Version September 21, 2018 submitted to Cryptography

- Abstract: The design of a practical code-based signature scheme is an open problem in post-quantum
- ² cryptography. This paper is the full version of a work appeared at SIN'18 as a short paper, which
- ³ introduced a simple and efficient one-time secure signature scheme based on quasi-cyclic codes.
- As such, this paper features, in a fully self-contained way, an accurate description of the scheme
- setting and related previous work, a detailed security analysis, and an extensive comparison and
- performance discussion.
- **Keywords:** Post-quantum cryptography, code-based cryptography, digital signatures.

8 1. Introduction

Digital signatures are a very important cryptographic primitive in the modern world. Among the q most popular there are, for instance, schemes based on the RSA assumptions, discrete logarithm (DSA) 10 and its elliptic curves version (ECDSA), all included in the FIPS standard 186-3 [1]. Many schemes 11 based on coding theory have been proposed over the years, that either follow a "direct" hash-and-sign 12 approach like CFS [2] and KKS [3], or rely on the Fiat-Shamir transform [4] to convert an identification 13 scheme into a signature scheme. The latter schemes are usually built via a 3-pass protocol [5] or, more 14 recently, a 5-pass protocol [6], in turn relying on the work of Stern [7,8]. Unfortunately, many of the 15 various proposals have been broken, and all those that are still considered secure suffer from one or 16 more flaws, be that a huge public key, a large signature or a slow signing algorithm, which make 17 them highly inefficient in practical situations. This is particularly evident in the identification schemes, where it is usually necessary to repeat the protocol many times in order to guarantee correctness or 19 security. 20

In [9], we introduced a code-based signature scheme following a different approach, inspired by the work of Lyubashevsky [10,11]. Such a proposal had been attempted before (see [12]) without success, the main issue being the choice of the setting (random binary codes) which proved to be too restrictive. Choosing quasi-cyclic codes allows to take advantage of the innate ring metric and makes the scheme viable in practice.

26 1.1. Our Contribution

This full version features a detailed security analysis, including a proof of security that guarantees one-time existential unforgeability against chosen-message attacks, i.e. 1-EUF-CMA. While one-time signatures are not used directly in most applications, they are still relevant since they can be embedded in a Merkle tree structure to obtain a full-fledged signature scheme, which allows to sign up to a predetermined number of times. Our scheme compares very well to other one-time code-based proposals, obtaining what are, to date, the smallest sizes for both signature and public data in the code-based setting. The paper is organized as follows: in the next section we give some preliminary notions about codes and code-based cryptography, as well as identification schemes. In Section 3 we describe the framework on which our scheme will be based, including the previous code-based proposal by Persichetti. Our scheme is presented in Section 4, together with a detailed security analysis (Section 5), and its performance and comparison with other code-base schemes are discussed in Section 6. We conclude in Section 7.

40 2. Preliminaries

41 2.1. Coding Theory

Let \mathbb{F}_q be the finite field with q elements. An [n, k] *linear code* C is a subspace of dimension k of the vector space \mathbb{F}_q^n . Codewords are usually measured in the Hamming metric: the *Hamming weight* of a word $x \in \mathbb{F}_q^n$ is the number of its non-zero positions, and the *Hamming distance* between two words $x, y \in \mathbb{F}_q^n$ is the number of positions in which they differ, that is, the weight of their difference.We denote those respectively by wt(x) and d(x, y).

Linear codes can be efficiently described by matrices. The first way of doing this is essentially choosing a basis for the vector subspace. A *generator matrix* a matrix *G* that generates the code as a linear map: for each message $x \in \mathbb{F}_q^k$ we obtain the corresponding codeword xG. Of course, since the choice of basis is not unique, so is the choice of generator matrix. It is possible to do this in a particular way, so that $G = (I_k | M)$. This is called *systematic form* of the generator matrix. Alternatively a code can be described by its *parity-check matrix*: this is nothing but a generator for the *dual code* of C, i.e. the code comprised of all the codewords that are "orthogonal" to those of C. The parity-check matrix describes the code as follows:

$$\forall x \in \mathbb{F}_{q}^{n}, x \in \mathcal{C} \Longleftrightarrow Hx^{T} = 0.$$

The product Hx^T is known as *syndrome* of the vector x. Note that, if $G = (I_k|M)$ is a generator matrix in systematic form for C, then $H = (-M^{\mathsf{T}}|I_{n-k})$ is a systematic parity-check matrix for C.

Code-based cryptography usually relies more or less directly on the following problem, connected
 to the parity-check matrix of a code.

⁵¹ **Problem 1** (Syndrome Decoding Problem (SDP)).

Given: $H \in \mathbb{F}_q^{(n-k) \times n}$, $s \in \mathbb{F}_q^{(n-k)}$ and $w \in \mathbb{N}$. Goal: find $e \in \mathbb{F}_q^n$ with $wt(e) \leq w$ such that $He^T = s$.

