On the tightness of the error bound in Ring-LWE

W. Castryck, I. Iliashenko and F. Vercauteren

Abstract

Since its introduction in 2010 by Lyubashevsky, Peikert and Regev, the Ring Learning With Errors problem (Ring-LWE) has been widely used as a building block for cryptographic primitives, due to its great versatility and its hardness proof consisting of a (quantum) reduction to ideal lattice problems. This reduction assumes a lower bound on the width of the error distribution that is often violated in practice. In this paper we show that caution is needed when doing so, by providing for any $\varepsilon > 0$, a family of number fields $K$ of increasing degree $n$ for which Ring-LWE can be broken easily as soon as the errors required by the reduction are scaled down by $|\Delta_K|^{\varepsilon/n}$ with $\Delta_K$ the discriminant of $K$.

1. The Ring-LWE problem

About a decade ago Regev [18] proposed a new hard problem for use in public-key cryptography, namely the learning with errors problem (LWE), which informally stated is about solving an approximate linear system

$$A \cdot \begin{pmatrix} s_1 \\ s_2 \\ \vdots \\ s_n \end{pmatrix} \approx \begin{pmatrix} b_1 \\ b_2 \\ \vdots \\ b_m \end{pmatrix}$$

for an unknown secret $s = (s_1, s_2, \ldots, s_n)$ over $\mathbb{Z}/q\mathbb{Z}$, with $q$ some integer modulus. The entries of $A$ have been selected independently and uniformly at random and the $b_i$'s carry small error terms, obtained by sampling from a fixed Gaussian centered around 0 and reducing the outcome mod $q$. These errors are elements of $\mathbb{R}/q\mathbb{Z}$, but in practice they are rounded to the nearest element of $\mathbb{Z}/q\mathbb{Z}$. To recover $s$ uniquely, the system has to be overdetermined, i.e. $m > n$. In fact in Regev’s model an attacker is allowed to ask for new equations indefinitely, in the hope of gradually unveiling $s$: hence the terminology learning with errors.

The LWE problem is being acclaimed for three reasons. Firstly it enjoys a ‘hardness proof’ in the form of a reduction to worst-case instances of certain well-established lattice problems [2, 17, 18], providing security guarantees that are lacking for classical hard problems such as integer factorization or discrete logarithm computation. Secondly, it seems that LWE would remain hard in a post-quantum world, unlike the classical problems [19]. Thirdly, LWE has proven to be very versatile for use in cryptography, enabling applications that were impossible before, such as homomorphic encryption [1, 3]. Its major drawback however is that the key sizes of the resulting cryptosystems are impractically large: typically one needs the entire $(m \times n)$-matrix $A$.

One idea to address this [3, 16] is to endow $(\mathbb{Z}/q\mathbb{Z})^n$ with a ring structure, for instance by identifying it with $\mathbb{Z}[x]/(q, f)$ for some monic degree $n$ polynomial $f \in \mathbb{Z}[x]$ (using the

2000 Mathematics Subject Classification 11T71(primary), 11R04, 11R11, 11R18, 11T22(secondary).

polynomial basis $1, x, x^2, \ldots, x^{n-1}$), and to replace $A$ by the matrix $A_a$ of multiplication by some ring element $a$. This is often referred to as Polynomial-LWE. By storing $a$ rather than $A_a$ one gains a factor $n$, thereby addressing the key size issue. But restricting to multiplication matrices comes at the cost of giving up on the randomness, thereby invalidating the mentioned hardness proof, and in fact it is possible to cook up instances of the problem having certain flaws [11, 14].

In [16] Lyubashevsky, Peikert and Regev tweaked this idea in a remarkable way by introducing Ring-LWE. To start with, one fixes a degree $n$ number field $K$ with ring of integers $R = \mathcal{O}_K$, and as before one chooses an integral modulus $q$. The central role is played by the codifferent $R^\vee$ of $K$, which is defined as the inverse (fractional) ideal of the different ideal $\partial \subset R$. Alternatively it can be viewed as the dual of $R$ with respect to the trace pairing:

$$R^\vee = \{ x \in K \mid \text{Tr}_{K/Q}(xR) \subset \mathbb{Z} \}. \quad (1.1)$$

The reductions of $R$ and $R^\vee$ modulo $q$ are denoted by $R_q$ and $R_q^\vee$, respectively. The Ring-LWE problem is then about guessing a secret $s \in R_q^\vee$ from an arbitrary number of approximate equations of the form

$$a \cdot s \approx b, \quad (1.2)$$

where $a \in R_q$ is chosen uniformly at random and $b$ is known to carry a small error term $e$ (that is, $b = a \cdot s + e$) sampled from a distribution that we will discuss in the next paragraph. After agreeing upon a $\mathbb{Z}$-basis of $R^\vee$ this can be rewritten as

$$A_a \cdot \begin{pmatrix} s_1 \\ s_2 \\ \vdots \\ s_n \end{pmatrix} \approx \begin{pmatrix} b_1 \\ b_2 \\ \vdots \\ b_m \end{pmatrix},$$

where the $s_i$ are the coordinates of $s$, the $b_i$ are the coordinates of $b$, and $A_a$ is the matrix of multiplication by $a$ with respect to the chosen $\mathbb{Z}$-basis, all considered modulo $q$.

