Modern Cryptography Through the Lens of Secret Sharing

Ilan Komargodski *  Mark Zhandry †

Abstract

Secret sharing is a mechanism by which a trusted dealer holding a secret “splits” the secret into many “shares” and distributes the shares to a collections of parties. Associated with the sharing is a monotone access structure, that specifies which parties are “qualified” and which are not: any qualified subset of parties can (efficiently) reconstruct the secret, but no unqualified subset can learn anything about the secret. In the most general form of secret sharing, the access structure can be any monotone \( \mathbf{NP} \) language.

In this work, we consider two very natural extensions of secret sharing. In the first, which we call distributed secret sharing, there is no trusted dealer at all, and instead the role of the dealer is distributed amongst the parties themselves. Distributed secret sharing can be thought of as combining the features of multiparty non-interactive key exchange and standard secret sharing, and may be useful in settings where the secret is so sensitive that no one individual dealer can be trusted with the secret. Our second notion is called functional secret sharing, which incorporates some of the features of functional encryption into secret sharing by providing more fine-grained access to the secret. Qualified subsets of parties do not learn the secret, but instead learn some function applied to the secret, with each set of parties potentially learning a different function.

Our main result is that both of the extensions above are equivalent to several recent cutting-edge primitives. In particular, general-purpose distributed secret sharing is equivalent to witness PRFs, and general-purpose functional secret sharing is equivalent to indistinguishability obfuscation. Thus, our work shows that it is possible to view some of the recent developments in cryptography through a secret sharing lens, yielding new insights about both these cutting-edge primitives and secret sharing.

1 Introduction

Secret sharing is a mechanism by which a trusted dealer holding a secret “splits” the secret into
many “shares” and distributes the shares to a collections of parties. Associated with the sharing
is a monotone access structure, that specifies which parties are “qualified” and which are not: any
qualified subset of parties can (efficiently) reconstruct the secret, but no unqualified subset can
learn anything about the secret.\(^1\) The first secret sharing schemes, due to Shamir [Sha79] and
Blakley [Bla79], were for the threshold access structure, where the subsets that can reconstruct the
secret are all the sets whose cardinality is at least a certain threshold. Such secret sharing schemes
provide a digital analog of the “two-man rule”, and are useful for splitting a sensitive key (say, for
nuclear launch codes) among several individuals so that no single individual knows the key. Secret
sharing schemes, even for the simple threshold access structure, have found numerous applications
in computer science (see [Bei11] for a thorough survey).

Since their introduction, it has been a major open problem to determine which access structures
can secret sharing be realized for. Benaloh and Leichter [BL88] constructed a secret sharing scheme
for any access structure that can be computed by a monotone formula. This result was generalized
and improved by Karchmer and Wigderson [KW93] for access structures that can be computed
by a monotone span program. In an unpublished work, Andrew Yao constructed a secret sharing
scheme for any access structure that can be computed by a \textit{monotone} circuit (see [Bei11, Nao06]),
assuming any one-way function. Recently, Komargodski, Naor and Yogev [KNY14] constructed
secret sharing schemes for all of monotone \textit{NP} (denoted \textit{mNP}),\(^2\) assuming one-way functions and a
recent new primitive called witness encryption [GGSW13].\(^3\) Monotone \textit{NP} is essentially the largest
class of access structures that we can hope for: if we cannot even efficiently identify a qualified set,
we cannot hope to have qualified sets reconstruct the secret.

In this work we take secret sharing even further, by pursuing two very natural directions.
First, we ask if the trusted dealer is required, or whether it is possible to \textit{distribute} the role of
the dealer amongst the parties themselves. Second, we ask if we can provide more fine-grained
access mechanism to the shared secret, whereby qualified sets of parties only learn some function
of the secret, each set of parties learning a possibly different function. Surprisingly, in both cases
we show equivalences between these natural extensions of secret sharing and several cutting-edge
cryptographic primitives that have recently been developed.

\textbf{Distributed secret sharing.} The usefulness of secret sharing schemes, as defined above, is limited
to settings in which there exists a \textit{trusted} dealer who knows the secret. What if we do not want any
one individual to know the secret outright? What if our secret is so sensitive that we cannot afford
anybody to know it? In this paper, we study the necessity of the trusted dealer in the setting of
secret sharing and ask the question:

\textit{Is it possible to secret share a secret without anybody knowing it?}

To address this question, we introduce the concept of \textit{distributed} secret sharing schemes. Specifi-
cally, given an access structure, each party can generate for itself a public share (which is published)
\footnote{In secret sharing, we always restrict our attention to \textit{monotone} access structures, where a superset of a qualified set must be qualified. This is necessary because, if a set of parties contains a qualified subset, they can always “pretend” to be the smaller subset, discard the shares outside that subset, and reconstruct the secret.}
\footnote{For access structures in \textit{mNP}, a qualified set of parties needs to know an \textit{NP} witness that they are qualified.
\footnote{We note that the schemes of [BL88, KW93] are unconditionally secure, while the schemes of Yao and [KNY14] are only secure against adversaries that run in polynomial-time.}
and a secret share (which is kept private). Then, there is a string $S$ such that every qualified subset of parties can compute $S$ (using their private shares and all public shares), whereas for every unqualified subset the secret $S$ remains hidden. Similarly to standard secret sharing schemes for $mNP$, for an access structure $M$ in $mNP$, a qualified subset $X$ should also provide a witness for the statements $X \in M$. Intuitively, one can view distributed secret sharing schemes as a hybrid of secret sharing schemes and non-interactive key-exchange: Indeed, non-interactive key-exchange is exactly the special case where $M$ is set to be the threshold access structure with threshold $t = 1$.

Distributed secret sharing schemes seem to be very appealing. Indeed, in the case of nuclear launch codes, if a dealer generates the key and shares it, the dealer can launch the missiles by himself, thus violating the two-man rule.

In this paper we construct and explore distributed secret sharing schemes. Our main result is that distributed secret sharing schemes for access structures in $mNP$ are equivalent to witness pseudorandom functions (witness PRFs) for $NP$. A witness PRF for a language $L \in NP$ is a function $F$ such that anyone with a valid witness that $x \in L$ can compute $F(x)$ without the secret key, but for all $x \notin L$, $F(x)$ is computationally hidden to anybody that does not know the secret key. Witness PRFs were recently introduced by Zhandry [Zha14] and shown to be very useful in constructing several important cryptographic primitives (including non-interactive multi-party key exchange without setup) that were previously only known to exist assuming seemingly much stronger assumptions.

In addition, we explore the possibility of distributed secret sharing for restricted classes of access structures based on weaker assumptions. To start, we consider the possibility of information-theoretic security for distributed secret sharing scheme (that is, security against unbounded adversaries). We show that such information-theoretic security is typically impossible: we prove that a distributed secret sharing scheme for any non-trivial access structure implies the existence of one-way functions.\footnote{We call an access structure $M$ trivial if $M$ is empty or if there exists a subset of parties $X \in M$ which is contained in any qualified set. For trivial access structures, we show that there is a simple perfectly-secure distributed secret sharing scheme.}

Next, we present a distributed secret sharing scheme for the threshold access structure, and prove its security based on the multilinear decisional Diffie-Hellman (MDDH) assumption. As an interesting application, we show that distributed secret sharing schemes for threshold access structures imply constrained PRFs that can be constrained to a Hamming ball around an arbitrary point and are secure for adversaries that obtain a single constrained key. Even though it is known that the MDDH assumption implies constrained PRFs for all circuits which are secure with respect to arbitrary collusions [BW13], our transformation is generic and applies to any threshold distributed secret sharing scheme, which perhaps can be based on simpler assumptions than multilinear maps.

**Functional secret sharing.** Traditional secret sharing schemes offer an all-or-nothing guarantee when reconstructing a shared secret — a qualified subset of parties can learn the entire secret, while unqualified subsets learn nothing about the secret. For many applications, especially in a distributed setting common to secret sharing, this notion is insufficient. Concretely, standard secret sharing schemes will not help in scenarios in which a dealer wants to share a secret such that every qualified subset of parties will learn a specific function of the secret (and nothing else). For example, a dealer holding a secret $S$, may want to distribute it such that any qualified subset $X$ will be able to learn only the inner product of $X$ and $S$, while making sure $S$ remains computationally hidden for unqualified subsets.
A related issue has appeared in the context of encryption schemes, giving rise to the concept of functional encryption and a very fruitful line of work (see e.g., [SW08, BSW11]). We study whether secret sharing schemes can be extended in an analogous way to support such functionalities: Given an efficiently computable two-input function $F$ (that can be thought of as a family of functions indexed by the first input), we ask the question:

*Is it possible to secret share a secret $S$ such that any qualified subset of parties $X$ can compute only $F(X, S)$, but for unqualified subsets, $S$ will be computationally hidden?*

To study this question, we introduce the concept of functional secret sharing schemes. Informally, such a scheme allows to secret share a secret $S$ with respect to a function $F$ and an access structure $M$, such that any qualified subset of parties $X$ can pull their shares together and compute $F(X, S)$. Security is formalized by requiring that for any function $F$, any two any subset of parties $X$ and any secrets $S_0$ and $S_1$, as long as either $M(X) = 0$ or $F(X', S_0) = F(X', S_1)$ for any $X' \subseteq X$, secret shares corresponding to $F$ and $S_0$ cannot be distinguished from secret shares corresponding to $F, X$ and $S_1$. Notice that the condition that $F(X', S_0) = F(X', S_1)$ for any $X' \subseteq X$ in the case that $M(X) = 1$ is necessary, as otherwise, by evaluating $F(X', S_0)$ an adversary can distinguish between the case that $b = 0$ and $b = 1$.

Our main result is that functional secret sharing schemes for access structures in $\text{mNP}$ and functions in $\text{P}$ are equivalent to indistinguishability obfuscation (iO) for $\text{P}$.\(^5\) An indistinguishability obfuscator [BGI+12, GGH+13b] guarantees that if two circuits compute the same function, then their obfuscated version are computationally indistinguishable. This primitive was introduced by Barak et al. [BGI+12] and later proven to be extremely useful for construction of cryptographic primitives some of which were unknown before (see e.g., [GGH+13b, SW14, BZ14]). To complement this, several candidate constructions of indistinguishability obfuscators were recently proposed [GGH+13b, BR14, BGK+14, PST14, GLSW14, AB15].

Note that when the function $F$ is defined to be the identity function over its second input parameter (i.e., $F(\cdot, S) = S$) we get the standard definition of secret sharing for $\text{mNP}$ of [KNY14]. Moreover, when the access structure is the set of all subsets, the secret $S$ is a description of a function and $F$ is the universal circuit (i.e., $F(X, S) = S(X)$), we obtain a definition of a function secret sharing scheme. In such a scheme, the goal is to split a function (and not a secret) into shares that hide the function under some conditions. Our construction gives a way to split a function $F$ into shares such that any subset of parties $X$ can compute $F(X')$ for every $X' \subseteq X$ and “nothing” else. We note that other forms of function secret sharing have been studied in the literature (cf. [DF89, SDFY94, BBDK00, BGI15]). However, our notion is quite different from these other notions. In particular, our notion is the first to allow for fine-grained access control to the secret by guaranteeing that any qualified set learns a possibly different function of the secret. Moreover, previous notions were mostly studied in the context of threshold access structures or only with very specific function classes.

**Conclusions.** Recent advances in cryptography, including the first constructions of multilinear maps [GGH13a] and obfuscation [GGH+13b], have lead to the development of many incredible new cryptographic objects. Applications include functional encryption, witness encryption, witness PRFs, deniable encryption, multi-party computation in very few rounds, traitor-tracing schemes

\(^5\)To show that iO implies functional secret sharing schemes, we also assume the existence of one-way functions. By a result of [KNY14] we can actually only assume iO and $\text{NP} \not\subseteq \text{io-BPP}$. Moreover, we note that in this paper we assume functions are represented as circuits, so we actually work with functions in $\text{P/poly}$ (and not $\text{P}$).
with very short messages, and many more. Our work can thus be seen as establishing a close connection between several of these advanced cryptographic capabilities and types of secret sharing, which at first appear totally unrelated. The known relationships, including our work, are depicted and summarized in Figure 1. Our hope is that the connections we develop can help shed light on the relationships between advanced primitives, or between types of secret sharing: which are equivalent, why do some tasks appear difficult, and so on.

For example, our results indicate why witness PRFs, which are closely related to witness encryption, may be the “right” primitive for building non-interactive key exchange, and why witness encryption may be insufficient. Indeed, distributed secret sharing essentially combines the features of secret sharing for $mNP$ (which is equivalent to witness encryption [KNY14]) with non-interactive key exchange. If these non-interactive key exchange features could be obtained from witness encryption, then perhaps witness encryption could also imply witness PRFs. In addition, at first it may not be obvious what is the relationship between functional secret sharing and distributed secret sharing. Our results and the simple observation that indistinguishability obfuscation implies witness PRFs, show that functional secret sharing implies distributed secret sharing (assuming one-way functions).

1.1 Overview of Our Techniques

Distributed secret sharing and witness PRFs. Here, we provide a high-level overview of our technique for transforming distributed secret sharing schemes into witness PRFs. At first, this seems like a difficult task. Indeed, distributed secret sharing only specifies a single secret: the shared secret for the groups of qualified parties. In contrast, in a witness PRF each instance corresponds to a secret, namely the output of the PRF on this instance. How can we obtain many secrets out of one?

