

Obtaining Universally Composable Security: Towards the Bare Bones of Trust*

Ran Canetti[†]

December 15, 2007

Abstract

A desirable goal for cryptographic protocols is to guarantee security when the protocol is composed with other protocol instances. **Universally Composable (UC)** security provides this guarantee in a strong sense: A UC-secure protocol maintains its security properties even when composed concurrently with an unbounded number of instances of arbitrary protocols. However, many interesting cryptographic tasks are provably impossible to realize with UC security in the standard, “plain” model of computation. Impossibility holds even if ideally authenticated communication channels are provided. In contrast, it has been demonstrated that general secure computation can be obtained in a number of idealized models. Each one of these models represents a form of trust that is put in some of the system’s components.

This survey examines and compares some of these trust models, both from the point of view of their sufficiency for building UC secure protocols, and from the point of view of their practical realizability. We start with the common reference string (CRS) model, and then describe several relaxations and alternatives including the Defective CRS model, the key registration models, the hardware token model, the global and augmented CRS models, and a timing assumption. Finally, we briefly touch upon trust models for obtaining authenticated communication.

1 Introduction

Designing protocols that guarantee security in open, multi-protocol, multi-party execution environments is a challenging task. In such environments a protocol instance is executed concurrently with an unknown number of instances of the protocol, as well as arbitrary other protocols. Indeed, it has been demonstrated time and again that adversarially-coordinated interactions between different protocol instances can compromise the security of protocols that were demonstrated to be secure when run in isolation (see, e.g., [GK89, DDN00, KSW97, DNS98, KLR06, Can06]).

A natural approach for guaranteeing security of protocols in such complex execution environments is to require that protocols satisfy a notion of security that provides a general *secure composability* guarantee. That is, it should be guaranteed that a secure protocol maintains its security even when composed with (i.e., runs alongside) arbitrary other protocols. Such a general notion of security is provided by the **universally composable (UC) security** framework [C01], which provides a very general composability property: A UC secure protocol is guaranteed to maintain its security (in the sense of emulating an ideally trusted and secure service) even when run concurrently with multiple copies of itself, plus arbitrary network activity.

Which cryptographic tasks are realizable by protocols that guarantee UC security? Are existing protocols, which are known to be secure in a stand-alone setting, UC secure? When the majority of the parties are honest (i.e., they are guaranteed to follow the protocol), the general feasibility results for stand-alone secure computations can be extended to the case of UC security. In fact, some known protocols for general secure function evaluation turn out to be UC secure. For instance, the [BGW88] protocol (both with

*This survey complements a talk given at Asiacrypt 2007.

and without the simplification of [GRR98]), together with encrypting each message using non-committing encryption [CFG96], is universally composable as long as less than a third of the parties are corrupted, and authenticated and synchronous communication is available. Using [RB89], any corrupted minority is tolerable. Asynchronous communication can be handled using the techniques of [BCG93, BKR94]. Note that here some of the participants may be “helpers” (e.g., dedicated servers) that have no local inputs or outputs; they only participate in order to let other parties obtain their outputs in a secure way.

However, things are different when honest majority of the parties is not guaranteed, and in particular in the case where only two parties participate in the protocol and either one of the parties may be corrupted: It turns out that many interesting tasks are impossible to realize in the “bare” model of computation. Impossibility holds even if ideally authenticated communication is guaranteed. (In keeping with common terminology, we use the terms **plain protocols** and **protocols in the plain model** to denote protocols that assume ideally authenticated communication but no other idealization.) For instance, basic cryptographic tasks such as Bit Commitment, Coin-Tossing, Zero-Knowledge, or Oblivious Transfer cannot be realized by plain protocols, when naturally translated to the UC framework. Impossibility also extends to many other tasks [CF01, C01, CKL03, DDMRS06], including multi-party extensions of these primitives, whenever the honest parties are not in majority.