This problem is well-known and was proved to be NP-complete by Berlekamp, McEliece and van Tilborg in [13]. Moreover, it is proved that there exists a unique solution to SDP if the weight *w* is

⁵⁶ below the so-called *GV Bound*.

Definition 1. Let C be an [n, k] linear code over \mathbb{F}_q . The Gilbert-Varshamov (GV) Distance is the largest integer d such that

$$\sum_{i=0}^{d-1} \binom{n}{i} (q-1)^i \le q^{n-k}.$$

If this is not the case, multiple solutions exist (see for example Overbeck and Sendrier, [14]). It follows that SDP is of particular interest when the weight w is "small".

- 59 2.1.1. Quasi-Cyclic Codes
- ⁶⁰ A special subfamily of linear codes is that of cyclic codes.

Definition 2. Let C be an [n, k] linear code over \mathbb{F}_q . We call C cyclic if

$$\forall a = (a_0, a_1 \dots, a_{n-1}), a \in \mathcal{C} \Longrightarrow a' = (a_{n-1}, a_0 \dots, a_{n-2}) \in \mathcal{C}.$$

 $_{61}$ Clearly, if the code is cyclic, then all the right shifts of any codeword have to belong to C as well. An

⁶² algebraic characterization can be given in terms of polynomial rings. In fact, it is natural to build

a bijection between cyclic codes and ideals of the polynomial ring $\mathbb{F}_q[X]/(X^n - 1)$. We identify the vector $(a_0, a_1 \dots, a_{n-1})$ with the polynomial $a_0 + a_1X + \dots + a_{n-1}X^{n-1}$, and then the right shift

 $u_0 + u_1 X + u_{n-1} X$ operation corresponds to the multiplication by X in the ring.

66

⁶⁷ Because of this correspondence, it is possible to see that both the generator matrix and the parity-check

matrix of a cyclic code have a special form, namely *circulant* form, where the *i*-th row corresponds to
the cyclic right shift by *i* positions of the first row.

Cyclic codes have been shown to be insecure in the context of cryptography, as they introduce too much recognizable structure. A subfamily, known as *quasi-cyclic* codes, has been then proposed with some success, mostly in the context of encryption.

Definition 3. Let C be an [n, k] linear code over \mathbb{F}_q . We call C Quasi-Cyclic if there exists n_0 such that, for any codeword a all the right shifts of a by n_0 positions are also codewords.

⁷⁵ When $n = n_0 p$, it is again possible to have both matrices in a special form, composed of n_0 ⁷⁶ circulant $p \times p$ blocks. The algebra of quasi-cyclic codes can be connected to that of the polynomial ⁷⁷ ring $\mathbb{F}_q[X]/(X^p - 1)$, where each codeword is a length- n_0 vector of elements of the ring.

For the remainder of the paper, we consider only binary codes, thus we set $\mathcal{R} = \mathbb{F}_2[X]/(X^p - 1)$, and we restrict our attention to the case $n_0 = 2$. We have the following ring-based formulation of SDP.

Problem 2 (Quasi-Cyclic Syndrome Decoding Problem (QC-SDP)).

⁸¹ Given: $h, s \in \mathcal{R}$ and $w \in \mathbb{N}$.

Goal: find $e_0, e_1 \in \mathcal{R}$ with $wt(e_0) + wt(e_1) \leq w$ such that $e_0 + e_1h = s$.

⁸³ This was shown to be NP-complete in [15]. When $n_0 = 2$, it has been proved in [16] that random ⁸⁴ quasi-cyclic codes lie on the GV bound with overwhelming probability. Moreover, the impact of ⁸⁵ cyclicity on SDP has been studied, for example in [17], revealing no substantial gain.

86 2.2. Identification Schemes and Signatures

An identification scheme is a protocol that allows a party \mathcal{P} , the Prover, to prove to another party \mathcal{V} , the Verifier, that he possesses some secret information x, usually called *witness*, without revealing to the verifier what that secret information is. The paradigm works as follows: \mathcal{V} is equipped with a public key pk and some public data D. To start, \mathcal{P} chooses some random data y and commits to it by sending Y = f(y) to \mathcal{V} , where f is usually a trapdoor one-way function or a hash function. \mathcal{V} then chooses a random challenge c and sends it to \mathcal{P} . After receiving c, \mathcal{P} computes a response z as a function of c, x and y and transmits z. Finally, \mathcal{V} checks that z is correctly formed using pk and D.