Our main observation is that distributed secret sharing schemes are reusable. Suppose a set $P_1$ of $n$ parties runs the distributed secret sharing protocol, each party in $P_1$ generating a secret/public share pair, and publishing the public share. Now, suppose a second set of $n$ parties $P_2$ wishes to run the distributed secret sharing protocol, and that there is some party $i$ that is in both $P_1$ and $P_2$. Distributed secret sharing is reusable in the sense that party $i$ does not need to generate a fresh secret/public share pair for the second invocation of the protocol, but can instead reuse the shares he already has. Thus, party $i$ does not need to publish any additional material to take part in the second sharing. Taking this a step further, $N \gg n$ parties can each generate secret/public shares and publish the public shares. Then, various sets of $n$ of them can engage in the distributed secret sharing protocol without any additional setup or interaction. This observation can be seen as a generalization of the fact that non-interactive key exchange (both in the two-party and multi-party setting) is reusable.

Since distributed secret sharing schemes are reusable, there are really many implicit secrets, one for every possible subset of the $N$ parties of size $n$. This will be the source of our many secrets for our witness PRFs. To show how we use this idea of reusability, we sketch our approach for a simpler task: using threshold distributed secret sharing schemes to build Hamming ball constrained PRFs.

Threshold distributed sharing schemes to Hamming ball constrained PRFs. Recall that a constrained PRF (as defined by Boneh and Waters [BW13]) is a regular PRF with some additional requirements: First, given the secret key $k$, and a subset $T \subset X$ where $X$ is the domain of the PRF, it is possible to constrain the key $k$ to the set $T$, producing a constrained key $k_T$. Next, given $k_T$ and a point $x \in T$, it is possible to compute $\text{PRF}_k(x)$. For security, we require that, even given $k_T$, for all $x \notin T$, $\text{PRF}_k(x)$ is pseudorandom. For this exposition, we will consider Hamming ball constraints, where $X = \{0,1\}^n$, and the possible sets $T$ consist of all points within Hamming distance $r$ of some center point $c$.

Suppose that $r$ is fixed a priori (this is assumed here for simplicity – our actual scheme handles the case in which $r$ is not fixed a priori). Our Hamming ball constrained PRF is defined as follows. Let $N = 2n$ be the total number of parties, and label each party by a pair $(i,b) \in [n] \times \{0,1\}$. Generate secret/public shares $(P_{i,b}, P_{i,b})$ for each of the $N$ parties for the threshold distributed secret sharing scheme on $n$ parties and threshold $n-r$. The secret key consists of all the public and secret shares. For every input $x \in \{0,1\}^n$, let $P_x$ be the subset of $n$ parties labeled by $(i,x_i)$ for $i \in [n]$. $\text{PRF}(x)$ is defined to be the shared secret $S$ for the set of parties $P_x$ defined by $x$. Since the secret key consists of $n \geq n-r$ of the secret shares for $P_x$, we can compute $\text{PRF}(x)$.

The constrained key $k_T$ for the Hamming ball $T$ of radius $r$ around center $c$ consists of all of the public shares, as well as the secret shares for the set $P_c$. For any input $x$ with Hamming distance at most $r$ from $c$, $k_T$ contains at least $n-r$ of the secret shares for $P_x$, and so $\text{PRF}(x)$ can be computed. For $x$ at distance more than $r$ away, $k_T$ contains fewer than $n-r$ secret shares for $P_x$,}
so the security of the threshold distributed secret sharing scheme implies that $\text{PRF}(x)$ is hidden.

For the general distributed secret sharing to witness PRF construction, we will make use of a similar strategy, defining the output of the PRF to be the shared secret $S$ corresponding to a subset of parties. However, the construction becomes somewhat more complicated. For starters, the class of Hamming balls is very simple, and moreover has a lot of symmetries. In contrast, the general $\text{NP}$ languages are much more complex and have no simple structural properties we can use. Additionally, we will need to support the parties to be able to input a witness. We refer to Section 3.4 for the full details.

**Functional secret sharing and iO.** The fact that general-purpose functional secret sharing implies iO is rather straight-forward. Indeed, as we mentioned, function secret sharing is a special case of functional secret sharing, and thus, an obfuscation of a circuit is just the shares generated by the function secret sharing. Security of the obfuscator follows directly from the security of the function secret sharing scheme.

The other direction (namely, from iO to functional secret sharing) is more complicated. To this end, we rely on ideas developed by [KNY14] in order to show that witness encryption implies (standard) secret sharing for $\text{mNP}$. Specifically, when sharing the secret $S$ with respect to a function $F$ and an access structure $M$, the share of party $i$ will be an opening of a commitment and the iO of a circuit that given as input the secret openings of a subset of parties $X$ verifies the openings, verifies the validity of the instance (together with a witness) with respect to $M$, and if all tests pass, it outputs the value $F(X, S)$. The security of this scheme relies on the perfect binding of the commitments and the indistinguishability guarantee of the obfuscator.

## 2 Preliminaries

In this section we present the notation and basic definitions that are used in this work. For a distribution $X$ we denote by $x \leftarrow X$ the process of sampling a value $x$ from the distribution $X$. Similarly, for a set $\mathcal{X}$ we denote by $x \leftarrow \mathcal{X}$ the process of sampling a value $x$ from the uniform distribution over $\mathcal{X}$. For a randomized function $f$ and an input $x \in \mathcal{X}$, we denote by $y \leftarrow f(x)$ the process of sampling a value $y$ from the distribution $f(x)$. For an integer $n \in \mathbb{N}$ we denote by $[n]$ the set $\{1, \ldots, n\}$. A function $\text{neg} : \mathbb{N} \rightarrow \mathbb{R}$ is negligible if for every constant $c > 0$ there exists an integer $N_c$ such that $\text{neg}(\lambda) < \lambda^{-c}$ for all $\lambda > N_c$. Throughout this paper we denote by $\lambda$ the security parameter.

Two sequences of random variables $X = \{X_\lambda\}_{\lambda \in \mathbb{N}}$ and $Y = \{Y_\lambda\}_{\lambda \in \mathbb{N}}$ are *computationally indistinguishable* if for any probabilistic polynomial-time algorithm $A$ there exists a negligible function $\text{neg}(\cdot)$ such that $|\text{Pr}[A(1^\lambda, X_\lambda) = 1] - \text{Pr}[A(1^\lambda, Y_\lambda) = 1]| \leq \text{neg}(\lambda)$ for all sufficiently large $\lambda \in \mathbb{N}$. The *statistical distance* between two random variables $X$ and $Y$ over a finite domain $\Omega$ is defined as $\text{SD}(X, Y) \triangleq \frac{1}{2} \sum_{\omega \in \Omega} |\text{Pr}[X = \omega] - \text{Pr}[Y = \omega]|$.

### 2.1 Monotone-$\text{NP}$ and Access Structures

A function $f : 2^n \rightarrow \{0, 1\}$ is said to be monotone if for every $X \subseteq [n]$ such that $f(X) = 1$ it also holds that $\forall Y \subseteq [n]$ such that $X \subseteq Y$ it holds that $f(Y) = 1$. Given a potentially non-monotone function $f : 2^n \rightarrow \{0, 1\}$, we define the *monotone closure* of $f$, denoted $\overline{f}$, such that $\overline{f}(Y) = 1$ if and only if there is some $X \subset Y$ such that $f(X) = 1$. 

7
A monotone Boolean circuit is a Boolean circuit with AND and OR gates (without negations). A non-deterministic circuit is a Boolean circuit whose inputs are divided into two parts: standard inputs and non-deterministic inputs. A non-deterministic circuit accepts a standard input if and only if there is some setting of the non-deterministic input that causes the circuit to evaluate to 1. A monotone non-deterministic circuit is a non-deterministic circuit where the monotonicity requirement applies only to the standard inputs, that is, every path from a standard input wire to the output wire does not have a negation gate.

**Definition 2.1 ([GS92])**. We say that a function $L$ is in $\text{mNP}$ if there exists a uniform family of polynomial-size monotone non-deterministic circuit that computes $L$.

**Lemma 2.2 ([GS92, Theorem 2.2])**. $\text{mNP} = \text{NP} \cap \text{mono}$, where $\text{mono}$ is the set of all monotone functions.

A computational secret-sharing scheme involves a dealer who has a secret, a set of $n$ parties, and a collection $A$ of qualified subsets of parties called the access structure. A computational secret-sharing scheme for $A$ is a method by which the dealer efficiently distributes shares to the parties such that (1) any subset in $A$ can efficiently reconstruct the secret from its shares, and (2) any subset not in $A$ cannot efficiently reveal any partial information on the secret. For more information on secret-sharing schemes we refer to [Bei11] and references therein.

Throughout this paper we deal with secret-sharing schemes for access structures over $n$ parties $\mathcal{P} = \mathcal{P}_n = \{p_1, \ldots, p_n\}$.

**Definition 2.3** (Access structure). An access structure $M$ on $\mathcal{P}$ is a monotone set of subsets of $\mathcal{P}$. That is, for all $X \in M$ it holds that $X \subseteq \mathcal{P}$ and for all $X \in M$ and $X'$ such that $X \subseteq X' \subseteq \mathcal{P}$ it holds that $X' \in M$.

### 2.2 Commitment Schemes

In some of our constructions we need a non-interactive commitment scheme such that commitments of different strings has disjoint support. Jumping ahead, since the dealer in the setup phase of a secret-sharing scheme is not controlled by an adversary (i.e., it is honest), we can relax the foregoing requirement and use non-interactive commitment schemes that work in the CRS (common random string) model (for ease of notation, we usually ignore the CRS).

**Definition 2.4** (Commitment scheme in the CRS model). Let $\lambda \geq 0$ be a parameter. Let $\text{Com}: \{0, 1\} \times \{0, 1\}^\lambda \times \{0, 1\}^\lambda \rightarrow \{0, 1\}^{g(\lambda)}$ be polynomial-time computable function. We say that $\text{Com}$ is a (non-interactive perfectly binding) commitment scheme in the CRS model if the following two conditions hold:

1. **Computational Hiding**: Let $\text{CRS} \xleftarrow{} \{0, 1\}^\lambda$ be chosen uniformly at random. The random variables $\text{Com}(0, \text{CRS})$ and $\text{Com}(1, \text{CRS})$ are computationally indistinguishable (given CRS). That is, with all but negligible probability over the CRS, for every probabilistic polynomial-time adversary $A$, there exists a negligible function $\text{neg}(\cdot)$ such that
   \[
   \text{Adv}_{A, \text{Com}}^{\text{COM}} = \left| \Pr_{r_1 \xleftarrow{} \{0, 1\}^\lambda} [A(\text{Com}(0, r_1, \text{CRS})) = 1] - \Pr_{r_2 \xleftarrow{} \{0, 1\}^\lambda} [A(\text{Com}(1, r_2, \text{CRS})) = 1] \right| 
   \leq \text{neg}(\lambda).
   \]

2. **Perfect Binding**: With all but negligible fraction of the CRSs, the supports of the above random variables are disjoint. That is, with all but negligible probability over the CRS

$$\text{SD} \left( \text{Com}(0, U_\lambda, \text{CRS}), \text{Com}(1, U_\lambda, \text{CRS}) \right) = 1,$$

where SD denotes statistical distance.

As usual, the above definition can be generalized to commitments of strings of polynomial size (rather than bits) by committing to each bit separately.

Commitment schemes that satisfy the above definition, in the CRS model, can be constructed based on any pseudorandom generator [Nao91] (which can be based on any one-way functions [HILL99]). For simplicity, throughout the paper we ignore the CRS and simply write \(\text{Com}(\cdot, \cdot)\). We say that \(\text{Com}(x, r)\) is the commitment to the value \(x\) with the opening \(r\).

### 2.3 Multilinear Maps

**Definition 2.5** (Multilinear maps). We say that a map \(e: \mathbb{G}_1^n \rightarrow \mathbb{G}_2\) is an \(n\)-multilinear map if it satisfies the following:

1. \(\mathbb{G}_1\) and \(\mathbb{G}_2\) are groups of the same prime order.
2. If \(a_1, \ldots, a_n \in \mathbb{Z}\) and \(x_1, \ldots, x_n \in \mathbb{G}_1\), then

\[
e(x_1^{a_1}, \ldots, x_n^{a_n}) = e(x_1, \ldots, x_n)^{\prod_{i=1}^n a_i}.
\]
3. The map \(e\) is non-degenerate in the following sense: if \(g \in \mathbb{G}_1\) is a generator of \(\mathbb{G}_1\), then \(e(g, \ldots, g)\) is a generator of \(\mathbb{G}_2\).

We say that \(e\) is an efficient \(n\)-multilinear map if it is efficiently computable, namely, there exists a polynomial-time algorithm that computes \(e(x_1^{a_1}, \ldots, x_n^{a_n})\) for any \(a_1, \ldots, a_n \in \mathbb{Z}\) and \(x_1, \ldots, x_n \in \mathbb{G}_1\).

An efficient multilinear map generator \(\text{MM}^n = \text{Gen}(1^n, n)\) is a probabilistic polynomial-time algorithm that gets as input two inputs \(1^n\) and \(n\), and outputs a tuple \((\Gamma, g, \ell)\), where \(\Gamma\) is the description of an efficient \(n\)-multilinear map \(e: \mathbb{G}_1^n \rightarrow \mathbb{G}_2\), \(g\) is a generator of \(\mathbb{G}_1\), and \(\ell\) is the order of the groups \(\mathbb{G}_1\) and \(\mathbb{G}_2\).