In analogy with LWE and Polynomial-LWE one might want each $b_i$ to carry an error that was sampled independently from the same univariate Gaussian distribution. But that property depends on the chosen basis, and Lyubashevsky et al. opted for a more intrinsic distribution using the canonical embedding

$$\sigma : K \to \mathbb{C}^n : \alpha \mapsto (\sigma_1(\alpha), \ldots, \sigma_n(\alpha)),$$

where $\sigma_1, \ldots, \sigma_s$ are the real monomorphisms from $K$ to $\mathbb{R}$ and $\sigma_{s+1}, \ldots, \sigma_{s+2t}$ are the complex monomorphisms from $K$ to $\mathbb{C}$ (so that $n = s + 2t$), ordered such that $\sigma_{s+i} = \tau \circ \sigma_{s+t+i}$ for $i = 1, \ldots, t$, where $\tau : \mathbb{C} \to \mathbb{C} : z \mapsto \bar{z}$ denotes complex conjugation. Thus $\sigma$ takes values in

$$H = \{ (z_1, \ldots, z_n) \in \mathbb{C}^n \mid z_1, \ldots, z_s \in \mathbb{R} \text{ and } \bar{z}_{s+i} = z_{s+t+i} \text{ for } i = 1, \ldots, t \},$$

which when equipped with the Hermitian inner product $\langle \cdot, \cdot \rangle$ is seen to be isomorphic to the standard inner product space $\mathbb{R}^n$, by considering the basis given by the columns of the unitary matrix

$$B = \begin{pmatrix} I_{s \times s} & 0 & 0 \\ 0 & \frac{1}{\sqrt{2}} I_{t \times t} & \frac{1}{\sqrt{2}} I_{t \times t} \\ 0 & \frac{1}{\sqrt{2}} I_{t \times t} & -\frac{1}{\sqrt{2}} I_{t \times t} \end{pmatrix}.$$ 

It is well-known that under this identification of $H$ with $\mathbb{R}^n$, the image $\sigma(I)$ of a fractional ideal $I \subset K$ is a lattice of rank $n$, and that $\sigma(R^\vee)$ is the complex conjugate of the dual lattice

$$\sigma(R)^* := \{ \alpha \in H \mid \langle \alpha, \sigma(R) \rangle \subset \mathbb{Z} \},$$
as is immediate from (1.1); more generally $\sigma(I)^* = \tau(\sigma(I'))$ where $I' = (\partial I)^{-1}$. Now consider a spherical Gaussian on $\mathbb{R}^n$, say with distribution function
\[
\Gamma^r_n(x) = \frac{1}{r^n} \exp\left(-\frac{\|x\|^2}{2r^2}\right),
\]
where we note that $\Gamma^r_1$ is a univariate Gaussian distribution with mean 0 and standard deviation $r/\sqrt{2\pi}$, and that
\[
\Gamma^r_n = \Gamma^r_1 \times \Gamma^r_1 \times \cdots \times \Gamma^r_1.
\]
We view $\Gamma^r_n$ as a distribution on $H$ through the above identification with $\mathbb{R}^n$. Pulling it back along the canonical embedding and wrapping it mod $q$, as is immediate from (1.1); more generally $\sigma$ results in a distribution $\Psi_r$ on the torus
\[
(R^\vee \otimes_{\mathbb{Z}} \mathbb{R})/qR^\vee,
\]
from which the errors are to be sampled. This distribution lies at the heart of Ring-LWE. As with LWE, in practice one of course rounds the errors to $R/\sqrt{2\pi}$, but for analytical reasons it is convenient not to do this.

In order to formulate Ring-LWE more formally, let $\mathcal{U}(R_q)$ and $\mathcal{U}(R'_q)$ denote the uniform distributions on $R_q$ and $R'_q$, respectively. For $s \in R'_q$ and $r \in \mathbb{R}_{>0}$ we let $A_{s,r}$ be the distribution over
\[
R_q \times (R'_q \otimes_{\mathbb{Z}} \mathbb{R})/qR^\vee
\]
obtained by sampling $a \leftarrow \mathcal{U}(R_q)$, $e \leftarrow \Psi_r$ and returning $(a, a \cdot s + e)$.

**Definition 1** (Ring-LWE). For a random but fixed choice of $s \leftarrow \mathcal{U}(R'_q)$ the (search) Ring-LWE problem is to recover $s$ with non-negligible probability from arbitrarily many independent samples from $A_{s,r}$.

In their seminal paper [16] Lyubashevsky, Peikert and Regev proved the following hardness result on Ring-LWE. For proof-technical reasons, they actually deal with a slight variant called the Ring-LWE$_{\leq r}$ problem. In this problem each sample is taken from $A_{s(x),r}$ for a new choice of $r$ which is chosen uniformly at random from $\{r_1, \ldots, r_n\} \in (\mathbb{R}^+)^n \mid r_i \leq r$ for all $i$. The distribution $A_{s(x),r}$ is defined in exactly the same way as $A_{s(x),r}$, except that the spherical Gaussian $\Gamma^r_n$ is to be replaced by the elliptical Gaussian $\Gamma^r_{r_1} \times \Gamma^r_{r_2} \times \cdots \times \Gamma^r_{r_n}$. Let $\omega$ denote any superlinear function and think of the error width $r$ and the modulus $q \geq 2$ as quantities that vary with $n$. Then the hardness result [16, Theorem 4.1] reads:

**Theorem 1.1.** If $r \geq 2\omega(\sqrt{\log n})$ then for some negligible $\varepsilon$ (depending on $n$) there is a probabilistic polynomial-time quantum reduction from DGS$_\gamma$ to Ring-LWE$_{\leq r}$, where

\[
\gamma : I \mapsto \max \left\{ \eta_\varepsilon(\varepsilon) \cdot (\sqrt{2q/r}) \cdot \omega(\sqrt{\log n}) \cdot \sqrt{2n}/\lambda_1(I') \right\}.
\]

Here $\eta_\varepsilon(I)$ is the smoothing parameter of $\sigma(I)$ with threshold $\varepsilon$, and $\lambda_1(I')$ is the length of a shortest vector of $\sigma(I')$.

The statement involves the discrete Gaussian sampling problem DGS$_\gamma$, which is about producing samples from a spherical Gaussian in $H$ with parameter $r'$, discretized to the lattice $\sigma(I)$, for any given non-zero ideal $I \subset R$ and any $r' \geq \gamma(I)$. As discussed in [16] there are easy reductions from standard lattice problems to the discrete Gaussian sampling problem. As an intermediate step in their proof Lyubashevsky et al. obtain a classical (i.e. non-quantum) reduction from an instance of the bounded distance decoding problem in ideal lattices to Ring-LWE$_{\leq r}$; see [16, Lem. 4.5].
Thus from a discriminant point of view the bound $r_1$ main result in this article. A more precise formulation is as follows. An observation also applies to the actual (i.e., dual) Ring-LWE problem: one cannot scale down the error parameter $r$.

