap the parts of  $\rho'$  used by  $D$  and its sibling, say  $D'$ ; output the new random tape.

**Lemma 3.** *Let  $\rho$  be a random tape (not necessarily bad). Let  $B$  be a robust block with sibling  $B'$ , with respect to  $h$  and  $s$ , when *recurse* is executed with random tape  $\rho$ . Further, let  $\rho'$  be the random tape obtained after swapping the parts of  $\rho$  used by blocks  $B$  and  $B'$ . Then,*

1. (*Goodness*):  $\rho'$  is a good random tape with respect to  $h$  and  $s$ .

2. (Robustness): If  $C$  is a robust block on  $\rho$  and  $C > B$ , then  $C$  is also robust on  $\rho'$ .
3. (Reversibility):  $\text{undo}(\rho') = \rho$ .

**Proof.**

Note that  $B$  and  $B'$  are not necessarily symmetric: inputs  $f, \text{aux}$  differ for them. Therefore, the swap may change the internal execution of these blocks. The key point is that the unmarked view of  $B$  after the swap “does not shrink.”

**Goodness.** Let us first establish the goodness property. Let  $\text{st}$  be the common starting-state and  $\mathcal{T}$  be the common solutions table of blocks  $B$  and  $B'$ . Let  $\text{aux}$  and  $\mathcal{T}_1$  be the auxiliary- and the output-tables of  $B'$ , respectively. By construction, the auxiliary table of  $B$  is  $\text{aux}_2 = (\text{aux}, \text{aux}_{B'})$  where  $\text{aux}_{B'} = \mathcal{T}_1 \setminus \mathcal{T}$ . The following claim says that  $\text{aux}_{B'}$  is never used to solve a session that lies in the unmarked view of  $B'$ :

**Claim 6.** *Let  $u$  be a session, and  $\text{id}$  an atomic block. If  $\text{extract}(u, \text{id})$  reads table  $\text{aux}_{B'}$ , then  $B$  contains  $\text{END}_u$ ; but it contains no  $\text{END}_u$  in the unmarked view of  $B$ . That is, a breakpoint  $\times$  occurs between  $\text{START}_u$  and  $\text{END}_u$ .*

**PROOF.** Consider an arbitrary main block  $\text{id}_1$  with sibling  $\text{id}'_1$ . By construction,  $\text{extract}(u, \text{id})$  reads  $\text{aux}_{\text{id}'_1}$  if and only if all of the following conditions hold: (a)  $\text{id}$  reaches  $\text{END}_u$ , (b)  $\text{id}_1$  contains  $\text{id}$  (and therefore  $\text{END}_u$ ), and (c)  $\times_{u, \text{id}_1} = \text{true}$  (meaning that a  $\times$  occurs in block  $\text{id}_1$  on the thread containing  $\text{END}_u$ ). Conditions (a) and (b) prove the first part of the claim.

Consider the requirement (c). By construction,  $\times_{u, \text{id}_1} = \text{true}$  if and only if execution in block  $\text{id}_1$  reaches a  $\times$  (i.e., a message of protocol  $\Pi$  is scheduled) while the session  $u$  is still “live”—i.e.,  $\text{START}_u$  has occurred, but  $\text{END}_u$  has not yet occurred on the current thread. Therefore, if  $\text{extract}(u, \text{id})$  reads  $\text{aux}_{\text{id}'_1}$  then block  $\text{id}_1$  contains a  $\times$  between  $\text{START}_u$  and  $\text{END}_u$ .

By this argument, if  $\text{extract}(u, \text{id})$  reads  $\text{aux}_{B'}$ , we have that block  $B$  contains a  $\times$  between  $\text{START}_u$  and  $\text{END}_u$ . This proves the second part of the claim.  $\square$