A signature scheme is defined by a triple (KeyGen, Sign, Ver), respectively the *key generation algorithm*, the *signing algorithm* and the *verification algorithm*. The key generation algorithm KeyGen takes as input a security parameter λ and outputs a signing key sgk and a verification key vk. The private signing algorithm Sign receives as input a signing key sgk and a message *m* and returns a signature σ . Finally, the public verification algorithm Ver uses a verification key vk to verify a signature σ that is transmitted together with the message *m*: it outputs 1, if the signature is recognized as valid, or 0 otherwise. The standard notion of security for digital signatures schemes is Existential Unforgeability under Chosen-Message Attacks (EUF-CMA), as described, for example, in [18]. In this scenario, the goal of an attacker is to produce a valid message/signature pair, and the attack model allows the attacker to obtain a certain, predetermined, number of signatures on arbitrarily chosen messages (signing queries). In particular, if the attacker is only allowed to obtain a single signature, we talk about 1-EUF-CMA security. Since this is the security target of this work, we give a precise definition below.

Definition 4. An adversary A is a polynomial-time algorithm that acts as follows:

- 1. Query a key generation oracle to obtain a verification key vk.
- 2. Choose a message m and submit it to a signing oracle. The oracle will reply with $\sigma = \text{Sign}_{sgk}(m)$.

110 3. Output a pair (m^*, σ^*) .

The adversary succeeds if $Ver_{vk}(m^*, \sigma^*) = 1$ and $(m^*, \sigma^*) \neq (m, \sigma)$. We say that a signature scheme is 1-EUF-CMA secure if the probability of success of any adversary A is negligible in the security parameter, i.e.

$$Pr[vk \xleftarrow{\$} KeyGen : Ver_{vk}(\mathcal{A}(vk, Sign_{sek}(m))) = 1] \in negl(\lambda).$$
(1)

Fiat and Shamir in [4] showed how to obtain a full-fledged signature scheme from an identification

scheme. With this paradigm, the signer simply runs the identification protocol, where, for the purpose

of generating the challenge, the verifier is replaced by a random oracle \mathcal{H} (usually a cryptographic hash

function). The signature is then accepted according to the validity of the response in the identification

115 scheme.

Table 1.	The Fiat-Sha	mir Signatu	re Scheme.
----------	--------------	-------------	------------

Setup	Select an identification scheme \mathcal{I} .
Sign	On input the private key of \mathcal{I} and a message m , commit Y , set $c = \mathcal{H}(Y, m)$, compute a response z and return the signature $\sigma = (Y, z)$.
Ver	On input the public key of \mathcal{I} , a message <i>m</i> and a signature σ , set $c = \mathcal{H}(Y, m)$ then output 1 if <i>z</i> is accepted in \mathcal{I} , else return 0.

Note that several signature schemes, including [11] and this work, use a slightly modified version of the above paradigm, where the signature is (c, z) instead of (Y, z). The verifier can then calculate Yfrom z and the public key, and check the equality between c and the hash digest obtained using this newly-generated Y and m.

120 3. A Framework for Signatures

121 3.1. Number Theory and Lattices

There is a relatively recent approach that provides an easy way to construct efficient signature 122 schemes based on any hard problem. The approach consists of successive reductions building on 123 the original hard problem, first deriving a collision-resistant hash function f, then converting it into a one-time signature where the private key is a pair of integers (x, y), the public key is the pair 125 (f(x), f(y)), and the signature of a message m is simply mx + y. The one-time signature can then 126 be turned into an identification scheme by replacing *m* with a challenge *c* chosen by the verifier and 127 letting y be the commitment (a distinct y is used in every run of the protocol). Finally, the identification 128 scheme is transformed into a full-fledged signature scheme using the Fiat-Shamir transform. Proposals 129 based on classical number theory problems such as RSA or discrete logarithm (see Okamoto [19]) are 130 easy and intuitive to design. 131

Lyubashevsky showed for the first time how to translate the framework to the lattice case, presenting 132 in [10] an identification scheme which was then refined and updated in [11]. The translation is rather direct, except for an issue which is inherent to the nature of the lattice schemes: unlike factoring or 134 discrete logarithm, in fact, the hardness of lattice problems comes from finding elements that live in a 135 specific subset of a ring, namely elements with small Euclidean norm. Transmitting several elements 136 of this nature can leak some parts of the private key. To overcome this limitation, the author makes 137 use of a technique, already introduced in [20], called *aborting*. In short, this consists of rejecting the challenge if in doing so the security of the scheme would be compromised. In practice, this is realized 139 by limiting the set of possible answers to a smaller "safe" subset, consisting of elements whose norm 140 satisfies a certain bound. 141

142 3.2. A Coding Theory Scenario

A first, direct translation of the framework to the case of code-based cryptography was proposed by Persichetti in [12]. The idea is for the scheme to rely on SDP, hence featuring a public matrix H, a secret x having weight below the GV bound and the public key $s_x = Hx^T$. Similarly to the lattice case, the final verification should include not only an algebraic formula consisting of H, the commitment Yand s_x , but also a check on the weight of the response z.