We refer to [16, §3.3] for a discussion motivating these choices, but note that in the recent literature there has been some temptation to pick the secret from the smaller space $R_q$ instead, for reasons of mathematical convenience. However, it is clear that one cannot expect the direct analogue of Theorem 1.1 to hold in this case. Indeed, because now the lattice $\sigma(R)$ may be very ‘sparse’ one should scale up the error parameter by a factor related to the covolume of $\sigma(R)$, which is $\sqrt{\Delta}$ where $\Delta = \Delta_K$ is the discriminant of $K$. As we will explain below, from the Ring-LWE point of view the natural choice of scaling factor is $|\Delta|^{1/n}$. For this choice we are unaware of classes of number fields for which the resulting non-dual Ring-LWE problem is easily solved (see [10] for a related discussion). But there is also a more aggressive Polynomial-LWE point of view, employed in [5, 6, 12] for instance, where one only scales up by the square root $|\Delta|^{1/2n}$.

We show that the latter choice may be problematic and that it may even be insufficient to scale up by $|\Delta|^{(1-\varepsilon)/n}$ for whatever fixed choice of $\varepsilon > 0$. In fact more interestingly, this observation also applies to the actual (i.e., dual) Ring-LWE problem: one cannot scale down the error parameter $r$ in the statement of Theorem 1.1 by $|\Delta|^{\varepsilon/n}$ without invalidating it. Thus from a discriminant point of view the bound $r \geq 2\omega(\sqrt{\log n})$ is optimal, which is our main result in this article. A more precise formulation is as follows.

**Theorem 1.2.** Let $\rho : \mathbb{N} \to \mathbb{R}_{>0}$ be in poly($n$), let $(q_n)_{n \in \mathbb{N}}$ be any sequence of integer moduli, and let $\varepsilon \in \mathbb{R}_{>0}$ be fixed. Then there exists a family of number fields $(K_\ell)_{\ell \in \mathbb{N}}$ such that the following properties are satisfied:

- Each $K_\ell$ is Galois over $\mathbb{Q}$.
- The degree $n_\ell := [K_\ell : \mathbb{Q}]$ tends to infinity as $\ell$ does.
- The Ring-LWE problem in $K_\ell$ using error parameter $r = \rho(n_\ell)/|\Delta_{K_\ell}|^{\varepsilon/n_\ell}$ and modulus $q_{n_\ell}$ can be solved in time poly($n_\ell \cdot \log q_{n_\ell}$) using $O(n_\ell)$ samples.

Moreover, the same statement is true for non-dual Ring-LWE, upon replacement of the error parameter $r = \rho(n_\ell)/|\Delta_{K_\ell}|^{\varepsilon/n_\ell}$ by $r = \rho(n_\ell) \cdot |\Delta_{K_\ell}|^{(1-\varepsilon)/n_\ell}$.

The fields $K_\ell$ are constructed in such a way that the canonical embedding is extremely skew, which together with the fact that the errors were scaled down leads to certain linear equations in the secret $s$ that carry negligible errors. Thus by rounding one obtains exact linear equations, and the secret can be recovered using elementary linear algebra over $\mathbb{Z}/q_{n_\ell}\mathbb{Z}$. This was also the observation behind [4], where in response to [12] we analyzed number fields defined by polynomials of the form $x^n + ax + b$. But the treatment given there was ad hoc, devoted to three concrete instantiations, and, moreover, number fields of the form $\mathbb{Q}[x]/(x^n + ax + b)$ are usually not Galois, which makes them less attractive (or at least less understood) from the Ring-LWE point of view. For instance it is known that in the Galois case the search version of Ring-LWE, as stated in Definition 1, is essentially equivalent to its decision version (which we did not state here); see [5, 11, 16].
2. Dual versus non-dual Ring-LWE

To allow for a comparison between dual and non-dual Ring-LWE we restrict our discussion to number fields \( K \) for which the different ideal \( \theta \) is principal, say generated by \( \theta \in R \), so that \( R' = R/\theta \). For instance this holds if \( K \) is monogenic, meaning that the ring of integers \( R \) is of the form \( \mathbb{Z}[x]/(f) \), in which case one can take \( \theta = f(x) \). More generally \( \theta \) is principal if and only if \( R \) is a so-called complete intersection, i.e. of the form \( \mathbb{Z}[x_1,x_2,\ldots,x_n]/(f_1,f_2,\ldots,f_n) \), in which case one can take \( \theta = [(\partial f_1/\partial x_j),\ldots] \); see [9].

Without loss of generality we can rewrite our sample (1.2) as

\[
a \cdot \frac{s}{\theta} \approx \frac{b}{\theta},
\]

where now \( s \in R_q \) and \( b/\theta = a \cdot s/\theta + e \) with \( e \) sampled from \( \Psi_r \). Multiplying by \( \theta \) then gives \( b = a \cdot s + \theta \cdot e \). This way of rewriting Ring-LWE samples in terms of \( \theta \) reads

\[
\begin{pmatrix}
  b_1 \\
  b_2 \\
  \vdots \\
  b_n 
\end{pmatrix} = A_{\theta} \cdot \begin{pmatrix}
  s_1 \\
  s_2 \\
  \vdots \\
  s_n 
\end{pmatrix} + A_{\theta} \cdot M^{-1} \cdot B \cdot \begin{pmatrix}
  e_1 \\
  e_2 \\
  \vdots \\
  e_n 
\end{pmatrix},
\]

(2.1)

where the \( s_i \) are the coordinates of \( s \), the \( b_i \) are the coordinates of \( b \), \( A_{\theta} \) is the matrix of multiplication by \( a \), \( A_{\theta} \) is the matrix of multiplication by \( \theta \), and \( M \) is the matrix of the canonical embedding \( \sigma \), all expressed with respect to the basis \( \alpha_1,\alpha_2,\ldots,\alpha_n \) and considered modulo \( q \). The \( e_i \) are sampled independently from the univariate Gaussian \( \Gamma_{\sigma} \). Note that on average the factor \( A_{\theta} \cdot M^{-1} \cdot B \) causes the errors to expand, because \( |\det A_{\theta}| = \Delta \) and \( |\det M| = \sqrt{\Delta} \); see [13]. Recall that \( B \) is unitary, so \( |\det B| = 1 \).