**Claim 7.** *The unmarked views of  $B$  and  $B'$  do not change after the swap.*

**PROOF.** Let us first consider the block  $B$ . Before the swap,  $B$  receives  $\text{aux}_{B'}$  as (part of) its auxiliary input table, whereas after the swap, it does not. The key observation is that the execution of the unmarked view of  $B$  does not read the table  $\text{aux}_{B'}$ . Indeed, suppose on the contrary, that it does. Then, there must exist a session  $u$  and an atomic block  $\text{id}$  such that  $\text{extract}(u, \text{id})$  reads the table  $\text{aux}_{B'}$ . From claim 6, there must occur a  $\times$  before  $\text{END}_u$  occurs. Therefore, the call to  $\text{extract}(u, \text{id})$  occurs only *after* the  $\times$  mark. By definition, this call will not occur during the unmarked view/execution of  $B$ . Therefore, we have that the unmarked view of  $B$  never reads the table  $\text{aux}_{B'}$ . Since  $\text{aux}_{B'}$  is the only missing part in  $B$ 's input, it follows that the claim holds for  $B$ .<sup>13</sup>

Now consider the block  $B'$ . After the swap,  $B'$  becomes a main block. If  $B'$  does not lie on the *main thread*, all threads will still stop as soon as the first  $\times$  mark occurs; therefore, by claim 6, the table  $\text{aux}_B$  (defined analogously to  $\text{aux}_{B'}$  in the swapped tape  $\rho'$ ) will not be accessed. On the other hand, if  $B$  lies on the main thread, some of its internal threads may continue the execution past their first (or even later)  $\times$  marks. However, even in this case, by claim 6, executions of these threads prior to the first  $\times$  do not use table  $\text{aux}_B$ , and therefore remain unchanged. The claim follows for  $B'$  as well.  $\square$

---

<sup>13</sup>Although input  $f = 0$  after the swap, this in fact only enforces that only the unmarked view of  $B$  executes.

**Claim 8.**  $\rho'$  is a good tape.

PROOF. Since  $B$  is a robust block, by definition, it contains a convincing slot of  $s$  and does not contain  $\text{END}_s$  in the *unmarked view* with tape  $\rho'$ . From claim 7, it follows that even after the swap,  $B$  will continue to have a convincing slot of  $s$  and no  $\text{END}_s$ .

Further, before the swap,  $B'$  does not contain  $\text{END}_s$ . Observe that since  $B'$  is a look-ahead block (see claim 5), this view is also its *unmarked view*. Therefore, the *unmarked view* of  $B'$  does not contain  $\text{END}_s$ . After the swap,  $B'$  lies on the target thread  $h$ . We have two cases:

1. If  $B'$  does not lie on the *main* thread, the execution of  $B'$  does not change (since  $f = 0$ ). Since  $B'$  does not contain  $\text{END}_s$ , if  $\text{END}_s$  ever occurs on the target thread  $h$ , it will occur after both  $B$  and  $B'$ , and therefore contain a slot of  $s$  that is opened twice. Hence  $\rho'$  is a good tape.
2. If  $B'$  lies on the main thread, some of the internal threads of  $B'$  may continue the execution past a  $\times$  mark. First note that by claim 7,  $\text{END}_s$  still does not occur in the *unmarked view* of  $B'$ . Therefore, if a  $\text{END}_s$  occurs in the full view of  $B'$  on a thread  $h'$  which contains a  $\times$  before  $\text{END}_s$ . When this happens, `extract` will access the table `auxB` and find a convincing slot of  $s$  (since  $B$  contains a convincing slot and stores it in `auxB`). Further, since  $\text{END}_s$  was reached in the full view  $B'$ , this slot must have been opened again. Hence  $\rho'$  is a good tape.  $\square$

**Robustness.** Let  $C$  be a robust block on tape  $\rho$  such that  $C > B$ . Let  $C'$  be the sibling of  $C$ .

CASE 1: ( $C$  occurs before  $B$ ). In this case, swapping of  $B$  and  $B'$  does not change the execution of either  $C$  or  $C'$ . It also does not change the execution between `START` and  $C$ , leaving all requirements of a robust block intact on  $\rho'$ .

CASE 2: ( $C$  contains  $B$ ). In this case, swapping of  $B$  and  $B'$  does not affect the execution of  $C'$ , and the execution between `START` of  $s$  and before  $C$ . Therefore the main block, good sibling, and locatable requirements still hold for  $C$  in  $\rho'$ . We have two cases.

The first case is when the *unmarked view* of  $B$  is *not* a part of the *unmarked view* of  $C$ . Note that this happens when  $C$  contains a  $\times$  on  $h$  before  $B$ . In this case, swapping of  $B$  and  $B'$  does not change the *unmarked view* of  $C$ , and therefore keeps the remaining requirements of a robust block—namely, full slot, good marking, and blocked `END`—intact on  $\rho'$ .