Next, we define the multilinear Diffie-Hellman assumption. Roughly speaking, the assumption is that given \(g, g^{a_1}, \ldots, g^{a_n}\), it is hard to compute \(e(g, \ldots, g)^{\prod_{i=1}^n a_i}\), or even distinguish it from a random value.

**Definition 2.6** (Multilinear decisional Diffie-Hellman assumption [BS02]). We say that an efficient \(n\)-multilinear map generator \(\text{MM}^n\) satisfies the multilinear decisional Diffie-Hellman (MDDH) assumption if for every polynomial time algorithm \(A\) there exists a negligible function \(\text{neg}(\cdot)\) such that for \(\lambda \in \mathbb{N}\) it holds that

\[
\text{Adv}^\text{MDDH}_{\text{MM}^n, A, n, \lambda} = \left| \Pr \left[ A \left( g, g^{a_0}, \ldots, g^{a_n}, e(g, \ldots, g)^{\prod_{i=0}^n a_i} \right) = 1 \right] - \Pr \left[ A \left( g, g^{a_0}, \ldots, g^{a_n}, K \right) = 1 \right] \right| \leq \text{neg}(\lambda),
\]

where the probability is over the execution of \((\Gamma, g, \ell) \leftarrow \text{MM}^n(1^n, n)\), the choice of \(a_0, \ldots, a_n \leftarrow (\mathbb{Z}/\ell\mathbb{Z})^{n+1}\), \(K \leftarrow \mathbb{G}_2\), and the internal randomness of \(A\).
We note that we do not know of any “ideal” multilinear maps as described above that plausibly support the MDDH assumption. Instead, current candidates are “noisy” [GGH13a, CLT15]. In particular, the group elements have some noise, and only a certain number of group operations are allowed before the multilinear identity fails. Moreover, each group element actually has many representations, and a special extraction procedure is required to obtain a unique “canonical” representation for a particular element. The extraction is only allowed in $G_2$. Despite this departure from the ideal notion described above, it is usually straightforward (though often tedious) to use current candidate maps in place of the ideal maps. Therefore, for ease of exposition, we will describe our applications of multilinear maps in terms of the ideal abstraction, noting that the applications can be adapted to use the noisy candidate multilinear maps from the literature.

2.4 Witness Pseudorandom Functions

Witness pseudorandom functions (witness-PRFs) were recently introduced by Zhandry [Zha14]. He showed that several important primitives, that were previously only known from iO (see Definition 2.8), follow from this seemingly weaker assumption. We note that witness-PRFs are related to witness encryption [GGSW13], but seem to be stronger.

**Definition 2.7 (Witness-PRFs [Zha14]).** A witness pseudorandom function is a tuple $(\text{Gen}, \text{PRF}, \text{Eval})$ where:

1. $\text{Gen}(1^\lambda, R)$ is a polynomial-time randomized procedure that takes as input a security parameter and a relation $R : \{0, 1\}^n \times \{0, 1\}^m \rightarrow \{0, 1\}$ represented as a circuit, and outputs a private function key $f_k$ and a public evaluation key $e_k$. The relation $R$ defines an NP language $L$.

2. $\text{PRF}(f_k, x)$ is a polynomial-time deterministic procedure that takes as input the function key $f_k$ and an instance $x \in \{0, 1\}^n$.

3. $\text{Eval}(e_k, x, w)$ is a polynomial-time deterministic procedure that takes as input the evaluation key $e_k$, an instance $x \in \{0, 1\}^n$, and a witness $w \in \{0, 1\}^m$.

4. **Correctness:** If $x \in L$, and moreover $w$ is a valid witness for $x$ (that is, $R(x, w) = 1$), then

   $\Pr[\text{Eval}(e_k, x, w) = \text{PRF}(f_k, x)] = 1$,

   where $(f_k, e_k) \leftarrow \text{Gen}(1^\lambda, R)$ and the probability is taken over the randomness $\text{Gen}$.

5. **Security:** For any relation $R$ and any probabilistic polynomial-time algorithm $D$, there exists a negligible function $\text{neg} \cdot \cdot$ such that for any $\lambda \in \mathbb{N}$ and any $x \notin L$, it holds that

   $|\Pr[D(e_k, \text{PRF}(f_k, x)) = 1] - \Pr[D(e_k, y) = 1]| < \text{neg}(\lambda)$,

   where $(f_k, e_k) \leftarrow \text{Gen}(1^\lambda, R)$, $y$ is chosen uniformly over the codomain of $\text{PRF}$, and the probabilities are taken over the randomness of $\text{Gen}$, $D$, and the choice of $y$.

2.5 Indistinguishability Obfuscation

We say that two circuits $C$ and $C'$ are *equivalent* and denote it by $C \equiv C'$ if they compute the same function (i.e., $\forall x : C(x) = C'(x)$).
Definition 2.8 (Indistinguishability obfuscation [BGI+12]). Let $\mathcal{C} = \{\mathcal{C}_n\}_{n \in \mathbb{N}}$ be a class of polynomial-size circuits, where $\mathcal{C}_n$ is a set of circuits operating on inputs of length $n$. A uniform polynomial-time algorithm $iO$ is called an indistinguishability obfuscator for the class $\mathcal{C}$ if it takes as input a security parameter and a circuit in $\mathcal{C}$ and outputs a new circuit so that following properties are satisfied:

1. **Preserving functionality:** There exists a negligible function $\alpha$ such that for any input length $n \in \mathbb{N}$, any $\lambda$ and any $C \in \mathcal{C}_n$ it holds that
   \[ \Pr_{iO}[C \equiv iO(1^\lambda, C)] = 1, \]
   where the probability is over the internal randomness of $iO$.

2. **Polynomial slowdown:** There exists a polynomial $p(\cdot)$ such that: For any input length $n \in \mathbb{N}$, any $\lambda$ and any circuit $C \in \mathcal{C}_n$ it holds that $|iO(1^\lambda, C)| \leq p(|C|)$.

3. **Indistinguishable obfuscation:** For any probabilistic polynomial-time algorithm $D$ and any polynomial $p(\cdot)$, there exists a negligible function $\neg(\cdot)$, such that for any $\lambda, n \in \mathbb{N}$, any two equivalent circuits $C_1, C_2 \in \mathcal{C}_n$ of size $p(\lambda)$, it holds that
   \[ \left| \Pr[D(\text{iO}(1^\lambda, C_1)) = 1] - \Pr[D(\text{iO}(1^\lambda, C_2)) = 1] \right| \leq \neg(\lambda), \]
   where the probabilities are over the internal randomness of $iO$ and $D$.

3 Distributed Secret Sharing

In this section we define the notion of distributed secret sharing schemes.

Definition 3.1 (Distributed secret sharing). A distributed secret sharing (DSS) scheme consists of a probabilistic setup procedure $\text{SETUP}$, a probabilistic sharing procedure $\text{SHARE}$ and a deterministic reconstruction procedure $\text{RECON}$ that satisfy the following requirements:

- **$\text{SETUP}(1^\lambda, 1^n, V_M)$** takes as input a security parameter $\lambda$ (in unary representation) the number $n$ of parties (also in unary), the verification procedure $V_M$ for an mNP access structure $M$ on $n$ parties. $\text{SETUP}$ outputs a common reference string $\text{CRS}$.

- **$\text{SHARE}(1^\lambda, 1^n, \text{CRS}, V_M, i)$** takes as input $\lambda, n$, the common reference string $\text{CRS}$, the verification procedure $V_M$ for an mNP language $M$, and a party index $i \in [n]$. It outputs a public share $P(i)$ and a secret share $\Pi(i)$. For $X \subseteq \mathcal{P}_n$ we denote by $\Pi(X)$ the random variable that corresponds to the set of secret shares of parties in $X$. We denote by $P$ the random variable that corresponds to the set of public shares of parties in $\mathcal{P}_n$.

- **$\text{RECON}(1^\lambda, 1^n, \text{CRS}, V_M, P, \Pi(X), w)$** gets as input $\lambda, n$, $\text{CRS}, V_M$, the public shares $P$ of all $n$ parties, the secret shares $\Pi(X)$ of a subset of parties $X \subseteq \mathcal{P}_n$, and a witness $w$, and outputs a shared secret. We will sometimes abuse notation, and also write $X \subseteq [n]$ to refer to the subset of the party indices appearing in $X$.

- **Correctness:** There is a string $S$ such that any set of qualified parties $X \subseteq \mathcal{P}_n$ with valid witnesses $w$ (i.e., $V_M(X, w) = 1$) can recover $S$. That is,
   \[ \Pr[\text{RECON}(1^\lambda, 1^n, \text{CRS}, V_M, P, \Pi(X), w) = S] = 1, \]
where the probability is taken over the generation of the shares, namely, over \( (P(i), \Pi(i)) \leftarrow \text{SHARE}(1^\lambda, 1^n, \text{CRS}, V_M, i) \) for \( i \in [n] \). We will sometimes refer to \( S \) as the shared secret.

- **Pseudorandomness of the secret:** For any language \( M \in \text{mNP} \) and any probabilistic polynomial-time algorithm \( D \), there exists a negligible function \( \text{neg}(\cdot) \) such that for any \( \lambda \in \mathbb{N} \) and any unqualified set \( X \subseteq \mathcal{P}_n \) (that is, \( X \notin M \)), it holds that

  \[
  |\Pr[D(P, \Pi(X), S) = 1] - \Pr[D(P, \Pi(X), K) = 1]| \leq \text{neg}(\lambda),
  \]

  where the probability is taken over the generation of the shares, namely, over \( (P(i), \Pi(i)) \leftarrow \text{SHARE}(1^\lambda, 1^n, \text{CRS}, V_M, i) \) for \( i \in [n] \), \( K \) is sampled uniformly at random, and \( S \) is the shared secret defined above.

**The shared secret \( S \).** Suppose \( M \) is non-empty, which is true for any interesting access structure \( M \). In this case, by the monotonicity of \( M \), \( \mathcal{P}_n \in M \) and there exists a witness \( w \) attesting to this fact. Then, the shared secret \( S \) is well defined, as we can use the correctness requirement for the set \( \mathcal{P}_n \) as the definition of \( S \) : \( S = \text{RECON}(1^\lambda, 1^n, \text{CRS}, V_M, P, \Pi, w) \).

   In the case where \( M \) is empty, correctness is trivially satisfied for any definition of \( S \). We can therefore take \( S \) to be a uniformly random variable that is completely independent of the scheme, and unconditional security will be trivially satisfied as well. Interestingly, this means that, when analyzing schemes, it is only necessary to analyze correctness and security for non-empty access structures \( M \), as any scheme will automatically be correct and secure for empty \( M \).

   In Section 3.2, we show how to obtain unconditional security for a slightly wider class of access structures, which we call trivial access structures.

**Reusability.** In this work, it will be useful to distinguish between party and index. A party is an entity that has run \( \text{SHARE} \), and obtained a secret and public share. That party’s index is the input \( i \) that was fed into \( \text{SHARE} \). Multiple parties may share the same index. We will say a set \( X \) of parties is complete if, for every index \( i \), there is exactly one party. Complete sets of parties are those for which \( \text{RECON} \) can be run, and therefore there is a shared secret \( S_X \) associated with every complete set of parties. In this sense, a DSS scheme is reusable: an individual party with index \( i \) can take part in multiple sharings as part of different complete sets of parties, while only running \( \text{SHARE} \) once and publishing a single public share. This observation generalizes the fact that non-interactive key exchange (in the 2-party or multi-party setting) is reusable. This reusability property will be crucial for building witness PRFs from DSS.

**Restricted access structures.** The above definition requires that the DSS algorithms work for any access structure \( M \) recognized by a polynomial-sized verification circuit \( V_M \). It is also possible to consider weaker versions where \( M \) is required to have a specific structure. For example, it is possible to consider \( M \) that are recognized by polynomial-size circuits (that is, \( M \in \mathcal{P} \)). In Section 3.3, we consider an even more restricted setting where \( M \) is just a threshold function: \( X \in M \) if and only if \( |X| \geq t \) for some threshold \( t \). We call these restrictions DSS for \( \mathcal{P} \) or DSS for threshold, respectively. When distinguishing DSS for these limited classes from the standard definition above, we call the standard definition DSS for \( \text{mNP} \). Finally, one can consider DSS for a specific, fixed access structure \( M \), which we call DSS for \( M \). For example, if \( M \) consists of all non-empty subsets (a special case of threshold where \( t = 1 \)), then DSS for \( M \) is exactly multiparty non-interactive key exchange with trusted setup [BS02].

---

\[^6\text{We note that to compute } S \text{ we need to know } w \text{ which may be computationally hard for some languages.} \]
3.1 Alternative Definitions

We introduce several alternative definitions for distributed secret sharing. We first give a strong variant in which the sharing procedure is independent of the access structure $V_M$ and of the party index $i$. Our second alternative is a witnessless version in which qualified sets are defined by an arbitrary circuit (possibly a non-monotone one). Our last variant is a definition of distributed secret sharing that has no setup (also known as no common reference string).

Definition 3.2 (Strong distributed secret sharing). A strong distributed secret sharing scheme is a special case of a regular distributed secret sharing scheme (as in Definition 3.1) with the following differences:

- $\text{SETUP}(1^\lambda, 1^n, V_M) = \text{SETUP}(1^\lambda, 1^n, |V_M|)$. That is, $\text{SETUP}$ does not depend on $V_M$, except through the size of the circuit for $V_M$, but is otherwise independent of $V_M$ or the language $M$.