In the non-dual Ring-LWE version where the secret is taken directly from \( R \), the multiplication-by-\( \theta \) step is left out. But as we remarked in the previous section, merely removing \( A_{\theta} \) leaves us with \( M^{-1} \cdot B \) which causes the errors to shrink on average by a factor \( \mathrm{covol}(\sigma(R)) = |\det M| = \sqrt{\Delta} \). So for a given choice of \( r \), which in view of Theorem 1.1 we prefer to think of as depending on \( n \) only, it is straightforward to find number fields \( K \) for which several errors become negligible, resulting in exact equations in the secret \( s \) that can be solved using linear algebra: just let \( K \) have a huge discriminant. In order to fix this one should scale up the errors.

In view of (2.1) the natural choice of scalar would be \( |\det A_{\theta}|^{1/n} = |\Delta|^{1/n} \):

\[
\begin{pmatrix}
  b_1 \\
  b_2 \\
  \vdots \\
  b_n 
\end{pmatrix} = A_n \cdot \begin{pmatrix}
  s_1 \\
  s_2 \\
  \vdots \\
  s_n 
\end{pmatrix} + |\Delta|^{1/n} \cdot M^{-1} \cdot B \cdot \begin{pmatrix}
  e_1 \\
  e_2 \\
  \vdots \\
  e_n 
\end{pmatrix},
\]

(2.2)

This compensates at least determinant-wise for the removal of \( A_{\theta} \). Equivalently, one can also just sample the errors \( e_i \) from \( \Gamma_{|\Delta|^{1/n}} \). If \( A_{\theta} \) happens to be a scalar matrix itself then (2.1) and (2.2) are of course equivalent. For instance this is the case if \( K \) is the \( 2^m \)-th cyclotomic field for some \( m \geq 2 \), where one can take \( \theta = 2^{m-1} = n \).

Note that switching to another basis of \( R \) boils down to multiplying both sides of (2.1) and (2.2) from the left by the same element of \( \mathrm{GL}_n(\mathbb{Z}) \), and similarly for taking another generator \( \theta \) of \( \theta \). Thus the resulting equations in \( s \) are equivalent.

**Example 1.** To illustrate these different flavors of Ring-LWE, we analyze a simple example that will act as one of the building blocks in our main theorem. Let \( d \equiv 1 \mod 4 \) be a positive squarefree integer and consider the real quadratic field \( K = \mathbb{Q}(\sqrt{d}) \). It has discriminant \( d \) and
its ring of integers $R = \mathbb{Z}[(1 + \sqrt{d})/2]$ admits the integral basis $1, (1 + \sqrt{d})/2$. The different ideal $\partial$ is the principal ideal generated by $\theta = \sqrt{d}$. With respect to this basis one has

$$A_\theta = \begin{pmatrix} -1 & -1+d/2 \\ 2 & 1 \end{pmatrix}, \quad M^{-1} = \frac{1}{\sqrt{d}} \begin{pmatrix} -1+\sqrt{d}/2 & 1+\sqrt{d}/2 \\ 1 & -1 \end{pmatrix}, \quad B = I_{2 \times 2}. \quad \square$$

So a Ring-LWE sample reads

$$\begin{pmatrix} b_1 \\ b_2 \end{pmatrix} = A_\theta \cdot \begin{pmatrix} s_1 \\ s_2 \end{pmatrix} + A_\theta \cdot M^{-1} \cdot \begin{pmatrix} e_1 \\ e_2 \end{pmatrix} = A_\theta \cdot \begin{pmatrix} s_1 \\ s_2 \end{pmatrix} + \begin{pmatrix} -1+\sqrt{d}/2 \\ 1 \end{pmatrix} \cdot \begin{pmatrix} e_1 \\ e_2 \end{pmatrix},$$

while a non-dual Ring-LWE sample with scaling factor $|\Delta|^{1/n}$ reads

$$\begin{pmatrix} b_1 \\ b_2 \end{pmatrix} = A_\theta \cdot \begin{pmatrix} s_1 \\ s_2 \end{pmatrix} + \sqrt{d} \cdot M^{-1} \cdot \begin{pmatrix} e_1 \\ e_2 \end{pmatrix} = A_\theta \cdot \begin{pmatrix} s_1 \\ s_2 \end{pmatrix} + \begin{pmatrix} -1+\sqrt{d}/2 \\ 1 \end{pmatrix} \cdot \begin{pmatrix} e_1 \\ e_2 \end{pmatrix}.$$

We will refer to this example in the next section.

Let us also compare with the Polynomial-LWE approach where one considers (2.1) with the entire matrix product $A_\theta \cdot M^{-1} \cdot B$ replaced by a scalar. Note that unlike the previous variants, the resulting problem is no longer invariant under basis change. In view of the foregoing discussion the most natural choice of scalar would be $|\det A_\theta \cdot M^{-1}|^{1/n} = |\Delta|^{1/2n}$:

$$\begin{pmatrix} b_1 \\ b_2 \\ \vdots \\ b_n \end{pmatrix} = A_\theta \cdot \begin{pmatrix} s_1 \\ s_2 \\ \vdots \\ s_n \end{pmatrix} + \sqrt{|\Delta|^{1/n}} \cdot \begin{pmatrix} e_1 \\ e_2 \\ \vdots \\ e_n \end{pmatrix}. \quad (2.3)$$

This appears to be conservative when compared to cryptographic practice, where one often simply removes the scalar and lets the errors depend on $n$ only. This may be motivated by the error bound in Regev’s original work on LWE [18] where there is no number field into play (see Remark 1), and by NTRU where the errors are even taken constant. Taking small errors has some advantages towards the efficiency of the resulting cryptosystems, but the security risks of doing so are not fully understood.