The other case is when the *unmarked view* of  $B$  is a part of the *unmarked view* of  $C$ . This happens when  $C$  does not contain any  $\times$  mark on  $h$  before  $B$ . After the swap,  $B$  does not line on  $h$ , but instead becomes the look-ahead thread. However, even after the swap,  $B$  continues to be contained in  $C$ ; further, the *unmarked view* of  $B$  also continues to be the part of *unmarked view* of  $C$ .<sup>14</sup> Since the *unmarked view* of  $B$  satisfies the remaining requirements of a robust block—namely, full slot, good marking, and blocked `END`, it follows that they hold for  $C$  as well on the tape  $\rho'$ .

**Reversibility.** Consider the execution of `undo`( $\rho'$ ). `undo` starts by locating the first special block  $D$ . That is,  $D$  contains a convincing slot of  $s$ , does not lie on  $h$ , and for every other special block  $E$ ,  $D$  either occurs before  $E$  or  $D$  contains  $E$ . After locating  $D$ , `undo` swaps the randomness used by  $D$  and its sibling  $D'$ .

---

<sup>14</sup>Note that the overall *unmarked view* of  $C$  in this case may have changed; in particular, this happens when before the swap: (a)  $B$  connects to some block  $D$ , (b)  $B$  contains a  $\times$  on its base thread, *but* (c)  $B'$  does not contain a  $\times$  on its base thread. Thus,  $D$  is not a part of the *unmarked view* of  $C$  on tape  $\rho$ . However, after the swap,  $D$  will be a part of the *unmarked view* of  $C$ .

We start by noting that on tape  $\rho'$ ,  $B$  does not lie on  $h$ ; further as argued before,  $B$  contains a convincing slot of  $s$ . Therefore  $B$  is special on  $\rho'$ . Further observe that every block that occurs before cannot have a convincing slot of  $s$  due to the locatable requirement. Also, any block  $E$  that contains  $B$  must also contains  $B'$ ; since  $B'$  which lies on  $h$  in tape  $\rho'$ , so does  $E$ . Therefore  $E$  cannot be special. It follows that  $B$  is always the first special block on  $\rho'$ , and `undo` swaps  $B$  with  $B'$ . This proves that  $\text{undo}(\rho') = \rho$ .  $\blacksquare$

The following claim shows that robust blocks can be swapped arbitrarily to generate many good tapes for each bad tape.

**Lemma 4.** *Let  $\rho$  be a bad random tape, and  $\mathcal{R} = \{B_1, \dots, B_m\}$  a set of robust blocks for  $\rho$ . Then, there exists a set of good tapes, denoted  $\mathcal{G}(\rho, \mathcal{R})$  such that:*

1.  $|\mathcal{G}(\rho, \mathcal{R})| \geq 2^m - 1$ .
2. For every bad random tape  $\rho' \neq \rho$ , and every set of robust blocks  $\mathcal{R}'$  for  $\rho'$ :  
 $\mathcal{G}(\rho, \mathcal{R}) \cap \mathcal{G}(\rho', \mathcal{R}') = \emptyset$ .

PROOF. By definition, all blocks lie on the same thread, and therefore have a total ordering. Without loss of generality, let  $B_1, \dots, B_m$ . Choose any non-empty subset  $R$  of blocks in  $\mathcal{R}$  and apply the swap operation on each one of them in the reverse order of their actual ordering (defined by relation  $>$ ). Denote by  $\rho_R$  the resulting tape. From lemma 3, each swap leaves the first block in  $R$  still robust, and swapping the last block gives a good tape. Therefore,  $\rho_R$  is a good random tape. Since there are  $2^m - 1$  non-empty subsets of  $\mathcal{R}$ , the first part of the claim follows.

To prove the second claim, assume that  $\gamma \in \mathcal{G}(\rho, \mathcal{R}) \cup \mathcal{G}(\rho', \mathcal{R}')$ . Since  $\gamma \in \mathcal{G}(\rho, \mathcal{R})$  by reversibility of swap, applying `undo` repeatedly on  $\gamma$  until a bad tape is obtained returns  $\rho$ . Likewise, since  $\gamma \in \mathcal{G}(\rho', \mathcal{R}')$ , the same process returns  $\rho'$ . But since `undo` is a deterministic function, this is a contradiction.  $\square$

We say that the simulator  $S$  gets *stuck* if it outputs `ExtractFail`. Further, we say that  $S$  gets *stuck on  $h$  in session  $s$*  if it outputs `ExtractFail` when sessions  $s$  ends on  $h$ —i.e.,  $\text{END}_s$  is scheduled by  $A^*$ . We now bound the probability of getting stuck.