One potential approach for circumventing these impossibility results is to come up with relaxed notions of security that would still guarantee meaningful composable security, and at the same time would be realizable by plain protocols. Indeed, some relaxed notions along these lines were proposed in e.g. [PS04, BS05, MMY06, MPR06]. It turns out, however, that such an approach will necessarily result in notions of security that either do not provide general composability guarantees, or alternatively are too weak to guarantee even stand-alone security as in, say, [C00]. Specifically, we any protocol that continues to realize some task, according to the notion of [C00], and continues to do so even when composed with arbitrary protocols, is guaranteed to realize the same task with UC security [L03, L04, Can06].

Another approach is to stick with UC security, but consider protocols that rely on some trust assumption on the system. Here the meaningfulness of the security guarantee hinges on the “reasonability” of the trust assumption, or in other words on the ability to realize the assumption in actual systems.

This survey studies some trust assumptions (or, models) that were recently proposed and shown to suffice for realizing essentially any cryptographic task in a universally composable way. The various trust models (also called “set-up models” in jargon) are compared to each other, and the relative strengths and weaknesses are discussed.

Organization. The survey is organized as follows. Section 2 provides a brief review of the UC security framework. Section 3 reviews the basic impossibility result for obtaining UC commitment in the plain model. Section 4 reviews the common reference string (CRS) model. We then study several relaxations of the CRS model, including the Defective CRS (aka “Sunspot”) model (Section 5) the Key Registration model (Section 6), and the Global Augmented CRS model (Section 7 reviews). We then turn to trust models of a different flavor: a model that puts trust in tamper-proof hardware (Section 8), and a model that trusts that messages are delivered with some bounded delays (Section 9). Section 10 briefly discusses trust models for the purpose of obtaining authenticated communication. Section 11 concludes and discussed some open problems.

2 UC security: A brief review

This section briefly reviews the UC framework. As in many other frameworks (e.g., [GL90, MR91, B91, C00, PW00, PW01]), the security of protocols with respect to a given task is defined via the “trusted party paradigm” [GMW87], where the protocol execution is compared with an ideal process where the outputs are computed by a trusted party that sees all the inputs. That is, a protocol is said to securely carry out a given task if running the protocol with a realistic adversary amounts to “emulating” the ideal process with the appropriate trusted party. We call the algorithm run by the trusted party an **ideal functionality**.

The UC framework substantiates this approach as follows. First, the process of executing a protocol in the presence of an adversary and in a given computational environment is substantiated. Next, the “ideal process” for carrying out the task is substantiated. Finally, one defines what it means for an execution of the protocol to “mimic” the ideal process. We sketch these three steps.

The model of protocol execution. The model for executing a multiparty protocol π consists of a system of computing elements (modeled as interactive Turing machines, or ITMs) $(\mathcal{Z}, \mathcal{A}, M_1, M_2, \dots)$ where \mathcal{Z} and \mathcal{A} are adversarial entities called the **environment** and **adversary**, respectively, and the machines M_1, M_2, \dots represent parties that run an “extended instance” of π . (An *instance* of protocol π is a set of ITMs that run π and in addition have a common identifier, called the *session ID*. The number of parties in an instance may vary from instance to instance, as well as during the lifetime of an instance.) Intuitively, the environment represents all the other protocols running in the system, including the protocols that provide inputs to, and obtain outputs from, the protocol instance under consideration. The adversary represents adversarial activities that are directly aimed at the protocol execution under consideration, including attacks on protocol messages and corruption of protocol participants.

An execution of the system consists of a sequence of activations of the individual elements, where the environment is activated first, and in each activation the active element determines the next element to be active, by sending information to it. This information may be labeled as either input, output, or protocol message. We impose the following restrictions on the way in which the above system runs. The environment \mathcal{Z} is allowed to provide only *inputs* to other machines. A party of π may send messages to \mathcal{A} , or give inputs to the environment. The adversary \mathcal{A} may give output to \mathcal{Z} , send messages to other parties, or corrupt parties. (Corrupting a party is modeled via sending a special message to that party.)