Nevertheless, this could tempt one into making similarly aggressive choices for (dual or non-dual) Ring-LWE. The analogue of removing the scalar in (2.3) would be to scale down the errors in (2.1) and (2.2) by $|\Delta|^{1/2n}$, as is done in [5, 6, 12]. But as announced in the previous section, we will show that even scaling down by $|\Delta|^\varepsilon/n$ for whatever fixed choice of $\varepsilon > 0$ leads to weak instances of (dual and non-dual) Ring-LWE.

**Remark 2.** We certainly do not claim that all number fields become vulnerable after scaling down the errors: the fields $K_\ell$ that will be constructed in the next section are very special. In particular our findings do not seem to apply to cyclotomic number fields, which are the main candidates for making their way to daily-life cryptography. Furthermore, for the conservative choices of scalars made in (2.2) and (2.3) we are unaware of number fields for which the non-dual Ring-LWE problem resp. the Polynomial-LWE problem is weak, even though these problems are not backed-up by a hardness statement of the kind of Theorem 1.1. It is an interesting open problem to show that the scalars in (2.2) and (2.3) are sufficient to obtain an equivalent hardness result.
3. Proof of the main theorem

Proof of Theorem 1.2: Fix an \( \ell \geq 2 \) and pick prime numbers \( p_1, \ldots, p_\ell \) congruent to 1 mod 4 such that

\[
m_\ell := p_1p_2 \cdots p_\ell \geq \frac{1}{\log(\varepsilon/2)} \cdot \log(2\sqrt{n_\ell} \rho(n_\ell) \sqrt{\log n_\ell}).
\]

(3.1)

For each \( p_i \) consider the corresponding quadratic field \( K_{\ell,i} = \mathbb{Q}(\sqrt{p_i}) \). It has discriminant \( p_i \) and ring of integers \( R_{\ell,i} = \mathbb{Z}[(1 + \sqrt{p_i})/2] \), which we equip with the basis \( \alpha_{i,1} = 1 \), \( \alpha_{i,2} = (1 + \sqrt{p_i})/2 \). We will analyze Ring-LWE in the field compositum

\[
\prod_{i=1}^\ell K_{\ell,i} \cong \prod_{i=1}^\ell K_{\ell,1} \otimes_{\mathbb{Q}} K_{\ell,2} \otimes_{\mathbb{Q}} \cdots \otimes_{\mathbb{Q}} K_{\ell,\ell},
\]

which is clearly of degree \( n_\ell := 2^\ell \). Because the discriminants \( p_i \) of \( \mathbb{Q}(\sqrt{p_i}) \) are mutually coprime this tensor structure carries over to the integral elements \([20, \text{Thm. 2.6}]\), i.e. the ring \( R_\ell \) of integers in \( K_\ell \) reads

\[
R_\ell = \mathbb{Z}[(1 + \sqrt{p_1})/2, (1 + \sqrt{p_2})/2, \ldots, (1 + \sqrt{p_\ell})/2] \cong R_{\ell,1} \otimes_{\mathbb{Z}} R_{\ell,2} \otimes_{\mathbb{Z}} \cdots \otimes_{\mathbb{Z}} R_{\ell,\ell}.
\]

Please do not confuse this notation with our previous notation \( R_q \) for the reduction of \( R \) mod \( q \) (in fact the modulus will not play an important role in the proof). Note that \( R_\ell \) is a complete intersection, so the different ideal \( \partial_\ell \subset R_\ell \) is generated by \( \theta_\ell = \sqrt{p_1} \sqrt{p_2} \cdots \sqrt{p_\ell} = \sqrt{m_\ell} \). Therefore the codifferent reads

\[
R_\ell^\vee = \frac{1}{\sqrt{m_\ell}} \mathbb{Z}[(1 + \sqrt{p_1})/2, (1 + \sqrt{p_2})/2, \ldots, (1 + \sqrt{p_\ell})/2] \cong R_{\ell,1}^\vee \otimes_{\mathbb{Z}} R_{\ell,2}^\vee \otimes_{\mathbb{Z}} \cdots \otimes_{\mathbb{Z}} R_{\ell,\ell}^\vee,
\]

i.e. it is again naturally compatible with the tensor structure of \( K_\ell \).

Towards breaking Ring-LWE we assume that the samples are expressed with respect to the product basis

\[
\{ \alpha_{1,i_1} \alpha_{2,i_2} \cdots \alpha_{\ell,i_\ell} \}_{i_1, i_2, \ldots, i_\ell},
\]

where \( \ell \) abbreviates \( (i_1, i_2, \ldots, i_\ell) \). With respect to this basis a Ring-LWE sample reads:

\[
(b_i)_i \equiv A_{\mathbf{a}} \cdot (s_i)_i + A_{\theta_\ell} \cdot M^{-1} \cdot (e_i)_i.
\]

(3.3)

Here \( A_{\mathbf{a}} \) and \( A_{\theta_\ell} \) are the matrices of multiplication by \( \mathbf{a} \) resp. \( \theta_\ell = \sqrt{m_\ell} \) and \( M^{-1} \) is the canonical embedding matrix. The \( e_i \)'s are sampled independently from \( \Gamma_{\ell} \) with \( r = \rho(n_\ell)/|\Delta_K|^{\varepsilon/n_\ell} \), and the whole expression is considered modulo \( q_{n_\ell} \). Note that \( B = I_{n_\ell \times n_\ell} \) can be left out because \( K_\ell \) is totally real.