**Lemma 5.** *Simulator  $S$  gets stuck with probability at most  $2^{-\Omega(\ell - k \cdot \log T)}$ .*

**Proof.**

We first prove the following claim.

**Claim 9.** *For every bad random tape  $\rho$ , the number of robust blocks is at least  $\ell - (k + 2) \cdot \log T$ .*

PROOF. Let us define the notion of a *minimal* block. We say that a block  $B$  is minimal for slot- $j$  of session  $s$ , if and only if:  $B$  contains (the convincing) slot- $j$ , but none of its children blocks contain slot- $j$ . It is easy to see that for every session  $s$  there are  $\ell$  minimal blocks. This is because each slot has at least one minimal block; furthermore, a block can be minimal for exactly one slot, since otherwise, it would have to contain two slots of  $s$  and at least one of them will be contained in one of its children blocks (by construction).

Next, each of these minimal blocks lies on  $h$ . Further, they all have a good sibling (requirement (c) in definition 2). This is because  $\rho$  is a bad tape and therefore it does not contain a convincing slot on any other look-ahead threads. Now, for every `START`, `END`, and  $\times$  there are at most  $\log T$  blocks that contain it. Such blocks cannot be robust, by definition, and there is a total of  $(k + 2) \cdot \log T$

of them. All the other remaining minimal blocks, satisfy the remaining requirements of definition 2, which is a total of  $\ell - (k + 2) \cdot \log T$ .  $\square$

By construction, the simulator can output `ExtractFail` if there exists a session  $s$  and thread  $h$  such that its random tape  $\rho$  is bad w.r.t.  $(h, s)$ . It can also output `ExtractFail` if in fact the tape is not bad, but the convincing slots were opened for the same PRS-challenge. However, the latter only happens with probability  $2^{-n} \cdot T^2 \cdot \text{poly}(n)$  throughout the simulation. Further, the former happens with probability  $2^{-\Omega(\ell - k \cdot \log T)}$ , and since there are only  $T^2 \cdot \text{poly}(n)$  threads and sessions total, the claim follows from the union bound.  $\blacksquare$

**Completing the proof of the robust concurrent-extraction.** It is easily seen that if a particular PRS preamble contains a valid value, it must be consistent. However, whenever it is consistent, the simulator indeed extracts the correct value unless either it gets stuck or the commitment is not binding. Since both of these events occur with negligible probability, the validity constraint follows. The second part of the lemma follows from the fact that the simulator behaves exactly like  $\mathcal{E}$ , and that when PRS-sessions are consistent, the provided values are the same except with negligible probability; further, where they are not consistent, both  $S$  and  $\mathcal{E}$  provides identically distributed values, to  $A^*$ . This completes the proof.

## A Generalized Version of the Robust Extraction Lemma

In the generalized version of the lemma, we allow  $A^*$  to open sessions of the PRS preambles that are *statistically hiding*. At the start of the preamble, it is already understood whether it is statistically-binding or statistically-hiding. Since statistically-hiding preambles are only computationally-binding, we require that  $A^*$  is a PPT machine. Furthermore, we make following new adjustments to the robust-concurrent attack:

At the successful completion of a *statistically-hiding* PRS preamble  $s$ , when  $A^*$  receives the string  $\alpha_s$  from  $\mathcal{E}$ , it can choose to respond with an opening of the committed value  $v_s$ . It does so by sending appropriate decommitment strings  $(v_s, d_s)$ . Furthermore, the scheduling of this message is decided by  $A^*$ .

Other than this, the attack remains unchanged. We now present the generalized version of the lemma. The essence of the lemma is still the same as before. We only need to add conditions to deal with the statistically-hiding preambles. For such preambles, the validity constraint requires that  $\alpha_s$  be equal to the opened value  $v_s$  (if any), except with negligible probability.