Formally, one can see the syndrome computation as a hash function $f(x) = Hx^{T}$, which is is 148 preimage-resistant provided that the weight of x is small. From now on, we will denote this function 149 as $synd_H(x)$. It follows that the scheme is subject to the additional constraint that the random element 150 *y* and the challenge *c* should be chosen such that $wt(z) \leq w$, where *w* is the value of the GV distance. 151 This means that *c* can only be an element of \mathbb{F}_q and that *x* and *y* must satisfy wt(*x*) = $\gamma_1 w$, wt(*y*) = $\gamma_2 w$, 152 for certain constants $\gamma_1, \gamma_2 \leq 1$ such that $\gamma_1 + \gamma_2 = 1$. In the sample instantiation that we are about to 153 present we have chosen $\gamma_1 = \gamma_2 = 1/2$ for simplicity. We will also use the notation \mathcal{D}_a to indicate the 154 distribution that samples uniformly at random a vector of \mathbb{F}_a^n of weight less or equal to a. The scheme 155 uses a cryptographic hash function \mathcal{H} as per the Fiat-Shamir paradigm. 156

157 KeyGen

Input: parameters $q, n, k, w \in \mathbb{N}$ and an $(n - k) \times n$ parity-check matrix H over \mathbb{F}_q .

- 159 1. Sample $x \stackrel{\$}{\leftarrow} \mathcal{D}_{w/2}$.
- 160 2. The signing key is x.
- 3. The verification key is $s_x = synd_H(x)$.

162 Sign

- Input: a message m and the signing key x.
- 164 1. Sample $y \stackrel{\$}{\leftarrow} \mathcal{D}_{w/2}$.
- 165 2. Compute $s_y = synd_H(y)$.
- 166 3. Compute $c = \mathcal{H}(m, s_y)$.
- 167 4. Compute z = cx + y.
- 168 5. The signature is $\sigma = (c, z)$

169 Ver

Input: a message *m*, a signature σ and the verification key s_x .

- 171 1. Compute $s_z = synd_H(z)$.
- 172 2. Use the verification key to compute $v = cs_x + s_z$.
- 3. Compute $c' = \mathcal{H}(m, v)$.
- 4. Accept if c' = c and $wt(z) \le w$.
- 5. Else, reject.

176 3.2.1. Vulnerability from Multiple Signatures

Unfortunately, if used to sign multiple messages, this simple proposal is vulnerable to an attacker 177 who tries to learn the secret. In fact, if an attacker can obtain a polynomial number of signatures, 178 it could store the corresponding values of z and c and then compute $z' = c^{-1}y + x$: this is always 179 possible, since *c* is a field element and is non-zero. Now, the vector $y' = c^{-1}y$ is randomly generated 180 and has low weight, so each of its coordinates is biased towards 0. Therefore, a simple statistical 181 analysis will eventually reveal all the positions of x. The problem seems to come from the scheme 182 metric itself. In fact, c is constrained to be a field element (to fit the verification equation) but doesn't 183 alter the weight of x, and so the low-weight vector y that is added is not enough to properly hide the 184 secret support. 185

186 4. The New Scheme

The core of our idea is to use quasi-cyclic codes in the framework that we have described above. The use of quasi-cyclic codes in cryptography is not a novelty: these have been proposed before in the context of encryption (e.g. [15]). Their originally suggested use (i.e. with GRS codes) was cryptanalyzed in [21] and it is thus not recommended, but other variants based on LDPC and MDPC codes are still considered safe. In both cases, the issue is that introducing the extra algebraic structure can compromise the secrecy of the private matrix used for decoding.

A big advantage of our proposal is that this issue does not apply. In fact, since there is no decoding involved, an entirely random code can be used, and the code itself is public, so there is no private matrix to hide. In this sense, our scheme is closer, to an extent, to the work of [22], which is centered on *random* quasi-cyclic codes.

As far as signature schemes go, Gaborit and Girault in [23] propose a variant of Stern's ID scheme that uses quasi-cyclic codes (called "double-circulant" by the authors). While this proves to be more efficient than the classical Stern scheme, the protocol still features the same flaw, i.e. a non-trivial cheating probability. This leads to the necessity of repeating the protocol several times, with an obvious impact on the efficiency of the scheme.

In our setting, we use 2-quasi-cyclic codes where words are vectors in $\mathcal{R} \times \mathcal{R}$. For a word 202 $x = (x_0, x_1)$, the syndrome function associated to $h \in \mathcal{R}$ is defined as $synd_h(x) = x_0 + x_1h$, following 203 the notation that takes a parity-check matrix in systematic form (and hence defined by h) as in 204 Problem 2. For a more general formulation, we also adapt the notation from the previous section, 205 indicating with \mathcal{D}_1 and \mathcal{D}_2 the distributions that sample uniformly at random vectors of $\mathcal{R} \times \mathcal{R}$ having 206 weight respectively less or equal to $w_1 = \gamma_1 w$ and $w_2 = \gamma_2 w$. Our signature scheme is presented 207 below. The scheme uses a hash function \mathcal{H} that outputs bit strings of fixed weight δ , which is one of 208 the system parameters. 209

210 KeyGen

- Input: parameters $p, \delta, w_1, w_2 \in \mathbb{N}$ and a vector $h \in \mathcal{R}$.
- 1. Sample $x \xleftarrow{\$} \mathcal{D}_1$.
- 213 2. The signing key is x.
- 3. The verification key is $s_x = synd_h(x)$.