- $\text{SHARE}(1^\lambda, 1^n, \text{CRS}, V_M, i) = \text{SHARE}(1^\lambda, 1^n, \text{CRS}, |V_M|)$. That is, $\text{SHARE}$ does not depend on $V_M$ except for its size, and also does not depend on the party index $i$.

- $\text{RECON}(1^\lambda, 1^n, \text{CRS}, V_M, P, \Pi(X), w)$ now interprets $P$ as a being ordered, and uses the order to determine the party index corresponding to each public share. From this information and $\Pi(X)$, $\text{RECON}$ can determine the subset $X \subseteq [n]$ of indices for which secret shares are provided.

- For each verification circuit $V_M$ and set of $n$ parties $\mathcal{P}_n$, correctness is defined using an associated secret $S_{V_M, \mathcal{P}_n}$ that potentially varies for different $V_M$ and $\mathcal{P}_n$ pairs. Notice that since a party is not assigned an index at sharing time, the only restriction we place on $\mathcal{P}_n$ is its size (i.e., $|\mathcal{P}_n| = n$), but we do not need $\mathcal{P}_n$ to be a complete set.

The advantage of a strong DSS scheme is that the access structure does not need to be specified at sharing time. This allows parties to play multiple roles in different sharing executions without having to generate new shares, and allows a single sharing to be used for many different access structures. This will result in significant communication savings if many sharings with different access structures are being executed. When differentiating between the strong and regular variants, we will call the regular distributed secret sharing variant a weak scheme.

Definition 3.3 (Witnessless distributed secret sharing). A witnessless distributed secret sharing is the following modification to (weak) distributed secret sharing, where the access structure $M$ is set to be the monotone closure $\overline{C}$ of some (potentially non-monotone) function $C$.\(^7\) In addition, we make the following modifications to the algorithms of the scheme:

- $\text{SETUP}(1^\lambda, 1^n, C)$, instead of taking as input the verification circuit $V_M$, now takes as input a circuit for the function $C$, which is potentially non-monotone. For the strong variant, $\text{SETUP}$ takes as input $|C|$ instead of $|V_M|$.

- $\text{SHARE}(1^\lambda, 1^n, \text{CRS}, C, i)$ also takes as input $C$ instead of $V_M$. For the strong variant, $\text{SHARE}$ takes as input $|C|$ instead of $|V_M|$, and does not take $i$ as input.

\(^7\)Recall that the monotone closure $\overline{C}$ of a function $C$ includes all sets $X$ such that some subset $X' \subseteq X$ satisfies $C(X') = 1$ (see Section 2.1).
• RECON($1^\lambda, 1^n, \text{CRS}, C, P, \Pi(X)$) similarly takes as input $C$ instead of $V_M$. Also, RECON does not take as input a witnesses, hence the term witnessless.

• Correctness is modified so that $\Pr[\text{RECON}(1^\lambda, 1^n, \text{CRS}, C, P, \Pi(X)) = S] = 1$ for any $X \subseteq \mathcal{P}_n$ such that $C(X) = 1$.

A set $X$ of qualified parties in $M = \overline{C}$ cannot simply feed in all of the secret shares $\Pi(X)$ into RECON to obtain the secret, as $C(X)$ may not be 1. Instead, if they know a subset $X' \subseteq X$ such that $C(X') = 1$ (which must exist since $X$ is qualified), they may simply feed the subset of their secret shares corresponding to $X'$, namely $\Pi(X')$, into RECON, and correctness guarantees that they will learn the secret. Thus, even though the algorithms in a witnessless distributed secret sharing scheme do not take a witness as input, reconstructing the secret still requires knowing a witness, namely the subset $X'$.

We note that the access structure $M$ is monotone, and is clearly in NP. Therefore, Lemma 2.2 shows that $M$ is recognized by a monotone nondeterministic verification procedure $V_M$. Thus, the above formulation of distributed secret sharing is equivalent to regular DSS (with witnesses) where we restrict to access structures of this form. Therefore, this notion is no stronger than regular DSS.

We note that many NP languages naturally are represented using a circuit $C$, such as Hamiltonian Cycle (where $C$ checks that the set of edges forms a Hamiltonian cycle) and Subset Sum (where $C$ checks that the subset of integers sums to 0).

**Definition 3.4 (Distributed secret sharing without setup).** In a distributed secret sharing scheme without setup, there is no SETUP algorithm, and SHARE and RECON do not take CRS as input. When distinguishing between schemes with and without setup, we call the standard notion (Definition 3.1) distributed secret sharing with trusted setup.

**Immediate relations between definitions.** All of the above variations are orthogonal, giving us 8 variants of distributed secret sharing. We make the following observation:

• Any of the 4 variants of strong distributed secret sharing imply the corresponding variant of weak distributed secret sharing. This is because being a strong scheme just imposes constraints on the form of the algorithms.

• Any of the 4 variants of distributed secret sharing with witnesses imply the corresponding witnessless variant, since the witnessless condition imposes a restriction on the languages allowed.

• Any of the 4 variants of distributed secret sharing without trusted setup imply the corresponding variant with trusted setup, where SETUP outputs an empty string.

In Section 3.4, we will show that they are all equivalent, and moreover that they are equivalent to witness PRFs.

### 3.2 Distributed Secret Sharing Implies One-Way Functions

Witness PRFs trivially imply one-way functions, and therefore information-theoretic distributed secret sharing is impossible for general access structures.

In this section, we consider DSS for specific access structures, and ask: for what access structures $M$ is information-theoretic DSS possible? To answer this question we first define trivial access
structures, and then in Theorem 3.6 we show that a DSS scheme for any non-trivial access structures implies one-way functions. DSS for trivial access structures, on the other hand, are shown to have a very simple information-theoretically secure construction.

**Definition 3.5** (Trivial access structures). We say that an access structure \( M \) for a set of parties \( P \) is *trivial* if either \( M \) is empty, or there exists a subset \( X \subseteq P \) such that \( Y \in M \) if and only if \( X \subseteq Y \).

We call such access structures trivial due to the following reasons:

- Parties outside of \( X \) are irrelevant to the access structure, as they can be added or removed from a set of parties without changing the set’s qualified status. Therefore, such a protocol is morally equivalent to the case where \( X = P \).
- When \( X = P \), all parties must get together to reconstruct the shared secret. In this case, there appears to be no reason to engage in the protocol in the first place, as the parties can just choose the group secret when they all coordinate at reconstruction time.

Note that trivial access structures are in \( P \), so there is no distinction between standard DSS and witnessless DSS.

**Theorem 3.6.** For an access structure \( M \), the following hold:

- If \( M \) is trivial, then there exists a perfectly-secure DSS for \( M \) in the strongest possible sense (that is, strong DSS without setup).
- If \( M \) is non-trivial, then the existence of any DSS for \( M \) in the weakest possible sense (that is, weak DSS with trusted setup) implies the existence of one-way functions.

**Proof.** Let \( M \) be trivial, with subset \( X \) such that \( Y \in M \) if and only if \( X \subseteq Y \). We then get the following strong DSS scheme for \( M \) without setup that has single-bit shared secrets:

- **SHARE():** sample a random \( \Pi(i) \leftarrow \{0, 1\} \), and publish an empty string as the public share \( P(i) = \emptyset \).
- **RECON(\( P, \Pi(Y) \)):** if \( X \subseteq Y \), simply XOR and output the shares for parties in \( X \), namely \( S \leftarrow \bigoplus_{i \in X} \Pi(i) \). If \( X \) is not a subset of \( Y \), abort.

The correctness of the protocol is trivial. For security, note that for any set \( Y \) that does not contain \( X \), there is some party \( i \in X \setminus Y \) such that the set of shares for \( Y \) does not contain the secret share \( \Pi(i) \). Therefore, \( \Pi(i) \) is independent of the shares \( \Pi(Y) \). Thus, \( S \) is independent of \( \Pi(Y) \). Perfect security follows.

Now we prove the other case in which \( M \) is a non-trivial access structure. Define \( X \) to be a *minimal qualified set* of parties if (1) \( X \in M \), and (2) any proper subset \( Y \subseteq X \) of \( X \) is not in \( M \) (i.e., \( Y \notin M \)). We then claim that there are at least two distinct minimal subsets \( X_0, X_1 \). First, if there were no minimal subset, then \( M \) must either contain all sets or none. In either case, \( M \) is trivial (with \( X = \emptyset \) in the case where \( M \) contains all sets). Second, suppose there is a single minimal subset \( X_0 \). By monotonicity, any set \( Y \) containing \( X_0 \) must be in \( M \). If \( M \) is not trivial, then there must exist an \( X_1 \in M \) such that \( X_1 \) does not contain \( X_0 \). We can also assume without
loss of generality that \( X_1 \) is minimal: if \( X_1 \) is not minimal, we can remove an element to get \( X'_1 \) that is strictly smaller than \( X_1 \), still is in \( M \), and still does not contain \( X_0 \). But then \( X_0, X_1 \) are distinct minimal qualified sets. Notice that neither \( X_0 \) nor \( X_1 \) can be empty.

Let \((\text{SETUP}, \text{SHARE}, \text{RECON})\) be a weak DSS with trusted setup for \( M \). We now build the following one-way function \( f \):

\[
f(r_0, r_1, \ldots, r_n) = \text{Compute } \text{CRS} \leftarrow \text{SETUP}(1^\lambda, 1^n; r_0), \text{Compute } (\Pi(i), P(i)) \leftarrow \text{SHARE}(1^\lambda, i; r_i), \text{Output } (\text{CRS}, P).
\]

That is, the input to \( f \) consists of the random coins for \text{SETUP} and the random coins each party feeds into \text{SHARE}, and the output is the \text{CRS} along with all of the public shares.

Suppose \( f \) is not one-way, and let \( I \) be an inverter for \( f \). We construct a DSS distinguisher \( D \), who receives the secret shares for the set \( X_0 \cap X_1 \), which is necessarily not in \( M \). \( D \) also receives a string \( K \), which is either the correct secret \( S \), or a random string, and attempts to distinguish the two cases.

\( D \) works as follows. Given \( \text{CRS} \), the public shares \( P \), and the secret shares \( \Pi(X_0 \cap X_1) \), \( D \) runs the inverter \( I \) on \( \text{CRS}, P \) to obtain (with high enough probability) some random coins \( r'_0, \ldots, r'_n \) that explain \( \text{CRS}, P \). Then, it runs \text{SHARE} for each \( i \in X_0 \cap X_1 \), using the randomness \( r'_i \), to obtain simulated secret shares \( \Pi'(i) \) (that are potentially different from the actual secret shares \( \Pi(i) \)). Next, it runs \text{RECON} on the secret shares for \( X_0 \), to obtain a secret \( S' \). Finally, \( D \) compares \( S' \) to \( K \), outputs 1 if they are identical, and 0 otherwise.

By the correctness of the DSS scheme for set \( X_0 \), we have that \( S = \text{RECON}(1^\lambda, \text{CRS}, P, \Pi(X_0)) \). Recalling that \((\Pi(i), P(i)) = \text{SHARE}(1^\lambda, i; r_i)\), we can express \( S = G_0(1^\lambda, \text{CRS}, P, \{r_i\}_{i \in X_0}) \) for some function \( G_0 \). This means that \( S \) is information-theoretically determined by \( 1^\lambda, \text{CRS}, P, \{r_i\}_{i \in X_0} \), and is therefore independent of \( r_i \) for \( i \notin X_0 \), except through \( P(i) \). Similarly, \( S = G_1(1^\lambda, \text{CRS}, P, \{r_i\}_{i \in X_1}) \) for some function \( G_1 \), meaning that \( S \) is independent of \( r_i \) for \( i \notin X_1 \), except through \( P(i) \). Together, this means that \( S \) can be expressed as a function \( G \) of \( 1^\lambda, \text{CRS}, P, \{r_i\}_{i \in X_0 \cap X_1} \) as \( S = G(1^\lambda, \text{CRS}, P, \{r_i\}_{i \in X_0 \cap X_1}) \).

This means that, when \( D \) runs \( S' \leftarrow \text{RECON}(1^\lambda, \text{CRS}, P, \{\Pi(i)\}_{i \in X_0 \cap X_1} \cup \{\Pi'(i)\}_{i \in X_0 \setminus X_1}) \), we have that

\[
S' = G_0(1^\lambda, \text{CRS}, P, \{r_i\}_{i \in X_0 \cap X_1} \cup \{r'_i\}_{i \in X_0 \setminus X_1}) = G(1^\lambda, \text{CRS}, P, \{r_i\}_{i \in X_0 \cap X_1}) = S.
\]

Since \( S = S' \), \( D \) can successfully distinguish \( S \) from random.

### 3.3 Distributed Secret Sharing for Threshold

In this section we present a distributed secret sharing scheme for the threshold access structure. The proof of security relies on the multilinear decisional Diffie-Hellman assumption (see Definition 2.6). This construction works in the trusted setup model (which is used for the setup of the multilinear map). Assume there are \( n \) parties and the threshold condition says that any \( t \) of them should be able to reconstruct the secret.