Let $\text{EXEC}_{\pi, \mathcal{A}, \mathcal{Z}}(z)$ denote the random variable (over the local random choices of all the involved machines) describing the output of environment \mathcal{Z} when interacting with adversary \mathcal{A} and parties running protocol π on input z as described above. Let $\text{EXEC}_{\pi, \mathcal{A}, \mathcal{Z}}$ denote the ensemble $\{\text{EXEC}_{\pi, \mathcal{A}, \mathcal{Z}}(z)\}_{z \in \{0,1\}^*}$. We restrict attention to the case where the environment outputs only a single bit; namely, the ensemble $\text{EXEC}_{\pi, \mathcal{A}, \mathcal{Z}}$ is an ensemble of distributions over $\{0,1\}$.

Subroutines. For the purpose of formulating the ideal process and the notion of protocol composition it will be convenient to allow designating an ITM as a *subroutine* of another ITM. If an ITM M is a subroutine of M' then M' can give input to M and M can give output to M' . Note that M and M' may have different session ID and run different codes. The above model of protocol execution is then extended in the natural way to protocols where the parties have subroutines, with the important restriction that the environment only provides inputs to and receives outputs from the parties of a single instance of π . In particular, the environment does not directly communicate with any subroutine of a party of that single instance.

Ideal functionalities and ideal protocols. Security of protocols is defined via comparing the protocol execution to an *ideal process* for carrying out the task at hand. For convenience of presentation, we formulate the ideal process for a task as a special protocol within the above model of protocol execution. (This avoids formulating an ideal process from scratch.) A key ingredient in this special protocol, called the **ideal protocol**, is an **ideal functionality** that captures the desired functionality, or the specification, of the task by way of a set of instructions for a “trusted party”.

That is, let \mathcal{F} be an ideal functionality (i.e., an algorithm for the trusted party). Then an instance of the ideal protocol $\text{IDEAL}_{\mathcal{F}}$ consists of **dummy parties**, plus a party \mathcal{F} that’s a subroutine of all the main parties. Upon receiving an input v , each dummy party forwards v as input to the subroutine \mathcal{F} . Any subroutine output coming from \mathcal{F} is forwarded by the dummy party as subroutine output for the environment. We note that \mathcal{F} can model reactive computation, in the sense that it can maintain local state and its outputs may depend on all the inputs received and all random choices so far. In addition, \mathcal{F} may receive messages directly from the adversary \mathcal{A} , and may contain instructions to send messages to \mathcal{A} . This “back-door channel” of direct communication between \mathcal{F} and \mathcal{A} provides a way to *relax* the security guarantees provided \mathcal{F} . Specifically, by letting \mathcal{F} take into account information received from \mathcal{A} , it is possible to capture the “allowed influence” of the adversary on the outputs of the parties, in terms of both contents and timing. By letting \mathcal{F} provide information directly to \mathcal{A} it is possible to capture the “allowed leakage” of information on the inputs and outputs of the parties.

Protocol emulation. It remains to define what it means for a protocol to “mimic” or “emulate” the ideal process for some task. As a step towards this goal, we first formulate a more general notion of emulation, which applies to any two protocols. Informally, protocol π emulates protocol ϕ if, from the point of view of any environment, protocol π is “just as good” as ϕ , in the sense that no environment can tell whether it is interacting with π and some (known) adversary, or with ϕ and some other adversary. More precisely:

Definition (protocol emulation): Protocol π UC-emulates protocol ϕ if for any adversary \mathcal{A} there exists an adversary \mathcal{S} such that, for any environment \mathcal{Z} the ensembles $\text{EXEC}_{\pi, \mathcal{A}, \mathcal{Z}}$ and $\text{EXEC}_{\phi, \mathcal{S}, \mathcal{Z}}$ are indistinguishable. That is, on any input, the probability that \mathcal{Z} outputs 1 after interacting with \mathcal{A} and parties running π differs by at most a negligible amount from the probability that \mathcal{Z} outputs 1 after interacting with \mathcal{S} and ϕ .