215 Sign

- **Input:** a message m and the signing key x.
- 1. Sample $y \xleftarrow{\$} \mathcal{D}_2$.
- 218 2. Compute $s_y = synd_h(y)$.
- 3. Compute $c = \mathcal{H}(m, s_y)$.
- 220 4. Compute z = cx + y.
- 5. The signature is $\sigma = (c, z)$.

222 Ver

- Input: a message *m*, a signature σ and the verification key s_x .
- 1. Compute $s_z = synd_h(z)$.
- 225 2. Use the verification key to compute $v = cs_x + s_z$.
- 226 3. Compute $c' = \mathcal{H}(m, v)$.
- 4. Accept if c' = c and $wt(z) \le w$.
- ²²⁸ 5. Else, reject.

Like before, we have a constraint on the weight of the response vector z: in this case $w \le \delta w_1 + w_2$ since c is no longer a constant. Then w is required to be below the GV bound to ensure that the response z is the unique solution to the corresponding QC-SDP instance. This is a consequence of the security requirements, as we will see next.

To conclude, note that it is easy to check that an honest verifier always gets accepted. In fact, in an honest run of the protocol, then $v = cs_x + s_z = c \cdot synd_h(x) + synd_h(z)$. Due to the transitivity of the syndrome computation, this is the same as $synd_h(cx + z) = synd_h(y) = s_y$. Therefore $c' = \mathcal{H}(m, v) =$ $\mathcal{H}(m, s_y) = c$ and the verification is passed.

237 5. Security

The change of metric in our proposal means that our scheme is substantially different from the 238 "naïve" SDP-based proposal of Section 3.2, and in fact resembles the lattice setting much more. In 239 fact, as in the lattice case, our objects are "vectors of vectors", namely in this case a length-2 vector 240 of length-*p* binary vectors. Due to the inherent arithmetic associated to the ring \mathcal{R} , this allows us to 241 choose *c* in the same realm, and perform an operation (ring multiplication) that is still compatible with 242 the verification operation, but does affect the weight of the response vector. Polynomial multiplication 243 simultaneously increases and scrambles the error positions, and in so doing prevents the simple attack 244 based on statistical analysis that affected the previous proposal. Unfortunately, this is still not enough 245 to hide the private information. The following procedure [24] shows that it is still possible to recover 246 the private key with a polynomial number of signatures. 247

Procedure 1. Start by obtaining a polynomial number ℓ of signatures, i.e. pairs $(c^{(i)}, z^{(i)})$ for $i, = 1, ..., \ell$. For each pair, $c^{(i)}$ is chosen uniformly at random among the vectors of weight δ , and $z^{(i)} = c^{(i)}x + y^{(i)}$ where $y^{(i)}$ is also chosen uniformly at random (sampled from D_2). For each i, write $c^{(i)} = X^{i_1} + \cdots + X^{i_{\delta}}$, that is, as a polynomial of weight δ in \mathcal{R} . Then calculate

$$\begin{aligned} & \stackrel{(i,j)}{=} & X^{-i_j} z^{(i)} \pmod{X^p - 1} \\ & = & X^{-i_j} (c^{(i)} x + y^{(i)}) \pmod{X^p - 1} \\ & = & (1 + \sum_{k \neq j, k \in \{1, \dots, \delta\}} X^{i_k - i_j}) x + X^{-i_j} y^{(i)} \pmod{X^p - 1} \\ & = & x + \sum_{k \neq j, k \in \{1, \dots, \delta\}} x^{(i,j)} + y^{(i,j)} \pmod{X^p - 1} \end{aligned}$$

252

²⁵³ where $x^{(i,j)} = X^{i_k - i_j} x \pmod{X^p - 1}$ and $y^{(i,j)} = X^{-i_j} y^{(i)} \pmod{X^p - 1}$.

Since $x^{(i,j)}$ is just a shift of x and $y^{(i,j)}$ is just a shift of $y^{(i)}$, and their support will likely have little to no intersection with the support of x (due to the weight of the vectors), it is possible to reveal the support of x simply by looking at the bits that belong to the support of a large enough number of $z^{(i,j)}$.

Note that the above procedure is in fact a refinement of the simple statistical analysis attack encountered before: in both cases, the problem is that the weight of the vectors is simply too low

Z

to properly mask the private vector. It is then clear that it is impossible to sign multiple times and preserve security. It follows that our scheme only achieves one-time security. To prove the one-time security of our scheme, we follow the paradigm for a generic one-time signature scheme of Pointcheval and Stern, which was already employed in the code-based setting in [25]. In this paradigm, signature schemes are treated in a unified way, as a protocol that outputs triples of the form (σ_1 , h, σ_2), where σ_1 represents the commitment¹, σ_2 the response², and h is the hash value, as in the Fiat-Shamir scheme. To obtain security it is necessary that σ_1 is sampled uniformly at random from a large set and that σ_2 only depends on σ_1 , the message m and the hash value h.