**Lemma 3.7.** Assuming an \((n-t)\)-multilinear map that satisfied the MDDH assumption, there is a \( t\)-out-of-\( n \) (weak) distributed secret sharing scheme (with trusted setup).\(^5\)

\(^5\)Since threshold is in \( P \), there are no witnessness, so there is no distinction between the standard and witnessless notions of DSS.
Proof. We start with the description of the scheme. The trusted setup will consists of an \( n - t \) multilinear map. For the sharing, party \( p_i \) generates a random \( s_i \) and published \( h_i = g^{s_i} \). The shared secret key is \( S = e(g, \ldots, g)^{\prod_{i=1}^{n-t} s_i} \). With \( t \) of the \( s_i \)'s one can easily compute \( S \) by pairing the other \( h_i \)'s, and then raising the result by each of the \( s_i \)'s. Security in the case of fewer than \( t \) shares follows from the security of the multilinear DH assumption.

More precisely, in the trusted setup we run \( \text{MMap.Gen}(1^\lambda, n) \) to get \( (\Gamma, g, \ell) \) which we set as the public parameters. The sharing procedure of party \( p_i \) samples a random \( s_i \) (which is kept secret) and outputs \( h_i = g^{s_i} \). The shared secret key is \( S = e(g, \ldots, g)^{\prod_{i=1}^{n-t} s_i} \). For correctness, we observe that given the secret shares of any subset of the \( t \) parties one can compute \( S \). Indeed, given \( h_{i_1}, \ldots, h_{i_{n-t}} \) one can compute

\[
e(h_{i_1}, \ldots, h_{i_{n-t}}) = e(g, \ldots, g)^{\prod_{j=1}^{n-t} s_{i_j}}
\]

and then, by raising the right-hand side to the powers \( s_{i_{n-t+1}}, \ldots, s_{i_{n}} \), compute

\[
e(g, \ldots, g)^{\prod_{j=1}^{n-t} s_{i_j}})^{\prod_{j=n-t+1}^{n} s_{i_j}} = S
\]

Security. To argue security, we observe that an adversary that knows less than \( t \) secret shares, cannot distinguish \( S \) from uniform. Assume, without loss of generality, that an adversary \( A \) knows \( h_1, \ldots, h_n \) and \( t - 1 \) secret shares \( s_{i_1}, \ldots, s_{i_{t-1}} \) and is able to distinguish \( S \) from uniform. Namely, there is a non-negligible \( \delta \) such that

\[
\left| \Pr[A(g, g^{s_1}, \ldots, g^{s_n}, s_{i_1}, \ldots, s_{i_{t-1}}, e(g, \ldots, g)^{\prod_{i=1}^{n-t} s_i}) = 1] - \Pr[A(g, g^{s_1}, \ldots, g^{s_n}, s_{i_1}, \ldots, s_{i_{t-1}}, K) = 1] \right| \geq \delta,
\]

where \( K \leftarrow \mathbb{G}_2 \) is chosen uniformly at random. We will use \( A \) to construct an adversary \( B \) that breaks the MDDH assumption (see Definition 2.6). Consider a challenge of \( (n - t)\)-MDDH \( (g, g^{s_1}, \ldots, g^{s_{n-t+1}}, Z) \), where \( Z \) is either \( e(g, \ldots, g)^{\prod_{i=1}^{n-t+1} s_i} \) or uniform in \( \mathbb{G}_2 \). The adversary \( B \) samples \( t - 1 \) random elements \( s_{n-t+2}, \ldots, s_n \) and computes \( Z' = Z^{\prod_{i=n-t+2}^{n} s_i} \). Then, \( B \) emulates the execution of \( A \) on input \( (g, g^{s_1}, \ldots, g^{s_n}, s_{n-t+2}, \ldots, s_n, Z') \) and outputs whatever bit \( A \) outputs. To see that \( B \) distinguishes between the two cases, notice that when \( Z \) is uniform, then \( Z' \) is uniform, and when \( Z = e(g, \ldots, g)^{\prod_{i=n-t+1}^{n} s_i} \), then \( Z' = e(g, \ldots, g)^{\prod_{i=1}^{n-t} s_i} \). This means that \( B \)'s advantage is at least \( \delta \) which was assumed to be non-negligible.

3.3.1 Hamming Ball Constrained PRFs

We show that any distributed secret sharing scheme for threshold implies constrained PRFs that can be constrained to a Hamming ball around an arbitrary point. One limitation of our construction is that the PRF only allows a single collusion: an adversary that sees the PRF constrained to two Hamming balls can potentially recover the entire secret key.

Of course, our construction of DSS for threshold relies on the multilinear Diffie-Hellman assumption, which already implies constrained PRFs for all circuits with arbitrary collusions [BW13]. However, our conversion here is generic and applies to any threshold DSS scheme, which perhaps can be based on simpler assumptions than multilinear maps. Perhaps more importantly, the ideas presented here will be used in Section 3.4 to show the equivalence of general DSS and witness PRFs. Thus, this construction can be viewed as a warm-up to Theorem 3.11.
Definition 3.8 (One-time constrained PRFs for Hamming balls). A constrained PRFs for Hamming balls is a tuple of algorithms \((\text{Gen}, \text{PRF}, \text{Constrain}, \text{Eval})\) where:

- \(\text{Gen}(1^\lambda, 1^n)\) is a polynomial-time randomized procedure that takes as input a security parameter \(\lambda\) and a bit length \(n\), and outputs a function key \(f_k\).
- \(\text{PRF}(f_k, x)\) is a polynomial-time deterministic procedure that takes as input the function key \(f_k\) and a bit string \(x \in \{0, 1\}^n\).
- \(\text{Constrain}(f_k, c, r)\) is a polynomial-time (potentially randomized) procedure that takes as input the function key \(f_k\), a point \(c \in \{0, 1\}^n\), and a radius \(r \in [0, n]\), and outputs the constrained evaluation key \(e_k\) corresponding to the Hamming ball of radius \(r\) centered at \(c\).
- \(\text{Eval}(e_k, x)\) is a polynomial-time deterministic procedure that takes as input the evaluation key \(e_k\) and a bit string \(x \in \{0, 1\}^n\).

**Correctness:** If \(x\) and \(c\) differ on at most \(r\) bits, then

\[
\Pr[\text{Eval}(e_k, x) = \text{PRF}(f_k, x)] = 1,
\]

where \(f_k \leftarrow \text{Gen}(1^\lambda, 1^n)\), \(e_k \leftarrow \text{Constrain}(f_k, c, r)\) and the probability is taken over the randomness of \(\text{Gen}, \text{Constrain}\).

**One-time security:** For any probabilistic polynomial time algorithm \(D\), there exists a negligible function \(\neg\) such that for any \(\lambda \in \mathbb{N}\) and any \(r \in [0, n]\), \(x \in \{0, 1\}^n\) and \(c \in \{0, 1\}^n\) such that \(x\) and \(c\) differ in strictly more than \(r\) points, it holds that

\[
|\Pr[D(e_k, \text{PRF}(f_k, x)) = 1] - \Pr[D(e_k, y) = 1]| < \neg(\lambda),
\]

where the probabilities are taken over the choice of \(f_k \leftarrow \text{Gen}(1^\lambda, 1^n)\), \(e_k \leftarrow \text{Constrain}(f_k, c, r)\), and \(y\) which is chosen uniformly at random over the co-domain of \(\text{PRF}\).

**Theorem 3.9.** If secure distributed secret sharing for threshold access structures exists, then secure one-time constrained PRFs for Hamming balls exists.

At first glance, building a Hamming ball constrained PRFs from threshold DSS appears to be a difficult task. Indeed, the natural approach to constructing witness PRFs would be to have the public evaluation key be the set of public shares \(P\), and perhaps some subset of secret shares \(\Pi(X)\) for \(X \subseteq P\); the secret function key would naturally be the complete set of secret shares \(\Pi(P)\). However, it is unclear how to define the PRF \(\text{PRF}(\cdot)\). One possibility is to try to set the outputs of the PRF to be the shared secret \(S\). However, our threshold DSS only explicitly has a single \(S\). Yet, we need many secret outputs, one for each possible input.

To get around these limitations, we make use of the fact that distributed secret sharing is reusable, as discussed in the beginning of Section 3. For example, suppose two distinct sets of parties \(P_0 \neq P_1\) wish to carry out the protocol, and there is some party \(i\) that is a member of both sets. Then, party \(i\) could reuse his public share for both runs of the protocol. More generally, for a large collection \(C\) of parties with \(|C| \gg n\), all parties can run \text{SHARE} exactly once, and then any subset \(P \subseteq C\) of \(n\) parties can then run the distributed secret sharing protocol without any interaction (assuming that \(P\) is complete, meaning every party index is present exactly once).
Our idea, then, is to have the PRF value be the shared secret for a subset of $C$, and the input to the PRF selects which subset to use. We need to be careful, though, as we need to ensure that the subset is complete and contains every party index exactly once. We show that such valid subsets can still be used to construct witness PRFs.

**Proof of Theorem 3.9.** Let $(\text{SETUP}, \text{SHARE}, \text{RECON})$ be a distributed secret sharing scheme for threshold. We start with the construction of the constrained PRF.

- **Gen$(1^\lambda, 1^n)$**: First, run $\text{CRS} \leftarrow \text{SETUP}(1^\lambda, 1^{2n}, \text{thr} = n)$. That is, initialize the setup procedure for the threshold DSS scheme with $2n$ parties and threshold $n$. Next, we will define a set $\mathcal{P} = \{(i, b) \}_{i \in [n]} \cup [n+1, 2n]$ of parties, where party $(i, b)$ for $i \in [n]$ has index $i$, and party $i$ for $i \in [n+1, 2n]$ has index $i$. Now run $\text{SHARE}$ for each party. That is, run

$$
(P_{i,b}, \Pi_{i,b}) \leftarrow \text{SHARE}(1^\lambda, 1^{2n}, \text{CRS}, \text{thr} = n, i) \text{ for } i \in [n],
$$

$$(P_i, \Pi_i) \leftarrow \text{SHARE}(1^\lambda, 1^{2n}, \text{CRS}, \text{thr} = n, i) \text{ for } i \in [n+1, 2n].$$

Let $\Pi = \{\Pi_{i,b}\}_{i \in [n]} \cup \{\Pi_i\}_{i \in [n+1, 2n]}$ be the set of secret shares, and $P$ the corresponding set of public shares. Output the function key $\text{fk} = (\text{CRS}, \Pi, P)$.

- **PRF($\text{fk}, x$)**: Define $\mathcal{P}_x$ to be the collection of parties $(i, x_i)$ for $i \in [n]$, together with parties $i$ for $i \in [n+1, 2n]$. Define

$$P(\mathcal{P}_x) = \{P_{i,x_i}\}_{i \in [n]} \cup \{P_i\}_{i \in [n+1, 2n]} \text{ and } \Pi(\mathcal{P}_x) = \{\Pi_{i,x_i}\}_{i \in [n]} \cup \{\Pi_i\}_{i \in [n+1, 2n]}.$$  

Notice that $\mathcal{P}_x$ is complete, in that each party index is present. Now, use the secret shares to reconstruct the shared secret for $\mathcal{P}_x$:

$$S \leftarrow \text{RECON}(1^\lambda, 1^{2n}, \text{CRS}, \text{thr} = n, P(\mathcal{P}_x), \Pi(\mathcal{P}_x))$$

and output $S$.

- **Constrain($\text{fk}, c, r$)**: Let

$$\text{ek} = (c, r, P, \{\Pi_{i,c_i}\}_{i \in [n]} \cup \{\Pi_i\}_{i \in [n+1, n+r]}$$

be the set of secret shares $\Pi_{i,c_i}$ for parties $(i, c_i), i \in [n]$, as well as $r$ of the secret shares $\Pi_i$ for for parties $i \in [n+1, 2n]$. Output ek.

- **Eval($\text{ek}, x$)**: Check that $x$ and $c$ differ in at most $r$ points, and otherwise abort. Let $T \subseteq [n]$ be the set of indices where $x$ and $c$ agree. Then, the set of parties $X = \{(i, x_i)\}_{i \in T} \cup [n+1, n+r]$ forms a subset of $\mathcal{P}_x$. Moreover, $X$ consists of $|T| + r \geq n = t$ parties (since $x$ and $c$ agree on at least $n - r$ points), and ek contains the secret shares $\Pi(X)$ for all of these parties. Therefore, run

$$K \leftarrow \text{RECON}(1^\lambda, 1^{2n}, \text{CRS}, \text{thr} = n, P(\mathcal{P}_x), \Pi(X))$$

and output $K$.

An example of our construction for the case $n = 5$ is given in Figure 2.

Correctness follows immediately from the observations above. Indeed, given $x$ and $r$ that differ on at most $r$ coordinates, one can generate the secret shares for the set of parties $X$ defined above. Now, the correctness of the distributed secret sharing scheme implies that $K$ must be equal to $S$, where $K$ and $S$ are as defined in the scheme above. For security, we have the following claim:
The underlying threshold DSS scheme is instantiated with 10 indices and threshold $t = 5$. For indices 1 through 5, SHARE is run twice, returning two sets of secret/public pairs for each index 1 through 5. For indices 6 through 10, SHARE is run once. The secret key $f_k$ consists of all public shares and secret shares. The shares highlighted in green correspond to the evaluation key $e_k$ for the Hamming ball centered at $c = 00101$ with radius $r = 3$. The public shares outlined in bold purple indicate the public shares whose shared secret $S$ is PRF($f_k, x = 10001$). Notice that $x$ and $c$ have a Hamming distance $2 \leq r$, so $S$ should be computable from $e_k$. Indeed $e_k$ contains $6 \geq t$ of the corresponding secret shares (also outlined in bold purple), meaning that it is possible to construct $S = PRF(f_k, x)$ from $e_k$.