Once the general notion of protocol emulation is defined, the notion of realizing an ideal functionality is immediate:

Definition (realizing functionalities): Protocol π UC-realizes an ideal functionality \mathcal{F} if π emulates $\text{IDEAL}_{\mathcal{F}}$, the ideal protocol for \mathcal{F} .

2.1 The composition theorem

As in the case of protocol emulation, we present the composition operation and theorem in the more general context of composing two arbitrary protocols. The case of composing ideal protocols follows as a special case.

The universal composition operation. The universal composition operation is a natural generalization of the “subroutine substitution” operation for sequential algorithms to the case of distributed protocols. That is, let ρ be a protocol that contains instructions to call protocol ϕ as a subroutine, and let π be a protocol that UC-emulates ϕ . The composed protocol, denoted $\rho^{\pi/\phi}$, is the protocol that is identical to ρ , except that each instruction to call protocol ϕ is replaced with an instruction to call protocol π with the same parameters as inputs. Similarly, any output from a party running π is treated as an input from a party running ϕ . In particular, if some party running ρ calls multiple instances of ϕ , differentiated via their session IDs, then the corresponding instance of $\rho^{\pi/\phi}$ will use multiple instances of π .

The composition theorem. In its general form, the composition theorem says that if protocol π UC-emulates protocol ϕ then, for any protocol ρ , the composed protocol $\rho^{\pi/\phi}$ emulates ρ . This can be interpreted as asserting that replacing calls to ϕ with calls to π does not affect the behavior of ρ in any distinguishable way.

There is one caveat: For this result to hold we need that protocols π and ρ are “nice” in that only the main parties of the protocol have I/O with the outside world. More precisely, say that a protocol π is *subroutine respecting* if only the main parties of any instance of π receive input from external parties and send output to external parties. In particular, subroutines of the main parties, and subroutines thereof, do not directly get inputs from or send outputs to an external party. Then:

Theorem (universal composition): Let ρ, ϕ, π be subroutine respecting protocols such that ρ uses ϕ as subroutine and π UC-emulates ϕ . Then protocol $\rho^{\pi/\phi}$ UC-emulates ρ . In particular, if ρ UC-realizes an ideal functionality \mathcal{G} then so does $\rho^{\pi/\phi}$.

A first, immediate corollary of the general theorem states that if protocol ρ makes subroutine calls to protocol $\text{IDEAL}_{\mathcal{F}}$, the ideal protocol for \mathcal{F} , and protocol π UC-realizes \mathcal{F} , then the composed protocol $\rho^{\pi/\phi^{\mathcal{F}}}$ UC-emulates ρ . Another corollary is that if ρ UC-realizes an ideal functionality \mathcal{G} , then so does $\rho^{\pi/\phi}$.

Remark: On the universality of universal composition. Many different ways of “composing together” protocols into larger systems are considered in the literature. Examples include sequential, parallel, and concurrent composition, of varying number of protocol instances, where the composed instances are run either by the same set of parties or by different sets of parties, use either the same program or different programs, and have either the same input or different inputs. A more detailed discussion appears in [Can06].

We observe that all of these composition methods can be captured as special cases of universal composition. That is, any such method for composing together protocol instances can be captured by an appropriate “calling protocol” ρ that uses the appropriate number of protocol instances as subroutines, provides them with appropriately chosen inputs, and arranges for the appropriate synchronization in message delivery among the various subroutine instances. Consequently, it is guaranteed that a protocol that UC-realizes an ideal functionality \mathcal{F} continues to UC-realize \mathcal{F} even when composed with other protocols using any of the composition operations considered in the literature.

2.2 Generalized UC security

In the UC framework, as presented so far, the UC theorem applies only for protocols which are subroutine respecting. This simplifies the model and the analysis of protocols within it, since it allows considering only a single execution of the analyzed protocol with an adversary and environment. However, this modeling does not allow arguing about security in those interesting cases where the same computational entity is used as a subroutine within multiple protocol instances.