Because we work with respect to the product basis, the matrix \( A_{\theta_\ell} \cdot M^{-1} \) arises as the Kronecker product of the corresponding matrices \( K_{\ell,i,i} \), which by Example 1 are given by

\[
\begin{pmatrix}
-1 + \sqrt{2} & -1 - \sqrt{2} \\
1 & 1
\end{pmatrix}.
\]

Note that

\[
\begin{pmatrix}
0 & 1
\end{pmatrix} \cdot \begin{pmatrix}
-1 + \sqrt{2} & -1 - \sqrt{2} \\
1 & 1
\end{pmatrix} = \begin{pmatrix}
1 & 1
\end{pmatrix},
\]

(3.4)

so through the Kronecker product we find that

\[
\begin{pmatrix}
0 & 0 & \ldots & 1
\end{pmatrix} \cdot A_{\theta_\ell} \cdot M^{-1} = \begin{pmatrix}
1 & 1 & \ldots & 1
\end{pmatrix},
\]

where the row vector on the left has 0's everywhere, except at index \( \ell = (2, 2, \ldots, 2) \) where it has a 1.

Thus given a Ring-LWE sample (3.3), we can multiply both sides from the left by the row vector \( (0 \ 0 \ \ldots \ 1) \) in order to end up with a single linear equation in the secret \( \mathbf{s} = (s_i)_i \),
perturbed by an error of the form
\[
\begin{pmatrix}
1 & 1 & \ldots & 1
\end{pmatrix}
\cdot (e_{t})^T,
\]
which behaves as if it were sampled from a univariate Gaussian \( \Gamma_{1/\sqrt{\log n}} \), with \( r' = \sqrt{n_{\ell}} \cdot r \). Now our primes \( p_{i} \) have been chosen in such a way that this error is most likely negligible. More precisely, our bound (3.1) on \( m_{\ell} \) implies that
\[
r' = \frac{\sqrt{n_{\ell}} \cdot \rho(n_{\ell})}{|\Delta_{K}|^{1/\eta_{\ell}}} \leq \frac{1}{2\sqrt{\log n_{\ell}}},
\]
whose absolute value is less than \( 1/2 \) with overwhelming probability, so a mere rounding results in an exact linear equation in the secret. In fact by the lemma below, with very high probability we can successfully repeat this during \( n_{\ell} \) consecutive rounds, to end up with an exact linear system of \( n_{\ell} \) equations in the \( n_{\ell} \) unknowns \( s_{\ell} \). This system is likely to have full rank (if not we can simply query a few more samples), so that the secret can be recovered using standard linear algebra over \( \mathbb{Z}/q_{n_{\ell}}\mathbb{Z} \). This concludes the proof in the case of dual Ring-LWE.

To obtain the analogous result for non-dual Ring-LWE using scaling factor \( |\Delta_{K}|^{1/\mathbb{Z} \mathbb{Q}_{n_{\ell}}} \), one repeats the foregoing reasoning with \( A_{\theta_{\ell}} \cdot M^{-1} \) replaced by \( |\Delta_{K}|^{1/\mathbb{Z} \mathbb{Q}_{n_{\ell}}} \cdot M^{-1} \). The analogue of (3.4) reads
\[
\begin{pmatrix}
0 & 1
\end{pmatrix}
\cdot
\begin{pmatrix}
1 & 1-
\frac{\sqrt{d}}{2}
\end{pmatrix}
\cdot
\begin{pmatrix}
1 & 1-
\frac{\sqrt{d}}{2}
\end{pmatrix}
= \begin{pmatrix}
1 & 1-
\frac{\sqrt{d}}{2}
\end{pmatrix},
\]
leading to
\[
\begin{pmatrix}
0 & 0 & \ldots & 1
\end{pmatrix}
\cdot
\begin{pmatrix}
1 & |\Delta_{K}|^{1/\mathbb{Z} \mathbb{Q}_{n_{\ell}}} \cdot M^{-1}
\end{pmatrix}
= \begin{pmatrix}
1 & \eta(\ell)
\end{pmatrix}
\cdot
\begin{pmatrix}
1 & 1-
\frac{\sqrt{d}}{2}
\end{pmatrix},
\]
where \( \eta(\ell) \) denotes the number of 2’s appearing in \( \ell \in \{1,2\}^{\ell} \). The right-hand side is again a norm \( \sqrt{n_{\ell}} \) vector, which is the main ingredient needed for the rest of the proof to apply.

\[\Box\]

**Lemma 3.1.** Let \( P_{n} \) denote the probability that \( n \) independent samples from the univariate Gaussian \( \Gamma_{1/2\sqrt{\log n}} \) are all at most \( 1/2 \) in absolute value. Then \( P_{n} \to 1 \) as \( n \to \infty \).

**Proof.** Write \( r = 1/2\sqrt{\log n} \) and let \( z \) be sampled from \( \Gamma_{r} \). Then \( P_{n} \) equals
\[
\left( 1 - 2P\left( z > \frac{1}{2}\right) \right)^{n} = \left( 1 - 2 \int_{1/2}^{\infty} \frac{r}{2\pi} \exp\left( -\frac{\pi x^2}{r^2} \right) dx \right)^{n} \geq \left( 1 - 2 \int_{1/2}^{\infty} 2x \exp\left( -\frac{\pi x^2}{r^2} \right) dx \right)^{n}
\]
so
\[
P_{n} \geq \left( 1 - \frac{\exp\left( -\pi \log n \right)}{\pi \sqrt{\log n}} \right)^{n},
\]
where the right hand side is seen to converge to 1 using l’Hôpital’s rule.

\[\Box\]

**Remark 3.** The fields \( K_{\ell} \) that were constructed in the above proof are totally real, but this is not essential. Indeed, if we would also allow primes \( p_{i} \equiv 3 \mod 4 \) and instead consider the field
\[
K_{\ell} = \mathbb{Q}(\sqrt{p_{1}}, \sqrt{p_{2}}, \ldots, \sqrt{p_{\ell}}),
\]
where
\[
p_{i}^* = (-1)^{\frac{p_{i} - 1}{2}} p_{i},
\]
then the same conclusions would have followed.
4. A cyclotomic point of view

The fields $K_\ell$ constructed in the previous section are abelian, more precisely they are Galois with Galois group

$$\text{Gal}(K_\ell / \mathbb{Q}) \cong C_2 \times C_2 \times \cdots \times C_2,$$

where $C_2$ denotes the group of order two. So by the Kronecker-Weber theorem it should be a subfield of some cyclotomic field. The following lemma shows that it is a subfield of $K := \mathbb{Q}(\zeta_{m_\ell})$. We identify the Galois group $\text{Gal}(K/\mathbb{Q})$ with $G := (\mathbb{Z}/(m_\ell))^\times$, where $a \in G$ acts on $K$ as $\zeta_{m_\ell} \mapsto \zeta_{m_\ell}^a$.