**Figure 2:** Example instantiation for $n = 5$. The underlying threshold DSS scheme is instantiated with 10 indices and threshold $t = 5$. For indices 1 through 5, SHARE is run twice, returning two sets of secret/public pairs for each index 1 through 5. For indices 6 through 10, SHARE is run once. The secret key $f_k$ consists of all public shares and secret shares. The shares highlighted in green correspond to the evaluation key $e_k$ for the Hamming ball centered at $c = 00101$ with radius $r = 3$. The public shares outlined in bold purple indicate the public shares whose shared secret $S$ is PRF($f_k, x = 10001$). Notice that $x$ and $c$ have a Hamming distance $2 \leq r$, so $S$ should be computable from $e_k$. Indeed $e_k$ contains $6 \geq t$ of the corresponding secret shares (also outlined in bold purple), meaning that it is possible to construct $S = PRF(f_k, x)$ from $e_k$.

**Claim 3.10.** If $(\text{SETUP}, \text{SHARE}, \text{RECON})$ is a secure distributed secret sharing scheme for threshold, then $(\text{Gen}, \text{PRF}, \text{Constrain}, \text{Eval})$ is a one-time secure constrained PRF for Hamming balls.

**Proof.** Let $r \in [0, n]$, and $x, c \in \{0, 1\}^n$ such that $x, c$ differ on strictly more than $r$ inputs. Let $D$ be a potential constrained PRF distinguisher, and let

$$
\varepsilon = |\Pr[D(e_k, PRF(f_k, x)) = 1] - \Pr[D(e_k, y) = 1]|,
$$

where $f_k = (\text{CRS}, \Pi, P) \leftarrow \text{Gen}(1^\lambda, 1^n)$, $e_k \leftarrow \text{Constrain}(f_k, c, r)$, and $y$ is chosen uniformly at random from the appropriate domain. We will show that $\varepsilon$ is negligible. Define $P = \{(i, b)\}_{i \in [n]} \cup [n + 1, 2n]$ and $P_x = \{(i, x_i)\}_{i \in [n]} \cup [n + 1, 2n]$ as above. Let $T \subseteq [n]$ be the set of indices where $x$ and $c$ agree.

We now construct a distinguisher $D'$, which will break the security of the threshold DSS protocol for $2n$ parties and threshold $n$ with probability $\varepsilon$. $D'$ gets as input $\text{CRS}$ (generated as $\text{CRS} \leftarrow \text{SETUP}(1^\lambda, 1^{2n}, \text{thr} = n)$), as well as the public shares $P(j)$ for parties $j \in [2n]$ and secret shares $\Pi(j)$ for parties $j \in T \cup [n + 1, n + r]$ (where $(P(j), \Pi(j)) \leftarrow \text{SHARE}(1^\lambda, 1^{2n}, \text{CRS}, \text{thr} = n, j)$). $D'$ also gets $K$, which is either the correct shared key $S$ for the set of parties $P$, or a random string. Notice that the size of $T \cup [n + 1, n + r]$ is $|T| + r < n$, since $x$ and $c$ are the same on strictly fewer than $n - r$ indices. Therefore, the set of parties for which $D'$ receives secret shares is unqualified.

$D'$ now associates the indices $j \in [n]$ with parties $(j, x_j) \in P$, and the indices $j \in [n + 1, 2n]$ with the parties $j \in P$. That is, $D'$ sets $P_{j,x_j} = P(j)$ for $j \in [n]$, and $\Pi_{j,x_j} = \Pi(j)$ for $j \in T$. Under this association, the set $P_x \subseteq P$ has the complete set of identities, and $P(P_x)$ corresponds exactly with the set of public shares received by $D'$. Now, $D'$ simulates the roles of parties $(j, 1 - x_j)$ for $j \in [n]$ by running $\text{SHARE}(1^\lambda, 1^{2n}, \text{CRS}, \text{thr} = n, j)$ and obtaining $(P_{j,1-x_j}, \Pi_{j,1-x_j})$. Then, $D'$ sets $P$ to be the set of all public shares (both those obtained and simulated), and

$$
e_k = (c, r, P, \{\Pi_{i,c_i}\}_{i \in [n]} \cup \{\Pi_i\}_{i \in [n+1,n+r]})$$
Notice that $D'$ has all of the secret shares $\Pi_{i,c_i}$ needed to construct $e_k$: for $i \in T$, $\Pi_{i,c_i} = \Pi_i x_i = \Pi(i)$ which $D'$ received as input, and for $i \notin T$, $\Pi_{i,c_i} = \Pi_{i,1-x_i}$ which $D'$ simulated. $D'$ then gives $e_k, K$ to $D$, and outputs the output of $D$.

Notice that $D'$ exactly simulates the evaluation key $e_k$ seen by $D$, with the implicit secret function key $f_k$ obtained by combining all the secret shared for parties in $P_x$ with the secret shares simulated by $D'$. Also, if $K$ is the correct shared key for the group of users $P_x$, then $K$ is equal to the correct value of $\text{PRF}(f_k, x)$. Therefore, if $D$ distinguishes $\text{PRF}(f_k, x)$ from random with advantage $\varepsilon$, $D'$ distinguishes $S$ from random with probability $\varepsilon$, thus breaking the security of the DSS scheme. Hence, $\varepsilon$ must be negligible and the constrained PRF is secure.

This completes the proof of the theorem.

### 3.4 Distributed Secret Sharing is Equivalent to Witness PRFs

In this section, we prove that all variants of distributed secret sharing are actually equivalent to witness PRFs. Together with Zhandry’s construction of witness PRFs [Zha14], this gives a construction of distributed secret sharing from simple assumptions on multilinear maps.

**Theorem 3.11.** The existence of the following are equivalent:

- Witness PRFs for $\text{NP}$.
- Any of the 8 variants of distributed secret sharing for $\text{mNP}$.

**Proof.** To prove the theorem, it suffices to prove the following:

1. Weak distributed secret sharing without witnesses and with trusted setup implies witness PRFs.
2. Witness PRFs imply strong distributed secret sharing with witnesses and without trusted setup.

**Distributed secret sharing implies witness PRFs.** We first give the construction of witness PRFs from weak witnessless DSS with a trusted setup. Our construction and proof leverage the reusability of distributed secret sharing, and is based on the threshold DSS to Hamming ball PRF conversion presented in Section 3.3.

Let $(\text{SETUP}, \text{SHARE}, \text{RECON})$ be a witnessless weak distributed secret sharing scheme with trusted setup. We build the following witness PRF $(\text{Gen}, \text{PRF}, \text{Eval})$:

- **Gen($R$):** Let $n$ be the instance size and $m$ the witness size. We will use a DSS scheme over a set of parties $\mathcal{P}$ with $2n + m$ party indices. We will generally think of the index set as containing $2n$ pairs $(i, b) \in [n] \times \{0, 1\}$, as well as $m$ integers $j \in [m]$. The set of pairs $[n] \times \{0, 1\}$ we will call the “instance set”, and the set of integers $[m]$ we will call the “witness set”.

Define a circuit $C : 2^\mathcal{P} \rightarrow \{0, 1\}$ that operates, given an input $S \subseteq \mathcal{P}$, as follows. If $S = \mathcal{P}$, output 1. For any $i$, if either both $(i, 0), (i, 1)$ from the instance set are in $S$ or neither are in $S$, then $C$ outputs 0. Otherwise if $(i, b) \in S$ (and therefore $(i, 1-b) \notin S$), set $x_i = b$. Let $x$ be the bit string $x_1x_2\ldots x_n$. Let $w_j$ be 1 if $j \in S$ and let $w$ be the bit string $w_1w_2\ldots w_n$. 21
Then, $C$ outputs $R(x, w)$. Recall that the monotone closure of $C$, $M = \overline{C}$, satisfies $X \in M$ if some subset $X' \subseteq X$ causes $C$ to accept.

First, we generate the CRS by running

$$\text{CRS} \leftarrow \text{SETUP}(1^\lambda, 1^{2n+m}, C).$$

Now, we define the set $\mathcal{P}$ to consist of the following parties: for each index $(i, b)$ in the instance set, we will associate two parties $\{(i, b, c)\}_{c \in \{0, 1\}}$, and for each index $j \in [m]$ in the witness set, we will associate a party $j$. Next, we run $\text{SHARE}$ for each party. That is, for each $i \in [n], b \in \{0, 1\}$ and $c \in \{0, 1\}$, run

$$(P_{i, b, c}, \Pi_{i, b, c}) \leftarrow \text{SHARE}(1^\lambda, 1^{2n+m}, \text{CRS}, C, (i, b))$$

and for each $j \in [m]$, run

$$(P_j, \Pi_j) \leftarrow \text{SHARE}(1^\lambda, 1^{2n+m}, \text{CRS}, C, j).$$

Let

$$P = \{P_{i, b, c}\}_{i \in [n], b, c \in \{0, 1\}} \cup \{P_j\}_{j \in [m]} \quad \text{and} \quad \Pi = \{\Pi_{i, b, c}\}_{i \in [n], b, c \in \{0, 1\}} \cup \{\Pi_j\}_{j \in [m]}$$

be the set of public and secret shares, respectively. Output the function key

$$\text{fk} = (\text{CRS}, P, \Pi)$$

and the evaluation key

$$\text{ek} = (\text{CRS}, P, \{\Pi_{i, b, b}\}_{i \in [n], b \in \{0, 1\}}, \{\Pi_j\}_{j \in [m]}).$$

That is, the evaluation key consists of all of the public shares, all of the secret shares for indices in the witness set, and one of the secret shares for each index $(i, b)$ in the instance set (recall that for each index in the instance set, we have two parties).

- $\text{PRF}(\text{fk}, x)$: Let

$$\mathcal{P}_x = \{(i, b, x_i)\}_{i \in [n], b \in \{0, 1\}} \cup [m]$$

so that

$$P(\mathcal{P}_x) = \{P_{i, b, x_i}\}_{i \in [n], b \in \{0, 1\}} \cup \{P_j\}_{j \in [m]} \quad \text{and} \quad \Pi(\mathcal{P}_x) = \{\Pi_{i, b, x_i}\}_{i \in [n], b \in \{0, 1\}} \cup \{\Pi_j\}_{j \in [m]}.$$  

Notice that $\mathcal{P}_x$ is complete, in the sense that each index is represented exactly once. Therefore, run

$$K \leftarrow \text{RECON}(1^\lambda, 1^{2n+m}, \text{CRS}, C, P(\mathcal{P}_x), \Pi(\mathcal{P}_x))$$

and output $K$.

That is, out of the entire collection of $4n + m$ parties, use the input $x$ to select the appropriate set of parties $\mathcal{P}_x$ of size $2n + m$. Then, compute the shared key for that set of parties.
• **Eval(ek, x, w):** Let \(\mathcal{P}_x\) and \(P(\mathcal{P}_x)\) be as above. Let

\[
S_{x,w} = \{(i, x_i, x_i)\}_{i \in [n]} \cup \{j\}_{j:w_j=1} \quad \text{and} \quad \Pi(S_{x,w}) = \{\Pi_{i,x_i,x_i} \}_{i \in [n]} \cup \{\Pi_j\}_{j:w_j=1}.
\]

Run

\[
K \leftarrow \text{RECON}(1^\lambda, 1^{2n+m}, \text{CRS}, C, P(\mathcal{P}_x), \Pi(S_{x,w}))
\]

and output \(K\).

To show correctness, we need to argue that \(\text{Eval}(ek, x, w) = \text{PRF}(fk, x)\) for all \(w\) such that \(R(x, w) = 1\). Indeed, \(\text{Eval}(ek, x, w)\) attempts to compute the shared secret for the set of parties \(\mathcal{P}_x\). Notice that the set \(S_{x,w}\) is a subset of the set \(\mathcal{P}_x\), and consists of the parties in \(\mathcal{P}_x\) with indices in \(T_{x,w} = \{(i, x_i)\}_{i \in [n]} \cup \{j\}_{j:w_j=1}\). Now notice that \(C(T_{x,w})\) computes exactly \(R(x, w) = 1\). Thus, the set of secret shares \(\Pi(S_{x,w})\) is sufficient to reconstruct the shares secret \(S\) for \(\mathcal{P}_x\). Notice that \(S\) is also the value outputted by \(\text{PRF}(fk, x)\). Therefore, \(\text{Eval}(ek, x, w) = \text{PRF}(fk, x)\) as desired. An example instantiation is given in Figure 3.

![Figure 3](image-url)

**Figure 3:** Example instantiation for instance size \(n = 3\) and witness size \(m = 4\). The underlying threshold DSS scheme is instantiated with 10 indices, 6 for the instance set having the form \((i, b)\), and 4 for the witness set having the form \(j\). For each instance set index \((i, b)\), \(\text{SHARE}\) is run twice, returning two sets of secret/public pairs for parties \((i, b, 0)\), \((i, b, 1)\). For witness set indices, \(\text{SHARE}\) is run once. The secret key \(fk\) consists of all public keys and secret shares, and the evaluation key consists of the green highlighted shares. An example evaluation on \(x = 100\) is given. The instance \(x\) selects the subset \(\mathcal{P}_x\), whose public shares are bolded in purple. For these shares, there is a shared secret \(S\), and the value of \(\text{PRF}\) on \(x\) is defined to be \(S\). Suppose \(w = 1010\) is a valid witness for \(x\). Then, the secret shares for parties in \(S_{x,w}\) are boxed in bold purple and represent the set of secret shares inside \(ek\) that can be fed into \(\text{RECON}\) to yield \(S\). Notice that, among the instance set of indices, \(ek\) only contains secret shares for the parties in \(\mathcal{P}_x\) that have indices \((i, x_i)\).