The generalized UC (GUC) framework [CDPW07] allows arguing about such situations. Specifically, the model of protocol execution is modified so that the environment can create and interact with other entities, in addition to the adversary and the parties of a single instance of the analyzed protocol, π . These additional entities may in turn provide inputs to and get outputs from participants in π and their subroutines. Say that protocol π GUC-emulates protocol ϕ if π UC-emulates ϕ with the modified protocol execution model. In [CDPW07] it is shown that, within the GUC framework, the UC theorem holds even with respect to protocols that are not subroutine respecting:

Theorem (generalized universal composition): *Let ρ, ϕ, π be protocols such that ρ uses ϕ as subroutine and π GUC-emulates ϕ . Then protocol $\rho^{\pi/\phi}$ GUC-emulates ρ . In particular, if ρ GUC-realizes an ideal functionality \mathcal{G} then so does $\rho^{\pi/\phi}$.*

Two results surveyed here use this generalized model, for different purposes. One is the modeling of the augmented CRS model in [CDPW07], with the purpose of modeling trusted information that’s available to more than one protocol instance. The other is the modeling of “defective” reference strings in [CPS07], for the purpose of capturing reference strings whose distribution is controlled by the environment.

3 Prologue: Impossibility of UC commitment

We recall some basic results regarding realizability of functionalities in the UC framework. These results shape the search for better trust assumptions.

In a nutshell, the natural formulations of Commitment, Zero-Knowledge, Coin Tossing, or Oblivious Transfer as ideal functionalities within the UC framework turn out to be “complete” for UC realizability. That is, UC-realizing any one of these functionalities is necessary and sufficient for obtaining general realizability results for practically any ideal functionality.

In other words, there exist ideal functionalities, called \mathcal{F}_{COM} , \mathcal{F}_{ZK} , $\mathcal{F}_{\text{COIN}}$, \mathcal{F}_{OT} , that naturally capture the security requirements from the corresponding primitives, and such that it is possible to UC-realize any “well-formed” ideal functionality by protocols that use any one of these functionalities as subroutines (see, e.g. [CLOS02]).

Furthermore, it is impossible to UC-realize any one of these functionalities via two-party protocols in the plain model.

Here we briefly recall the impossibility result for UC-realizing the ideal commitment functionality, \mathcal{F}_{COM} . Impossibility for the other primitives follow similar lines; some can even be obtained by reduction to the case of \mathcal{F}_{COM} . Let us first recall the formulation of \mathcal{F}_{COM} .

The ideal commitment functionality. The ideal commitment functionality, \mathcal{F}_{COM} , formalizes the “sealed envelope” intuition in a straightforward way. That is, when receiving from the committer C an input requesting to commit to value x to a receiver R , \mathcal{F}_{COM} records (x, R) and notifies R and the adversary that C has committed to some value. (Notifying the adversary means that the fact that a commitment took place need not be hidden.) The opening phase is initiated by the committer inputting a request to open the recorded value. In response, \mathcal{F}_{COM} outputs x to R and the adversary. (Giving x to the adversary means that the opened value can be publicly available.)

In order to correctly handle adaptive corruption of the committer during the course of the execution, \mathcal{F}_{COM} responds to a request by the adversary to corrupt C by first outputting a corruption output to C , and then revealing the recorded value x to the adversary. In addition, if the **Receipt** value was not yet delivered to R , then \mathcal{F}_{COM} allows the adversary to modify the committed value. This last stipulation captures the fact that the committed value is fixed only at the end of the commit phase, thus if the committer is corrupted during that phase then the adversary might still be able to modify the committed value. (Corruption of the

receiver does not require any move.)

\mathcal{F}_{COM} is described in Figure 1. For brevity, we use the following terminology: The instruction “send a delayed output x to party P ” should be interpreted as “send (x, P) to the adversary; when receiving ok from the adversary, output x to P .”