**Lemma 4.1.** Let $G^2$ be the subgroup of squares in $G$. Then $K_\ell$ is the subfield of $K$ fixed by $G^2$.

**Proof.** Denote the subfield of $K$ fixed by $G^2$ as $K^{G^2}$. For each $c \in G/G^2$ consider

$$w_c = \text{Tr}_{K/K^{G^2}}(\zeta_{m_\ell}^c) = \sum_{h \in G^2} \zeta_{m_\ell}^{hc} \in K^{G^2}.$$

By the Chinese remainder theorem (CRT) we have the isomorphism

$$G \cong \mathbb{F}_{p_1}^\times \times \mathbb{F}_{p_2}^\times \times \cdots \times \mathbb{F}_{p_t}^\times,$$

according to which the $w_c$’s can be decomposed as follows:

$$w_c = \sum_{h \in G^2} \zeta_{m_\ell}^{hc} = \sum_{h \in (\mathbb{F}_{p_i}^\times)^2} \zeta_{p_i}^{h_1 c_1} \zeta_{p_2}^{h_2 c_2} \ldots \zeta_{p_t}^{h_t c_t} = \prod_{i=1}^t \sum_{h_i \in (\mathbb{F}_{p_i}^\times)^2} \zeta_{p_i}^{hc_i} = \sum_{i=1}^t \zeta_{p_i}^{hc_i}.$$

Every sum in the last product is a so-called Gaussian period, where the exponents run through either the quadratic residues or the quadratic non-residues modulo $p_i$. As all $p_i$’s are congruent to 1 modulo 4, such sums result in

$$\beta_{i,1} := \frac{-1 + \sqrt{p_i}}{2}, \quad \text{resp.} \quad \beta_{i,-1} := \frac{-1 - \sqrt{p_i}}{2}$$

(see [8]). One sees that $\{w_c\}_c$ is the product basis of $K_\ell$ obtained by equipping the $R_{i,1}$’s with the $\mathbb{Z}$-bases $\beta_{i,1}, \beta_{i,-1}$ rather than $\alpha_{i,1}, \alpha_{i,2}$. In particular the $w_c$’s generate $K_\ell$, so $K_\ell \subset K^{G^2}$ and the lemma follows by comparing degrees. \hfill \Box

As a byproduct of the above proof, we obtain that the $w_c$’s form a $\mathbb{Z}$-basis of $R_\ell$, which is a special case of a more general statement [15, Prop. 6.1]. This kind of ‘trace basis’ is also used in the recent work on Ring-LWE by Chen, Lauter and Stange [5], an example of which we will analyze later in this section. It is interesting to have a quick look at our proof of Theorem 1.2, where now we express the samples with respect to the basis $\{w_c\}_c$ instead of (3.2). Here the factors in the Kronecker product decomposition of $A_B \cdot M^{-1}$ read

$$\left( \begin{array}{cc} -1-p_i & -1-p_i \\ -1+p_i & 1+p_i \end{array} \right) \cdot \frac{1}{\sqrt{p_i}} \left( \begin{array}{cc} 1-\sqrt{p_i} & -1-\sqrt{p_i} \\ -1-\sqrt{p_i} & 1+\sqrt{p_i} \end{array} \right) \left( \begin{array}{cc} 1-\sqrt{p_i} & 1+\sqrt{p_i} \\ -1-\sqrt{p_i} & -1+\sqrt{p_i} \end{array} \right).$$

One sees that

$$\left( \begin{array}{cc} 1 & -1 \\ -1 & 1 \end{array} \right) \cdot \left( \begin{array}{cc} 1-\sqrt{p_i} & 1+\sqrt{p_i} \\ -1-\sqrt{p_i} & -1+\sqrt{p_i} \end{array} \right) = \left( \begin{array}{cc} 1 & -1 \\ 1 & 1 \end{array} \right).$$
So expanding the Kronecker product gives 
\[(J(i))_\ell \cdot A_{\theta_i} \cdot M^{-1} = (1 \ 1 \ \ldots \ 1),\]  
(4.2)
where \(\ell\) runs over all tuples \((i_1, i_2, \ldots, i_\ell) \in \{1, -1\}^\ell\) and 
\[J(i) = J(i_1, i_2, \ldots, i_\ell) = \prod_{j=1}^\ell i_j\]
(this formula explains why we indexed the \(\beta_i\)'s by \(\pm 1\) rather than 1, 2). The row vector \((1 \ 1 \ \ldots \ 1)\) on the right-hand side of (4.2) has norm \(\sqrt{n_\ell}\), so as before this can be used to obtain linear equations in the coordinates of the secret \(s\) that carry negligible error terms, allowing one to recover \(s\) by means of simple linear algebra.

**Remark 4.** As before, the same claims apply to non-dual Ring-LWE and/or to the setting where we allow primes \(p_i \equiv 3 \mod 4\), upon replacement of every appearance of \(\sqrt{p_i}\) by \(\sqrt{p_i}/\ell\).