**Lemma 6** (Robust Extraction: General Version). *There exists an interactive Turing machine  $S$  (“robust simulator”), such that for every PPT  $A^*$ , for every  $\Pi := \langle B, A \rangle$ , there exists a party  $\mathcal{E}$  (“online extractor”), such that for every  $n \in \mathbb{N}$ , for every  $x \in \text{dom}_B(n)$ , and every  $z \in \{0, 1\}^*$ , the following conditions hold:*

**1. Validity constraint.** *For every output  $\nu$  of  $\text{REAL}_{\mathcal{E}, \Pi}^{A^*}(n, x, z)$ , we have:*

- (a) *for every statistically-binding preamble  $s$  (appearing in  $\nu$ ) with transcript  $\tau_s$ , if there exists a unique value  $v \in \{0, 1\}^n$  in the commitment-transcript  $\tau_s$ , then  $\alpha_s = v$ ,*
- (b) *for every statistically-hiding preamble  $s$  (appearing in  $\nu$ ) with transcript  $\tau_s$ , if there exists a valid opening  $(v_s, d_s)$  in the view  $\nu$ , then  $\alpha_s = v_s$ ,*

*where  $\alpha_s$  is the value  $\mathcal{E}$  sends at the completion of  $s$ .*

**2. Statistical simulation.** *If  $k = k(n)$  and  $\ell = \ell(n)$  denote the round complexities of  $\Pi$  and the PRS preamble respectively, then the statistical distance between distributions  $\text{REAL}_{\mathcal{E}, \Pi}^{A^*}(n, x, z)$  and  $\text{OUT}_S[B(1^n, x) \leftrightarrow S^{A^*}(1^n, z)]$  is given by:*

$$\Delta(n) \leq 2^{-\Omega(\ell - k \cdot \log T(n))},$$

*where  $T(n)$  is the maximum number of total PRS preambles between  $A^*$  and  $\mathcal{E}$ .<sup>15</sup> Further, the running time of  $S$  is  $\text{poly}(n) \cdot T(n)^2$ .*

The proof of this general version of the lemma is identical to the proof of the original lemma, presented in appendix 5. We only need to show that condition 1(b) also holds. We show that if it does not then we can violate the computational binding of the statistically-hiding PRS. Suppose that  $\text{Com}_{sh}$  is the underlying commitment scheme of the statistically hiding PRS. Then, if  $\alpha_s$  is not equal to  $v_s$ , look at the two opened challenges in the execution of `recurse` whose XOR results in  $\alpha_s$ ; let them belong to slot  $i$  of this session. Both of these strings must have been decommitted to correctly (for the scheme  $\text{Com}_{sh}$ ). Further, since opening  $v_s$  requires opening of all slots of PRS such that pairs in each slot XOR to the same  $v_s$ , we have that all pairs of slot  $i$  must have been correctly opened to strings that are different from what `recurse` learned. Therefore, we must have an instance of  $\text{Com}_{sh}$  with correct openings to two different values. The details are standard and omitted. We note that the value of  $\Delta(n)$  in the second condition does not change since both  $\mathcal{E}$  and  $S$  extract value  $\alpha_s$  identically for the statistically-hiding PRS.

<sup>15</sup>The lemma allows for exponential  $T(n)$  as well. However, if it is too large—e.g.,  $T(n) = 2^{2n}$ , the PRS preamble should be modified suitably. For example, the value  $v$  as well as the challenges in each slot, must be of length at least  $n + 2 \log T(n)$ .

## B Proof of Security for CCA-Com\*

We do not present a full proof of security for this protocol here, since it follows closely the structure of proof for CCA-Com (based on collision-resistant hash functions). Instead, we present here the main changes to the proof, and how we proceed, during simulation.

We first start with the protocol `CoinFlip` and show that it actually has a robust simulator as well (i.e., the one that does not rewind the external party  $B$  of protocol  $\Pi$ ), so long as the number of rounds are appropriately high.

**A robust simulator for protocol `CoinFlip`.** We now show that protocol `CoinFlip` admits a robust “simulator” w.r.t.  $k$ -round protocols, so long as  $q - k \in \omega(1)$ . Let us denote the protocol `CoinFlip` :=  $\langle P_1, P_2 \rangle$  where  $P_1$  follows the step 2(a) whereas  $P_2$  follows the step 2(b) defined in figure 4. Recall that protocol has  $q \in \omega(1)$  rounds, where in round  $i$   $P_1$  commits to  $\log n$  size string  $u_i$ , and  $P_2$  responds with a  $\log n$  size string  $\sigma_i$ .