In our scheme, the first element $\sigma_1 = s_y$ is sampled uniformly at random from \mathcal{D}_2 , which has size 267 $\binom{n}{w_2}$. Note that, even though this value is not explicitly output as part of the signature, it is immediate 268 to recover it from the signature, as shown in Step 2. of the verification algorithm. The vector c is 269 exactly the hash value obtained from the message *m* and σ_1 , i.e. the element *h* in the Pointcheval-Stern 270 notation³. Finally, we show that $\sigma_2 = z$ indeed only depends on the message *m*, σ_1 and *c*. The 271 dependence is obvious, given that z is computed using only the private key, c itself and y, which is in a 272 one-to-one correspondence with s_u (due to w_2 being below the GV bound). Furthermore, z is uniquely 273 determined by those values. In fact, suppose there existed a distinct valid triple (s_y, c, z') with $z' \neq z$. 274 Since the triple is valid, it needs to satisfy the verification equation, thus $synd_h(z') = cs_x + s_y = s_z$. 275 This is clearly not possible because both z and z' have weight below the GV bound, which implies 276 there exists only one vector having syndrome s_{z_i} i.e. z' = z. 277

The next step is to show that in our signature scheme, it is possible to simulate the target triples without knowing the private key, unbeknownst to the adversary.

Lemma 1. It is possible to obtain artificially-generated triples of the form (s_y, c, z) which are indistinguishable from honestly-generated triples, unless the adversary is able to solve an instance of QC-SDP.

Proof. To begin, notice that any valid triple is required to satisfy two constraints. First, the weight of z has to be below the GV bound; in fact, wt(z) is expected to be statistically close to the bound $w \le w_2 + \delta w_1$. Second, the triple needs to pass the verification equation, and so $s_y = cs_x + s_z$. Then, to simulate a valid triple it is enough to sample two elements at random and set the third to match. More precisely, one would sample $c \stackrel{\$}{\leftarrow} \mathcal{D}_c$ and $z \stackrel{\$}{\leftarrow} \mathcal{R}^2$, the second one chosen such that wt(z) $\approx w$. Then, one would proceed by setting s_y to be exactly $cs_x + s_z$, which is possible since the public key s_x is known.

Now, it is easy to see that all honestly-generated triples correspond to syndromes $s_y = synd_h(y)$ where

²⁰⁰ *y* has weight w_2 below the GV bound, while for simulated triples the syndrome s_y is obtained from

²⁰¹ a vector y = cx + z which has expected weight *above* the GV bound with overwhelming probability. ²⁰² This is because both *c* and *z* are generated independently and at random, and so the expected weight

is simply $\delta w_1 + wt(z)$, which is bigger than the bound with overwhelming probability.

In conclusion, distinguishing a simulated triple from an honest one corresponds to solving a QC-SDP instance as claimed.

The last piece necessary for our proof is the well-known *forking lemma*. We report it below, as formulated in [26].

¹ Or a sequence of commitments, if the protocol needs to be repeated multiple times.

² Or a sequence of responses.

³ We clearly use c from now on, to avoid confusion as h is used to denote the vector defining the parity-check matrix in a QC code.

Theorem 1 (General Forking Lemma). Let $\Sigma = (KeyGen, Sign, Ver)$ be a signature scheme with security parameter λ . Let \mathcal{A} be an adversary, running in time T and performing at most q random oracle queries and ℓ signing queries. Suppose \mathcal{A} is able to produce a valid signature $(m, \sigma_1, h, \sigma_2)$ with probability $\varepsilon \geq$ $10(\ell + 1)(\ell + q)/2^{\lambda}$. If the triples (σ_1, h, σ_2) can be simulated without knowing the private key with only a negligible advantage for \mathcal{A} , then there exist a polynomial-time algorithm \mathcal{B} that can simulate the interaction with \mathcal{A} and is able to produce two valid signatures $(m, \sigma_1, h, \sigma_2)$ and $(m, \sigma_1, h', \sigma'_2)$, for $h' \neq h$, in time $T' \leq 120686qT/\varepsilon$.

³⁰⁵ We are now ready for our security result.

Theorem 2. Let A be a polynomial-time 1-EUF-CMA adversary for the signature scheme with parameters p, δ , w_1 , w_2 , running in time T and performing at most q random oracle queries. Let the probability of success of A be $\varepsilon \ge 20(q+1)/2^{\lambda}$. Then the QC-SDP problem with parameters n = 2p, $w = \delta w_1 + w_2$ can be solved in time $T' \le 120686\ell qT/\varepsilon$.