**Remark 5.** The letter \(J\) refers to the Jacobi-symbol. Indeed, through the CRT we have 
\[G/G^2 \cong \mathbb{F}_{p_1}^\times / (\mathbb{F}_{p_1}^\times)^2 \times \mathbb{F}_{p_2}^\times / (\mathbb{F}_{p_2}^\times)^2 \times \cdots \times \mathbb{F}_{p_{\ell}}^\times / (\mathbb{F}_{p_{\ell}}^\times)^2 = \{\pm 1\} \times \{\pm 1\} \times \cdots \times \{\pm 1\},\]
where if \(c \in G/G^2\) corresponds to \(\ell = (i_1, i_2, \ldots, i_\ell) \in \{1, -1\}^\ell\), then \(w_c = \beta_{i_1,i_2} \beta_{i_2,i_3} \cdots \beta_{i_\ell,i_1}\) and \(J(\ell) = (c/m_\ell)\). Thus if we prefer to think of the rows and columns of the matrices \(A_\theta\) and \(M\) as being indexed by \(c \in G/G^2\) rather than \(\ell \in \{1, -1\}^\ell\), then (4.2) becomes 
\[\left(\left(\frac{c}{m_\ell}\right)\right)_c \cdot A_{\theta_\ell} \cdot M^{-1} = (1 \ 1 \ \ldots \ 1),\]
an identity which we found remarkable at first sight.

To conclude this article, we note that more generally, the presence of factors of the form \(\mathbb{Z}/(1 + \sqrt{d})/2\) for some \(d \equiv 1 \mod 4\) may lead to unexpectedly short linear combinations of the rows of \(A_\theta \cdot M^{-1}\), and thus to weaker instances of Ring-LWE than one might hope (for an aggressive choice of scaling factor).

For instance, let us analyze the first example listed in [5, §5.1]; the other examples admit a similar analysis. Here Chen et al. let \(m = 2805 = 3 \cdot 5 \cdot 11 \cdot 17\) and they consider the fixed field \(K^{G'}\) of \(K = \mathbb{Q}(\zeta_m)\) under the action of 
\[G' := \langle 1684, 1618 \rangle \subset G = \text{Gal}(K/\mathbb{Q}) = (\mathbb{Z}/(m))^\times.\]
Under the CRT decomposition \((\mathbb{Z}/(m))^\times \cong \mathbb{F}_3^\times \times \mathbb{F}_{15}^\times \times (\mathbb{Z}/(85))^\times\) this subgroup corresponds to \(\{1\} \times \{1\} \times G'_85\) where \(G'_85\) denotes the index two subgroup of elements having Jacobi symbol 1. We again work with respect to the trace basis 
\[w_c = \sum_{h \in G'} \zeta_{m}^{hc} = \zeta_3^c \cdot \zeta_{11}^c \cdot \sum_{h \in G'_85} \zeta_{85}^{hc},\]
where \(c \in G/G'\). The latter sum equals \(\beta_1 := (1 + \sqrt{85})/2\) or \(\beta_{-1} := (1 - \sqrt{85})/2\) depending on whether \((\zeta_{85}) = 1\) or not. So we conclude similarly as before that the ring of integers equals 
\[R := \mathcal{O}_{K^{G'}} = \mathbb{Z}[\zeta_3, \zeta_{11}, (1 + \sqrt{85})/2] \cong \mathbb{Z}[\zeta_3] \otimes \mathbb{Z}[\zeta_{11}] \otimes \mathbb{Z}[\zeta](1 + \sqrt{85})/2\]
and that \(\{w_c\}_c\) is the product basis 
\[\{\zeta_3^i \zeta_{11}^j \beta_k\} \quad i=1,2 \quad j=1,2,\ldots,10 \quad k=1,-1\]
As in [5], let us have a look at non-dual Ring-LWE with scaling factor $|\Delta|^{1/2n}$, where $\Delta = \Delta_{K^G} = (-3) \cdot (-11^9) \cdot 85$ and $n = |K^G : \mathbb{Q}| = 40$. Let $M$ denote the matrix of the canonical embedding of $K^G$ with respect to the above basis. Then the last Kronecker factor of $|\Delta|^{1/2n} \cdot M^{-1}$ is given by

$$
\frac{1}{\sqrt{85}} \cdot \begin{pmatrix}
\frac{1+\sqrt{85}}{2} & -\frac{1+\sqrt{85}}{2} \\
-\frac{1+\sqrt{85}}{2} & \frac{1+\sqrt{85}}{2}
\end{pmatrix}.
$$

So multiplying from the left by $(1 - 1)$ leads to the row vector $(1 1)/\sqrt{85}$ of norm $\approx 0.4658$, which is ‘unexpectedly short’. The other Kronecker factors correspond to cyclotomic fields and have less surprising behavior. Here taking the first row (for instance) of each factor leads to norms $\sqrt{2}/\sqrt{3} \approx 1.0746$ and $\sqrt{10}/\sqrt{11} \approx 1.0750$, respectively. Thus multiplying $|\Delta|^{1/80} \cdot M^{-1}$ from the left by

$$(1, 0) \otimes (1, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0) \otimes (1, -1)$$

yields a row vector of norm $\approx 1.0746 \cdot 1.0750 \cdot 0.4658 \approx 0.5303$. Since Chen et al. let $r = 1$, this results in a linear equation in the secret $s$ carrying an error term sampled from $T_{0.5381}$, roughly. By taking other rows of the cyclotomic parts one in fact finds 20 independent such equations. This is insufficient to break this concrete instance of non-dual Ring-LWE using mere rounding (a substantial number of equations will carry an error that exceeds $1/2$ in absolute value), but it is tight, so it provides an explanation why this was indirectly helpful for Chen et al. to successfully apply their $\chi^2$-analysis.

5. Conclusion

In this paper we have shown, by explicitly constructing a family of counterexamples, that the lower bound on the noise in the hardness result for Ring-LWE by Lyubashevsky, Peikert and Regev [16] is tight in a very natural sense: scaling down the noise even by a factor $|\Delta_K|^{r/n}$, for any $\varepsilon$, invalidates the hardness result. Our proof also implies that one cannot simply use non-dual Ring-LWE without scaling up the noise by a factor that depends explicitly on $\Delta_K$, which is often violated in practice. Our results can also be seen as further evidence that the original construction using the dual $R^\vee$ really is the most natural. Finally, we note that our counterexamples implicitly exploit the structure of the Galois group, which raises the question to what extent the structure of the Galois group can be exploited further in the analysis of the hardness of Ring-LWE.