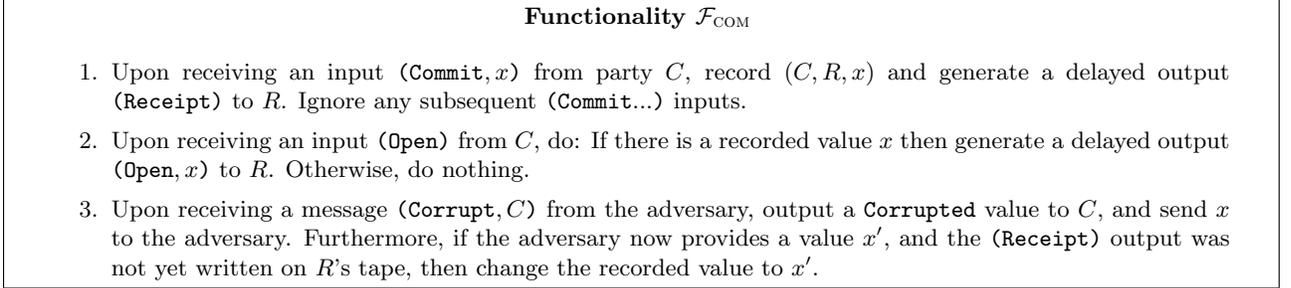

Figure 1: The Ideal Commitment functionality, \mathcal{F}_{COM}

Impossibility of realizing \mathcal{F}_{COM} in the plain model. Roughly speaking, the requirements from a protocol that UC-realizes \mathcal{F}_{COM} boil down to the following two requirements from the ideal-process adversary (simulator) \mathcal{S} . (a). When the committer is corrupted (i.e., controlled by the adversary), \mathcal{S} must be able to “extract” the committed value from the commitment. That is, \mathcal{S} has to come up with a value x such that the committer will almost never be able to successfully decommit to any $x' \neq x$. This is so since in the ideal process \mathcal{S} has to explicitly provide \mathcal{F}_{COM} with a committed value. (b). When the receiver is uncorrupted, \mathcal{S} has to be able to generate a “simulated commitment” c that looks like a real commitment and yet can be “opened” to any value, to be determined at the time of opening. This is so since \mathcal{S} has to provide adversary \mathcal{A} and environment \mathcal{Z} with the simulated commitment c before the value committed to is known. All this needs to be done *without rewinding the environment* \mathcal{Z} .

Intuitively, these requirements look impossible to meet: A simulator that has the above abilities can be used by a dishonest receiver to “extract” the committed value from an honest committer. This intuition can indeed be formalized to show that in the plain model it is impossible to UC-realize \mathcal{F}_{COM} by a two-party protocol. Essentially, the proof proceeds as follows. Let π be a protocol that UC-realizes \mathcal{F}_{COM} . Consider an execution of π by an adversarially controlled committer C and an honest receiver R , and assume that the adversary merely sends messages that are generated by the environment, and delivers to the environment any message received from R . The environment, \mathcal{Z}_C , secretly picks a random bit b at the beginning and generates the messages for C by running the protocol of the honest committer for b and R 's answers. Once \mathcal{Z}_C received a “receipt” output from R , it starts running the honest opening protocol in the name of C . Finally, \mathcal{Z}_C outputs 1 iff the b' that R outputs equals the secret bit b . We know that the in an execution of π with honest receiver and committer, in the opening stage the receiver always outputs the bit committed to by the committer. However, since π UC-realizes \mathcal{F}_{COM} , there should exist an ideal-model adversary \mathcal{S} that interacts with \mathcal{F}_{COM} and generates a view for \mathcal{Z}_C that is indistinguishable from a real execution with π . In particular, it must also be the case that $b = b'$ almost always even in the ideal process. For this to hold, it must be that \mathcal{S} must have given to \mathcal{F}_{COM} the correct bit b at the commitment stage. Now, given \mathcal{S} , we can construct another environment, \mathcal{Z}_R , and a corrupted receiver \mathcal{A}_R , such that \mathcal{Z}_R successfully distinguishes between an execution of π and an interaction with \mathcal{F}_{COM} and *any* adversary \mathcal{S}_R . \mathcal{Z}_R and \mathcal{A}_R proceed as follows: \mathcal{Z}_R chooses a random bit b and hands b as input to the honest committer C . It then waits to receive a bit b' from \mathcal{A}_R (which controls the receiver). \mathcal{Z}_R outputs 1 iff $b = b'$. \mathcal{A}_R proceeds as follows: Recall that \mathcal{S} can “extract” the committed bit b via simple interaction with the committers messages, without rewinding or any additional information. Therefore, \mathcal{A}_R can simply run \mathcal{S} and guess b almost always. In contrast, when \mathcal{Z}_R interacts with \mathcal{F}_{COM} , the adversary’s view is independent of b , and thus $b = b'$ with probability exactly one half.