Proof. We have seen in Procedure 1 that it is possible to recover the private key using a polynomial number ℓ of signatures. The forking lemma can be iterated so that it is guaranteed to produce ℓ distinct, valid signatures in time less or equal to $T' \leq 120686\ell qT/\varepsilon$. The thesis naturally follows from the combination of these two facts. \Box

6. Performance and Comparison

To properly evaluate the performance, we start by recalling the main components of our scheme. 315 First of all, the public data consists of the vector h (of length p) and the syndrome s_x (also of length 316 p), for a total of 2p bits. The signature, on the other hand, is given by the challenge string c and 317 the response z. In our scheme, this corresponds respectively to a vector of length p and a vector of 318 length 2p. It is possible to greatly reduce this size thanks to a storing technique [27] which allows to 319 represent low-weight vectors in a compact manner. Namely, a binary vector of length n and weight w320 is represented as an index, plus an indication of the actual vector weight, for a total of $\log \binom{n}{w} + \log(w)$. 321 Note that in our case this applies to both *c* and *z*. 322

We now provide some parameters for the codes in our scheme. These are normally evaluated with respect to general decoding algorithms such as Information-Set Decoding [28–32]: the amount of security bits is indicated in the column "Security".

p	w_1	<i>w</i> ₂	δ	Security (λ)	Public Data	Signature Size
4801	90	100	10	80	9602	4736
9857	150	200	12	128	19714	9475
3072	85	85	7	80	6144	3160
6272	125	125	10	128	12544	6368

Table 2. Parameters (all sizes in bits).

The first two rows report well-known parameters suggested in the literature for QC-MDPC codes; however, since our codes do not need to be decodable, we are able to slightly increase the number of errors introduced. The last two rows, instead, are parameters chosen ad hoc, in order to optimize performance.

330 6.1. Existing Code-Based Solutions

We are now going to briefly discuss the three main approaches to obtain code-based signatures, and related variants. This will give an insight into why designing an efficient code-based signature scheme is still an open problem.

334 6.1.1. CFS

The CFS scheme [2] follows the "hash and sign" paradigm, which is a very natural approach 335 for code-based cryptography, and thus it retains most of its traits, both good and bad. For instance, 336 the verification consists of a single matrix-vector multiplication and so it is usually very fast. On the 337 other hand, the scheme features a very large public key (the whole parity-check matrix). Structured 338 instances as proposed for example in [33] reduce this size drastically and are therefore able to deal 339 with this issue, although with a potential few security concerns. However, the main downfall of CFS is 340 the extremely slow signing time. This is a consequence of the well-known fact that a random word is 341 in general not decodable, thus finding a decodable syndrome requires an incredibly high number of 342 attempts (at least 2^{15} in the simplest instances). To lower this number, the common solution is to use 343 codes with very high rate, which in itself could lead to potential insecurities (e.g. the distinguisher of). 344 Thus it seems unrealistic to obtain an efficient signature scheme in this way. 345

346 6.1.2. KKS

The KKS approach [3] still creates signatures in a "direct" way, but without decoding. Instead, 347 the scheme relies on certain aspects of the codes such as a carefully chosen distance between the 348 codewords, and uses a secret support. Unfortunately, the main drawback of KKS-like schemes is the 349 security. In fact, it has been shown in [34] that most of the original proposals can be broken after 350 recovering just a few signatures. Furthermore, not even a one-time version of the scheme (e.g. [25]) 351 is secure, as shown by Otmani and Tillich [35], who are able to break all proposals in the literature 352 without needing to know any message/signature pair. It is therefore unlikely that the KKS approach 353 could be suitable for a credible code-based signature scheme. 354

355 6.1.3. Identification Schemes

All of the code-based identification schemes proposed so far are 3-pass (or 5-pass) schemes with 356 multiple challenges. Thus, the prover sends 2 or 3 entirely different responses depending on the value 357 of the challenge (usually a bit or $\{0,1,2\}$). In this sense, our proposal represents a big novelty. In fact, multiple challenges allow for a malicious user to be able to cheat in some instances. For example, in 359 the original proposal by Stern [7], it is possible to choose any 2 out of 3 possible responses and pass 360 verification for those even without knowing the private key, thus leading to a cheating probability 361 of 2/3. This cheating probability is subsequently lowered in most recently proposals, approaching 362 1/2. Nevertheless, this causes a huge issue, since the protocol needs to be repeated several times in 363 order for an honest prover to be accepted. The 35 repetitions of the original scheme can be lowered to 364 approximately 16 repetitions in recent variants, but even so, communication costs prove to be very 365 high, leading to a very large signature size. Below, we report a comparison of parameters for different 366 variants of the scheme, where the column Véron refers to [5], CVE to [6] and AGS to [36]. Note that all 367 of these parameters refer to a cheating probability of 2^{-16} , a weak authentication level. 368

In the latest proposal (column AGS), the size of the public matrix is considerably smaller thanks to the use of double-circulant codes. However, the signature size is still very large (about 93Kb). Moreover, for a signature to be considered secure, one would expect computational costs to produce a forgery to be no less than 2⁸⁰; this would require, as claimed by the authors in [36], to multiply all the above data by 5, producing even larger sizes.