It remains to prove that the scheme is secure:

**Claim 3.12.** If \((\text{SETUP}, \text{SHARE}, \text{RECON})\) is a secure weak distributed secret sharing scheme without witnesses and with trusted setup, then \((\text{Gen}, \text{PRF}, \text{Eval})\) is a secure witness \(\text{PRF}\).

**Proof.** Let \(R\) be an NP relation with associated language \(L\), and let \(x \notin L\). Let \(D\) be a potential distinguisher for \((\text{Gen}, \text{PRF}, \text{Eval})\), and define

\[
\varepsilon = |\Pr[D(ek, \text{PRF}(fk, x)) = 1] - \Pr[D(ek, y) = 1]|,
\]

23
where \((ek, fk) \leftarrow \text{Gen}(R)\). We will show that \(\varepsilon\) is negligible. To that end, let \(\{(n \times \{0, 1\}) \cup [m]\) be the index set for the distributed secret sharing scheme, and let \(C\) be the circuit derived from \(R\), and \(M\) be the associated access structure. Let \(X = \{(i, x_i)\}_{i \in [n]} \cup [m]\). Then, notice that \(x \notin L\) implies \(X \notin M\).

We now construct a distinguisher \(D'\) for (\text{SETUP}, \text{SHARE}, \text{RECON}). \(D'\) receives the public shares \(P = \{P(i, b)\}_{i \in [n], b \in \{0, 1\}} \cup \{P(j)\}_{j \in [m]}\), the secret shares \(\Pi(X) = \{\Pi(t)\}_{t \in X}\) for the parties in \(X\). More precisely, \(D'\) receives \(\Pi(i, x_i)\) for \(i \in [n]\) and \(\Pi(j)\) for \(j \in [m]\). \(D'\) also receives common reference string \(\text{CRS}\). Lastly, \(D'\) receives a key \(K\), and tries to decide if \(K\) is the correct shared key, or if \(K\) is random.

Define \(\mathcal{P} = \{(i, b, c)\}_{i \in [n], b, c \in \{0, 1\}} \cup \{j\}_{j \in [m]}\) be the set of all parties, and let
\[
P_{i, b, x_i} = P(i, b), \quad \Pi_{i, b, x_i} = \Pi(i, b), \quad P_j = P(j) \quad \text{and} \quad \Pi_j = \Pi(j).
\]
By this definition, \(D'\) has all of the public shares for parties of the form \((i, b, x_i)\), and all of the secret shares for the subset of parties of the form \((i, x_i)_i\). Next, \(D'\) simulates the public and secret shares for all parties \((i, b, x_i)\).

\[
(\Pi_{i, b, 1-x_i}, P_{i, b, 1-x_i}) \leftarrow \text{SHARE}(1^\lambda, 1^{2n+m}, \text{CRS}, C, (i, b)).
\]

Now, \(D'\) has all secret shares for parties \((i, b, b)\). Define \(ek\) to consist of \(\text{CRS}\), all the public shares \(P = \{P_{i, b, c}\}_{i \in [n], b, c \in \{0, 1\}} \cup \{P_j\}_{j \in [m]}\) as well as the secret shares \(\{\Pi_{i, b, x_i}\}_{i \in [n], b \in \{0, 1\}} \cup \{\Pi_j\}_{j \in [m]}\). Finally, \(D'\) simulates the execution of \(D\) on inputs \(ek\) and \(K\), and output the whatever bit \(D\) outputs.

Notice that the evaluation key \(ek\) simulated by \(D'\) is correctly distributed. Moreover, recall that \(\text{PRF}(fk, x)\) is the shared secret for the parties \(\mathcal{P}_x = \{(i, b, x_i)\}_{i \in [n], b \in \{0, 1\}} \cup [m]\), which have public shares \(\{P(i, b)\}_{i \in [n], b \in \{0, 1\}} \cup \{P_j\}_{j \in [m]}\). These are exactly the public shares provided to \(D'\), and it is the shared secret corresponding to these public shares that \(D'\) is trying to distinguish from random. Therefore, if \(K\) is the true secret key, then \(K\) is also the correct \(\text{PRF}\) value. Thus, the distinguishing advantage of \(D'\) is identical to the distinguishing advantage of \(D\), and is therefore \(\varepsilon\).

The security of (\text{SETUP}, \text{SHARE}, \text{RECON}) shows that \(\varepsilon\) is negligible.

**Witness PRFs imply distributed secret sharing.** Given a Witness PRF \((\text{Gen}, \text{PRF}, \text{Eval})\), we can easily obtain a one-way function, and from this we can obtain a pseudorandom generator \(f\) [HILL99]. We construct the following strong distributed secret sharing scheme \((\text{SHARE}, \text{RECON})\) without trusted setup.

- **SHARE**\((1^\lambda, 1^n, 1^k)\): Run \((fk, ek) \leftarrow \text{Gen}(R)\) where \(R\) is the following NP circuit. \(R\) takes as input an instance \((V_M, \{y_i\}_{i \in \mathcal{P}_n})\), where \(V_M\) is the description of an \(m\)\(\text{NP}\) circuit of size at most \(k\), and witness \(w' = (w, \{s_i\}_{i \in X})\) for some subset \(X \subseteq \mathcal{P}_n\). It outputs 1 if (1) \(V_M(X, w) = 1\) and (2) \(y_i = f(s_i)\) for each \(i \in X\). Otherwise, \(R\) outputs 0.

  Let \(s \leftarrow \mathcal{S}\) where \(\mathcal{S}\) is the domain of \(f\), and \(y = f(s)\). Output public share \(P(i) = (ek, y)\) and secret share \(\Pi(i) = s\).

- **RECON**\((1^\lambda, 1^n, V_M, P, \Pi(X), w)\): Write \(\Pi(X) = \{s_i\}_{i \in X}\) and \(P = \{(ek_i, y_i)\}_{i \in \mathcal{P}}\). Let \(x\) be the instance \((V_M, \{y_i\}_{i \in \mathcal{P}})\), and let \(w' = (w, \{s_i\}_{i \in X})\) be a witness. For each \(i\), compute

  \[S_i = \text{Eval}(ek_i, x, w'),\]

  and then compute \(S = S_1 \oplus S_2 \oplus \cdots \oplus S_n\). Output \(S\).

24
The correctness of the scheme follows immediately from the correctness of the underlying witness PRF. The security of the scheme follows from the following claim.

**Claim 3.13.** If (Gen, PRF, Eval) is a secure witness PRF and f is a secure PRG, then (SHARE, RECON) is a secure strong distributed secret sharing scheme with witnesses and without trusted setup.

**Proof.** Let M be an access structure with verification procedure V_M. Let X \notin M and X \neq \mathcal{P}_n. Let (P(i), \Pi(i)) \leftarrow SHARE(1^\lambda, 1^n, 1^k) (and let fk_i be the function key constructed in the i-th execution of SHARE) and S is the shared secret relative to V_M. That is, s_i \leftarrow S, y_i \leftarrow f(s_i), x \leftarrow (V_M, \{y_i\}_{i \in \mathcal{P}_n}), and S = S_1 \oplus S_2 \oplus \cdots \oplus S_n, where S_i = PRF(fk_i, x). Our goal is to show that S is pseudorandom, even given all of the public shares P and the secret shares \Pi(X) for parties in X. Let i^* \notin X, as guaranteed by the assumption that X \neq \mathcal{P}_n. By the definition of S, it suffices to show that S_{i^*} is pseudorandom.

To this end, let D be a potential distinguisher for S_{i^*}, and define

$$
\varepsilon = |\Pr[D(P, \Pi(X), S_{i^*}) = 1] - \Pr[D(P, \Pi(X), K) = 1]|.
$$

We need to show that \varepsilon is negligible. Notice that P(i), \Pi(i) are independent of S_{i^*} for every i \neq i^*. Therefore, the values P(i), \Pi(i) can be simulated, given only P(i^*) and the challenge (either S_{i^*} or a random K). Notice that D does not receive the secret share \Pi(i^*) since i^* \notin X. Thus, we can obtain a distinguisher D', such that

$$
|\Pr[D'(ek, \{y_i\}_{i \notin X}, \{s_i\}_{i \in X}, PRF(fk, x)) = 1] - \Pr[D'(ek, \{y_i\}_{i \notin X}, \{s_i\}_{i \in X}, K)] = \varepsilon,
$$

where y_i = f(s_i), s_i for all i are random in S, x = (V_M, \{y_i\}_{i \in \mathcal{P}_n}), (fk, ek) \leftarrow Gen(R) where R is as in the definition of SHARE, and the probabilities are over the random coins of D'.

We now introduce a modified experiment where y_i for i \notin X are chosen at random from the co-domain of f. The security of the PRG f guarantees that the advantage of D' is only negligibly better. Namely,

$$
|\Pr[D'(ek, \{y_i\}_{i \notin X}, \{s_i\}_{i \in X}, PRF(fk, x)) = 1] - \Pr[D'(ek, \{y_i\}_{i \notin X}, \{s_i\}_{i \in X}, K)]| \geq \varepsilon - \text{neg}(\lambda),
$$

where the only difference from above is that the y_i are truly random. Now, since f is expanding, with overwhelming probability all of the y_i are outside the image space of f. This means the instance x = (V_M, \{y_i\}_{i \in \mathcal{P}_n}) is not in the language L specified by R to the contrary suppose x \in L. Then, there is some subset X' \subseteq \mathcal{P}_n such that (1) X' is in the language M defined by V_M, and (2) each y_i for i \in X' are in the image space of f. Since by assumption X \notin M, constraint (1) shows that X' is not a subset of X. However, constraint (2) and the fact that y_i for i \notin X are not images of f implies that X' must be a subset of X. Thus, we have reached a contradiction, showing that no such X' can exist.

Since x \notin L, then s_{i^*} = PRF(fk_{i^*}, x) is pseudorandom by the security of the witness PRF. However, D' breaks the pseudorandomness with probability \varepsilon - \text{neg}(\lambda). Therefore, this quantity, and hence \varepsilon must be negligible.

We have shown that the weakest variant of distributed secret sharing implies witness PRFs, which in turn imply the strongest variant of distributed secret sharing. Thus, all variants of DSS and witness PRFs are equivalent, completing the proof.

---

\[9\] A similar approach is used in the proof of Theorem 4.3.
4 Functional Secret Sharing

We start this section with a definition of functional secret sharing. Later, in Theorem 4.3, we show that general-purpose functional secret sharing is equivalent to indistinguishability obfuscation for polynomial-size circuits.

**Definition 4.1 (Functional secret sharing).** Let $\mathcal{F} = \{F: 2^P \rightarrow \{0,1\}^*\}$ be a class of functions. Let $M: 2^P \rightarrow \{0,1\}$ be an access structure corresponding to a language $L \in \text{mNP}$ and let $V_M$ be a verifier for $L$. A functional secret sharing scheme for $M$ and $\mathcal{F}$ consists of a setup procedure $\text{SETUP}$ and a reconstruction procedure $\text{RECON}$ that satisfy the following requirements:

1. **Completeness:** If $\text{RECON}(1^\lambda, \Pi(F, S, X), w)$ gets as input the shares of a “qualified” subset of parties and a valid witness, and outputs the value of $F$ on $X$ and the shared secret. Namely, for $X \subseteq P$ such that $M(X) = 1$ and any valid witness $w$ such that $V_M(X, w) = 1$, it holds that:
   \[
   \Pr \left[ \text{RECON}(1^\lambda, \Pi(F, S, X), w) = F(X, S) \right] = 1,
   \]
   where the probability is over the internal randomness of the scheme and of $\text{RECON}$.

2. **Indistinguishability of the Secret:** For every probabilistic polynomial-time algorithm $D$, every function $F \in \mathcal{F}$, every subset of parties $X \subseteq P$ and every pair of secrets $S_0, S_1$, as long as either $M(X) = 0$ or $F(X', S_0) = F(X', S_1)$ for every $X' \subseteq X$, there exists a negligible function $\text{neg}(\cdot)$ such that for $\lambda \in \mathbb{N}$ it holds that
   \[
   \left| \Pr \left[ D(1^\lambda, \Pi(F, S_b, X)) = b \right ] - \frac{1}{2} \right| \leq \text{neg}(\lambda),
   \]
   where the probability is over the internal randomness of the scheme, the internal randomness of $D$ and $b \leftarrow \{0,1\}$ chosen uniformly at random.

A remark on the condition in the security definition. We note that in Definition 4.1, given a set of shares $\Pi(F, S, X)$, it is possible to derive for any $X' \subseteq X$ the set of shares $\Pi(F, S', X')$ simply by removing the shares for parties not in $X'$. Feeding $\Pi(F, S, X')$ into $\text{RECON}$ then gives $F(X', S)$ for any $X' \subseteq X$. Thus, in the security definition above, the condition that $F(X', S_0) = F(X', S_1)$ for all $X' \subseteq X$ is required to have a satisfiable assumption. Our definition states that this is the only requirement.