1. We say that  $P_2$  *wins* if it can set  $u_i = \sigma_i$  for every  $i \in [q]$  with noticeable probability. Note that since  $q \in \omega(1)$  no cheating prover  $P_1^*$ , even with unbounded running time, can win this game. The probability of winning the game for any  $P_1^*$  is at most  $n^{-q}$ .
2. We say that a machine  $S_{CF}$  is a simulator for protocol `CoinFlip` if for every  $P_2^*$ , if its output is computationally indistinguishable from the view of  $P_2^*$  in a real execution with  $P_1$ ; furthermore, if  $P_2^*$  completes the protocol successfully, then  $S_{CF}$  outputs a trapdoor  $(u, d)$  such that except with negligible probability:  $u_i = \sigma_i$  and  $d_i$  is a correct decommitment-string for round  $i$  commitment  $c_i$  to the value  $u_i$ . We require that  $S_{CF}$  be a strict polynomial time machine.
3. First observe that for the protocol `CoinFlip` such a simulator  $S_{CF}$  indeed does exist: trivial and standard. Simulator  $S_{CF}$  simply rewinds  $P_2^*$  in each slot- $i$  until it succeeds in setting up  $u_i = \sigma_i$ , up to a maximum of  $n$  times. The simulator fails in output a view only with probability  $n^{-q}$ .
4. We now explain a robust version of this simulator. Suppose that  $P_2^*$ , in addition to interacting with  $P_1$ , also interacts with a party  $B$  of some protocol  $\Pi$  (which has  $k$  rounds). We would like a simulator which satisfies the same conditions as our simulator above  $S_{CF}$  above, but without “rewinding” party  $B$ . Therefore the new  $S_{CF}$  will interact with  $B$  as participant of  $\Pi$ , yet be able to output a view for  $P_2^*$  such that the “trapdoor” and the indistinguishability conditions are satisfied as above. Call such an  $S_{CF}$  robust.
5. It is easy to obtain a robust  $S_{CF}$  for `CoinFlip`. Modify  $S_{CF}$  during  $n$  rewinds of any given slot, if it encounters a message of  $\Pi$ —a breakpoint—as before, it simply gives up that rewind, and goes on to the next. It is easy to see that with this modification,  $S_{CF}$  is indeed robust. It fails only with probability  $n^{q-k}$  which is negligible since  $q - k \in \omega(1)$ .

**Composing the two robust simulators.** Having defined the robust  $S_{CF}$  for `CoinFlip` we now show how to modify our proof by composing  $S_{CF}$  with our robust-concurrent simulator  $S$ . The modifications follow:

1. As a first step, we view `CoinFlip` as a “replacement” for the statistically hiding phase  $PRS_2$ . Therefore, the simulator will always to look for  $\alpha_s = (u, d)$  coming from outside (just like before where the  $PRS$ -secret was being provided from outside). Party  $\mathcal{E}$  simply returns a random value, whereas simulator  $S$ , will expect it to come from outside, and be included in the transcript when `CoinFlip` ends.

2. In order to do this, without rewinding  $B$ , simulator  $S$  will run with respect to a modified protocol  $B'$  which runs both  $B$  as well as  $\text{CoinFlip}$ . This will have a total of  $q + k$  messages, and by choice of  $\ell$  this will still keep the statistical distance negligible.
3. Now the simulator  $S$  is an adversary for the protocol  $\text{CoinFlip}$  and  $S_{\text{CF}}$  will simulate its view without rewinding  $B$ . Messages of  $B$  will be forwarded to  $S$  by  $S_{\text{CF}}$  unaltered. It is not hard to see that although the probabilities of aborting add up, they still remain negligible with our choice of parameters.
4. Therefore, the composed simulator  $S_{\text{CF}} \circ S$  is now a robust simulator which provides the trapdoor for  $\text{CoinFlip}$  as well.

The rest of the proof is now goes through trivial changes: instead of using  $S$  used the composed simulator  $S_{\text{CF}} \circ S$  and modify internal syntax to deal with this change. Details are repetitive and easy to fill in.