	Stern 3	Stern 5	Véron	CVE	AGS
Rounds	28	16	28	16	18
Public Data	122500	122500	122500	32768	350
Private Key	700	4900	1050	1024	700
Public Key	350	2450	700	512	700
Total Communication Cost	42019	62272	35486	31888	20080

Table 3. Comparison of the most popular identification schemes. All the sizes are expressed in bits.

374 6.2. Comparison

A comparison of our scheme with the full-fledged schemes described above would not be entirely 375 accurate. We can however compare our scheme to other code-based proposals that are one-time secure, 376 such as [25] and [37]. Both of these schemes follow the KKS approach, and therefore come with some 377 potential security concerns, as mentioned in the previous section. For simplicity, we will refer to [25] as 378 BMS and to [37] as GS. Note that the latter comes in two variants, which use respectively quasi-cyclic 379 codes, and a newly-introduced class of codes called "quadratic double-circulant" by the authors. All 380 the parameters and sizes (in bits) are reported in the following table, and correspond to a security level 381 of 2⁸⁰. 382

Table 4. Comparison of code-based one-time signature schemes.

	BMS	GS 1	GS 2	Our Scheme
Public Data	930080	75000	17000	6144
Signature Size	3739	18900	7000	3160

It is immediate to notice that our scheme presents the smallest amount of public data (which 383 groups together public key and any additional public information) and the smallest signature size. 384 To be fair, the BMS scheme employs the same indexing trick used in this work, while this is not the 385 case for the other scheme. Since the signature of the GS scheme (in both variants) also includes a 386 low-weight vector, we expect that it would be possible to apply the same technique to the GS scheme 387 as well, with the obvious reduction in size. We did not compute this explicitly but it is plausible to 388 assume it would be very close to that of our scheme. Nevertheless, the size of the public data remains 389 much larger even in the most aggressive of the two variants (GS 2). 390

391 6.3. Implementation

To confirm the practicality of our scheme, we have developed a simple implementation in C. The implementation is a straightforward translation to C with the addition of the steps for generating public and private keys. The hash function used was SHA-256. We ran the protocol on a small microprocessor, namely a 580 MHz single-core MIPS 24KEc. The choice of this microprocessor was made based on the usage of it, since this type of microprocessor is commonly used in the Internet of Things (IoT) applications. The measurements are reported below.

Note that key generation is dominated by the syndrome computation necessary to obtain the verification key, while sampling the signing key has a negligible cost. The signing operation is the most expensive, which makes sense, while the verification is of the same order of magnitude as the key generation. Both signing and verification algorithm are relatively fast but could be sped up even further, since the hash function used was, at the time the measurements were taken, not optimized to run in such a small device.

 Table 5. Implementation Results.

p	w_1	<i>w</i> ₂	δ	Key Generation (sgk/vk)	Signing	Verification
4801	90	100	10	0.061 ms / 22.754 ms	89.665 ms	22.569 ms
9857	150	200	12	0.169 ms / 104.655 ms	374.206 ms	99.492 ms
3072	85	85	7	0.052 ms / 14.017 ms	35.150 ms	14.271 ms
6272	125	125	10	0.116 ms / 67.972 ms	150.063 ms	42.957 ms

404 7. Conclusions

In this paper, we have presented a new construction for a one-time signature scheme based 405 on coding theory assumptions. In particular, our scheme uses quasi-cyclic codes and relies on the 406 hardness of the quasi-cyclic version of the syndrome decoding problem (QC-SDP), while making use 407 of the inherent ring structure for its arithmetic properties. Quasi-cyclic codes allow for a compact 408 description, and a drastic reduction in the public key size, resulting in a very lightweight scheme. In 409 addition, the ring arithmetic, similar to Lyubashevsky's lattice-based proposal, is very efficient, and 410 we expect to obtain extremely fast and practical implementations. Thanks to all these features, as well 411 as the simplicity of its design, our protocol is very competitive: it features a compact public key, fast 412 signing and verification algorithms, and the signature size is much shorter than other one-time secure 413 code-based protocols. In particular, the protocol is naturally very appealing in lightweight applications, 414 where resources are limited and aspects such as execution time and memory requirements are of crucial 415 importance. Examples could be embedded devices such as microprocessors, or the Internet-of-Things 416 (IoT). Moreover, our scheme could be a very efficient solution for protocols that require only one-time 417 signatures as building blocks, such as the work of [38] based on the *k*-repetition paradigm. 418

In summary, we believe that our proposal represents a very interesting solution per se, as well as an important step forward in the long quest for an efficient code-based signature scheme.