**Two relaxations of Definition 4.1.** We remark that when the function $F$ is defined to be the identity function over its second input parameter (i.e., $F(\cdot, S) = S$) we get the definition of Rudich secret sharing for NP of [KNY14]\.\textsuperscript{10} Moreover, when $M = 2^P$ (i.e., the access structure includes

\textsuperscript{10}[KNY14] considered a uniform version of the above definition. We remark that our definitions from above can also be given in a uniform version and our results also apply to them (using ideas from [KNY14]). For simplicity, we focus on the non-uniform versions.
all subsets of parties), the secret $S$ is a description of a function and $F$ is the universal circuit (i.e., $F(X, S) = S(X)$), then Definition 4.1 boils down to the definition of function secret sharing which we formalize next.

Definition 4.2 (Function secret sharing). Let $\mathcal{F} = \{F : 2^P \rightarrow \{0, 1\}^*\}$ be a class of functions. A functional secret sharing scheme for $\mathcal{F}$ consists of a setup procedure $\textsc{Setup}$ and a reconstruction procedure $\textsc{Recon}$ that satisfy the following requirements:

1. $\textsc{Setup}(1^\lambda, F)$ gets as input a function $F \in \mathcal{F}$, and distributes a share for each party. For $i \in [n]$ denote by $\Pi(F, i)$ the random variable that corresponds to the share of party $p_i$. Furthermore, for $X \subseteq P_n$, we denote by $\Pi(F, X)$ the random variable that corresponds to the set of shares of parties in $X$.

2. Completeness: $\textsc{Recon}(1^\lambda, \Pi(F, X))$ gets as input the shares of some subset $X$ of parties, and outputs $F(X)$. More precisely,
   $$\Pr[\textsc{Recon}(1^\lambda, \Pi(F, X)) = F(X)] = 1,$$
   where the probability is over the internal randomness of the scheme and of $\textsc{Recon}$.

3. Indistinguishability of the function: For every probabilistic polynomial-time algorithm $D$, every equal size $F_0, F_1 \in \mathcal{F}$ and $X \subseteq 2^P$ such that $F_0(X') = F_1(X')$ for all $X' \subseteq X$, there exists a negligible function $\text{neg}(\cdot)$ such that for $\lambda \in \mathbb{N}$ it holds that
   $$\left| \Pr[D(1^\lambda, \Pi(F_b, X)) = b] - \frac{1}{2} \right| \leq \text{neg}(\lambda),$$
   where the probability is over the internal randomness of the scheme, the internal randomness of $D$ and $b \leftarrow \{0, 1\}$ chosen uniformly at random.

4.1 Functional Secret Sharing is Equivalent to iO

In this section we state and prove our main result.

Theorem 4.3. The following holds:

1. Function secret sharing (Definition 4.2) for polynomial-size circuits implies iO for polynomial-size circuits.

2. iO for polynomial-size circuits and one-way functions imply functional secret sharing (Definition 4.1) for access structures in $mNP$ and functions computed by polynomial-size circuits.

Recall that Definition 4.1 is a generalization of Definition 4.2. Thus, Theorem 4.3 implies that functional secret sharing is equivalent to function secret sharing and is equivalent to iO.\footnote{One of the directions requires one-way functions which can be relaxed to require a worst-case hardness assumption by [KMN+14].}

Next, we provide a proof for each of the items in Theorem 4.3 separately.
Proof of Item 1 in Theorem 4.3. Given a circuit $C$ with $n$ inputs the indistinguishability obfuscator works as follows. We first run the $\text{SETUP}(1^\lambda, C)$ procedure with the circuit $C$ as input and get back a list of $n$ shares $\Pi(C,1), \ldots, \Pi(C,n)$. The obfuscation consists of these $n$ shares. To evaluate an obfuscated circuit at a point $x \in \{0,1\}^n$, we run $\text{RECON}(1^\lambda, \Pi(C,x))$ and get a value $y$ that we output. By the correctness of the functional secret sharing scheme, we have that $y = C(x)$, as required.

To prove security consider two equal size functionally equivalent circuits $C_1$ and $C_2$ and an adversary $A$ that can distinguish their obfuscations with noticeable probability. Hence, $A$ can distinguish secret shares corresponding to $\text{SETUP}(1^\lambda, C_1)$ from secret shares corresponding to $\text{SETUP}(1^\lambda, C_2)$. Since the circuits are equal size and functionally equivalent, this is a contradiction to the security guarantee of the function secret sharing scheme.

Proof of Item 2 in Theorem 4.3. We start with the description of the functional secret sharing scheme. For every $i \in [n]$, the share of party $p_i$ is composed of 2 components: (1) $r_i \in \{0,1\}^\lambda$, an opening of a commitment to the value $i$, and (2) an obfuscated circuit $\text{io}(C)$. The circuit $C$ to be obfuscated has the following hardwired: the function $F$, the secret $S$ and the commitments of all parties (i.e., $c_i = \text{Com}(i, r_i)$ for $i \in [n]$). We stress that the openings $r_1, \ldots, r_n$ of the commitments are not hardwired into the circuit. The input to the circuit $C$ consists of alleged $k$ openings $r'_{i_1}, \ldots, r'_{i_k}$ corresponding to a set of parties $X \subseteq P_n$ denoted $p_{i_1}, \ldots, p_{i_k}$ where $k, i_1, \ldots, i_k \in [n]$ and an alleged witness $w$. The circuit $C$ first checks that the openings are valid, i.e., verifies that for every $j \in [k]$: $c_{i_j} = \text{Com}(i_j, r'_{i_j})$. Then, it verifies that the given $w$ is a valid witness, i.e., that $v_M(X, w) = 1$. If all the tests pass, $C$ outputs $F(X, S)$; otherwise, if any of the tests fail, the circuit $C$ outputs $\text{NUL}$. The secret sharing scheme is formally described next.

Let $\text{io}$ be an efficient indistinguishability obfuscator (see Definition 2.8). Let $\text{Com} : [2n] \times \{0,1\}^\lambda \rightarrow \{0,1\}^{q(\lambda)}$ be a string commitment scheme where $q(\cdot)$ is a polynomial (see Definition 2.4). Let $M \in \text{NP}$ be an access structure.

The $\text{SETUP}(S)$ procedure. Gets as input a secret $S$ and does the following:

1. For $i \in [n]$:  
   (a) Sample uniformly at random an opening $r_i \in \{0,1\}^\lambda$.  
   (b) Compute the commitment $c_i = \text{Com}(i, r_i)$.

2. Compute the circuit $C$ from Figure 1, where $C = C^{F,S,c_1,\ldots,c_n}$ has the secret $S$ and the list of commitments $c_1, \ldots, c_n$ hardwired.

3. Set the share of party $p_i$ to be $\Pi(S,i) = \langle r_i, \text{io}(C) \rangle$.

The $\text{RECON}(X,w)$ procedure. Gets as input a non-empty subset of parties $X \subseteq P_n$ together with their shares and a witness $w$ of $X$ for $M$.

1. Let $\text{io}(C)$ be the obfuscated circuit in the shares of $X$.

2. Evaluate the circuit $\text{io}(C)$ with the shares of $X$ and $w$ and return its output.
The Circuit $C^{F, S, c_1, \ldots, c_n}(r'_1, \ldots, r'_n, w)$

**Hardwired:** The function $F$, the secret $S$ and the commitments of all parties $c_1, \ldots, c_n$.

**Input:** The secret shares corresponding to a subset of parties $X$ and an alleged witness $w$. The secret shares are a sequence of $n$ values $r'_1, \ldots, r'_n \in \{0, 1\}^\lambda \cup \text{NUL}$ such that for any $i \in [n]$ if $p_i \in X$, then $r'_i$ is the alleged opening of party $p_i$, and otherwise $r'_i = \text{NUL}$.

**Algorithm:**

1. Execute the following tests:
   
   (a) For every $i \in [n]$ such that $r_i \neq \text{NUL}$, verify that the opening $r'_i$ is valid. That is, verify that $c_i = \text{Com}(i, r'_i)$.

   (b) Verify that the given alleged witness $w$ is a valid one. That is, verify that $V_M(X, w) = 1$.

2. If any of the above tests fails, output $\text{NUL}$; otherwise, output $F(X, S)$.

**Figure 1:** The circuit to be obfuscated as part of the secret shares.

Observe that if $iO$ and $\text{Com}$ are both probabilistic polynomial-time algorithms, then the scheme is efficient (i.e., $\text{SETUP}$ and $\text{RECON}$ are probabilistic polynomial-time algorithms). $\text{SETUP}$ generates $n$ commitments and an obfuscated circuit of polynomial-size. $\text{RECON}$ only evaluates this polynomial-size obfuscated circuit once.

**Security.** Fix two secrets $S_0, S_1$, a subset of parties $X$, and a function $F$ such that $F(X', S_0) = F(X', S_1)$ for every $X' \subseteq X$. The proof of security follows by a sequence of hybrid experiments.

**Experiment $\text{Exp}^{(1)}(\lambda)$:** This experiment corresponds to the original game in which each party gets a pair $(r_i, iO(C))$ of an opening and an obfuscated circuit $C = C^{S_b, c_1, \ldots, c_n}$ has the secret $S_b$ and the list of commitments $c_1, \ldots, c_n$ hardwired.

**Experiment $\text{Exp}^{(2)}(\lambda)$:** This experiment is obtained from the experiment $\text{Exp}^{(1)}(\lambda)$ by modifying the share of each party as follows. Denote by $p_{i_1}, \ldots, p_{i_k}$ the parties that the adversary chooses to open their shares. Each party gets the obfuscation of a different circuit $C' = C^{F, S_b, z_1, \ldots, z_n}$ that has the secret $S_b$ and the list of commitments $z_1, \ldots, z_n$ hardwired, where $z_i = c_i$ if $i \in \{i_1, \ldots, i_k\}$ and $z_i = \text{Com}(n + i, r_i)$ for $r_i \leftarrow \{0, 1\}^\lambda$ otherwise.

The hiding property of the commitment scheme guarantees that an adversary cannot distinguish experiments $\text{Exp}^{(1)}$ and $\text{Exp}^{(2)}$. This statement crucially relies on the fact that we changed the hardwired commitments corresponding to parties the adversary does not have the shares of.

**Claim 4.4.** There exists an adversary $B$ such that

$$\Pr[\text{Exp}^{(1)}(\lambda)] - \Pr[\text{Exp}^{(2)}(\lambda)] \leq \text{neg}(\lambda).$$

**Proof.** The proof follows immediately from the observation that for any computationally hiding commitment scheme $\text{Com} : [2k] \times \{0, 1\}^\lambda \rightarrow \{0, 1\}^{q(\lambda)}$, where $q(\cdot)$ is a polynomial, for any distinguisher $D$ it holds that

$$\Pr[D(\text{Com}(1, U_\lambda), \ldots, \text{Com}(k, U_\lambda)) = 1] - \Pr[D(\text{Com}(k + 1, U_\lambda), \ldots, \text{Com}(2k, U_\lambda)) = 1] \leq k \cdot \text{Adv}^{\text{COM}}_{D, \text{Com}}.$$
Equation (4.1) can be proved by a simple hybrid argument; see [KNY14, Lemma 4.2].

Now, the claim follows since the only difference between the two hybrids is in commitments corresponding to parties the adversary does not know the opening of. For every \( i \in \{i_1, \ldots, i_k\} \), we have that \( z_i \) is distributed as \( c_i \). For the rest, namely \( i \notin \{i_1, \ldots, i_k\} \), \( z_i \) is distributed as \( \text{Com}(n + i, \mathbf{U}_\lambda) \). Thus, Equation (4.1) and the hiding property of the commitment ensure that an adversary can tell the difference with probability at most \( k \cdot \text{neg}(\lambda) \leq \text{neg}(\lambda) \).

**Experiment Exp\(^{(3)}\)(\(\lambda\)).** This experiment is obtained from the experiment \( \text{Exp}\(^{(2)}\)(\(\lambda\)) \) by modifying the share of each party so that instead of giving the obfuscation of the circuit \( C' \), we do the following:

1. If \( M(X) = 1 \), then each party gets the obfuscation of the circuit \( C'' = C^{F, S_0, z_1, \ldots, z_n} \). Notice that since \( F(X', S_0) = F(X', S_1) \) for every \( X' \subseteq X \), we have that \( C' \equiv C'' \).

2. If \( M(X) = 0 \), then each party gets the obfuscation of the zero circuit of the appropriate size denoted by \( Z \). Notice that by monotonicity of \( M \), we have that \( C' \equiv Z \).

Thus, in both cases the security of iO guarantees that experiments \( \text{Exp}\(^{(2)}\) \) and \( \text{Exp}\(^{(3)}\) \) are indistinguishable. Namely, we have the following claim.

**Claim 4.5.**

\[
\Pr[\text{Exp}\(^{(2)}\)(\(\lambda\))] - \Pr[\text{Exp}\(^{(3)}\)(\(\lambda\))] \leq \text{neg}(\lambda).
\]

Moreover, notice that in both cases this experiment is completely independent of the bit \( b \), and therefore \( \Pr[\text{Exp}\(^{(3)}\)(\(\lambda\)) = 1] = 1/2 \).

Finally, putting together Claims 4.4 and 4.5, and using the fact that \( \Pr[\text{Exp}\(^{(3)}\)(\(\lambda\)) = 1] = 1/2 \), we observe that there exists a negligible function \( \text{neg}(\cdot) \) such that

\[
\left| \Pr \left[ \text{Exp}\(^{(1)}\)(\(\lambda\)) = 1 \right] - \frac{1}{2} \right| \leq \text{neg}(\lambda).
\]

Recall that \( \text{Exp}\(^{(1)}\)(\(\lambda\)) \) corresponds to the original game which completes the proof.