## C Robust Non-malleable Commitments

We recall the notion of a robust non-malleable commitment scheme [LP09]. We only need a non-malleable commitment scheme that is robust with respect to constant round protocols. The notion of  $k$ -robust non-malleability, roughly speaking, requires non-malleability w.r.t. every  $k$ -round protocol, in addition to itself.

Formally, let  $n$  be the security parameter,  $\langle C, R \rangle$  be a tag-based statistically-binding commitment scheme for identities of length  $l(n)$ . Consider a man-in-the-middle adversary  $A^*$  that, on inputs  $n$  and (advice)  $z$ , participates in one left and one right interaction simultaneously. In the left interaction,  $A^*$  interacts with  $C$ , receiving a commitment to value  $v \in \{0, 1\}^n$  using identity  $\text{id}$  of its choice. In the right interaction  $A^*$  interacts with  $R$  attempting to commit to a related value  $\tilde{v}$ , again using identity  $\tilde{\text{id}}$  of its choice. If the right commitment is invalid, or undefined, its value is set to  $\perp$ . In addition, if  $\text{id} = \tilde{\text{id}}$ , the value  $\tilde{v}$  is again set to  $\perp$ . That is, if  $A^*$  copies the left identity  $\text{id}$ , it is not a valid adversary. Let  $\text{nmc}_{\langle C, R \rangle}^{A^*}(n, v, z)$  denote a random variable that describes the value  $\tilde{v}$  and the view of  $A^*$  in this experiment. Then, following [DDN91, LPV08]: We say that  $\langle C, R \rangle$  is *non-malleable w.r.t. itself*, if for every PPT  $A^*$ , and every pair of  $n$ -bit strings  $(v_1, v_2)$ , and every  $z \in \{0, 1\}^*$ , variables  $\text{nmc}_{\langle C, R \rangle}^{A^*}(n, v, z)$  and  $\text{nmc}_{\langle C, R \rangle}^{A^*}(n, v', z)$  are computationally indistinguishable.

Let  $\langle C, R \rangle$  be commitment scheme as above that is non-malleable w.r.t. itself. Further, let  $\Pi := \langle B, A \rangle$  be a protocol of  $k(n)$  rounds, and  $\text{dom}_B(n)$  denote the set of valid inputs for  $B$ . We say that  $\Pi$  is an *interesting* protocol if for every PPT  $\tilde{A}$ , every  $n \in \mathbb{N}$ , every pair of inputs  $x_1 \in \text{dom}_B(n)$  and  $x_2 \in \text{dom}_B(n)$ , and every  $z \in \{0, 1\}^*$ , we have that the following two random variables are computationally indistinguishable:  $\text{OUT}_{\tilde{A}}[B(1^n, x_1) \leftrightarrow \tilde{A}(1^n, z)]$  and  $\text{OUT}_{\tilde{A}}[B(1^n, x_2) \leftrightarrow \tilde{A}(1^n, z)]$ .

We consider a man-in-the-middle  $A^*$  who participates in a left interaction—with the honest party  $B(1^n, x)$  for  $x \in \text{dom}_B(n)$ —as well as in a right interaction with  $R$  (as before) committing to  $\tilde{v}$  using identity  $\tilde{\text{id}}$  (defined and adaptively chosen as before). Denote by  $\text{nmc}_{\langle C, R \rangle}^{B, A^*}(n, x, z)$  the random variable that describes the value  $\tilde{v}$  along with the view of  $A^*$  in this experiment. Then, following [LP09]: We say that  $\langle C, R \rangle$  is  *$k()$ -robust*, if for every PPT  $A^*$ , every *interesting* protocol  $\Pi$  of round-complexity  $k(n)$ , every  $n \in \mathbb{N}$ , every pair of inputs  $(x_1, x_2)$  chosen from  $\text{dom}_B(n)$ , and every  $z \in \{0, 1\}^*$ , variables  $\text{nmc}_{\langle C, R \rangle}^{B, A^*}(n, x_1, z)$  and  $\text{nmc}_{\langle C, R \rangle}^{B, A^*}(n, x_2, z)$  are computationally indistinguishable. Constant round protocols that are non-malleable and 4-robust are now known [GOLV12, LP11, Goy11, Wee10, LP09].