In a nutshell, what allows the proof to go through is the fact that \mathcal{S} can extract the committed bit by simple interaction with an honest committer. This allows the adversary \mathcal{A}_R to run \mathcal{S} and extract the hidden bit as well.

4 The Common Reference String model

The common reference string model, first proposed in [BFM88] and used extensively since, assumes that the parties have access to a common string that is guaranteed to come from a pre-specified distribution. Furthermore, it is guaranteed that the string was chosen in an “opaque” way, namely that no information related to the process of choosing this string is available to any party. A very natural distribution for the common string, advocated in [BFM88], is the uniform distribution over the strings of some length. Still, it is often useful to consider reference strings that are taken from other distributions.

In the Zero-Knowledge context of [BFM88], the fact that the reference string comes from an external source that is unrelated to the actual computation is captured by allowing the simulator to choose the reference string as it wishes — as long as the adversary cannot distinguish this “simulated string” from a “real string” taken from the prescribed distribution. Indeed, it is this extra freedom given to the simulator which makes this model powerful.

Within the present framework, the CRS model can be captured in a natural way by modeling the reference string as coming from an appropriate ideal functionality. More specifically, we formulate functionality \mathcal{F}_{CRS} , presented in Figure 2 below. The functionality is parameterized by a distribution D and a set \mathcal{P} of recipients of the reference string. Upon invocation, it first draws a value r from distribution D . Next, on input from a party $P \in \mathcal{P}$, $\mathcal{F}_{\text{CRS}}^D$ returns r to P .

Letting the adversary know r models the fact that r is public, and cannot be assumed secret. Prohibiting parties not in \mathcal{P} (and, in particular, the environment) from obtaining r directly from \mathcal{F}_{CRS} models the fact that r is treated as local to a specific protocol instance, and is intended to be used only within this protocol instance. (We further elaborate on this point in Section 7.) Other protocol instances should use independent “draws” from distribution D . This restriction on the use of the reference string limits the applicability of the CRS model: To realize \mathcal{F}_{CRS} in reality, the participants of each protocol execution need to somehow “get together” and obtain a reference string that they all trust to be taken from the specified distribution. The next sections discuss trust assumptions that are aimed at mitigating this limitations in a number of different ways.

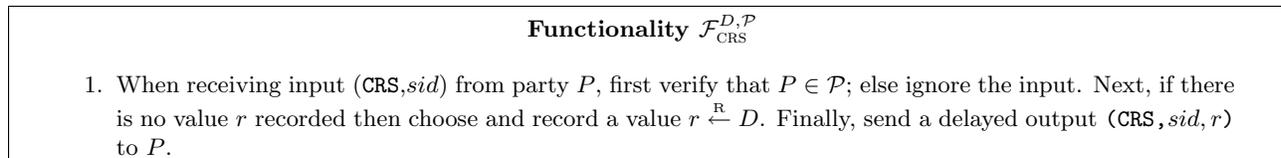

Figure 2: The Common Reference String functionality

From \mathcal{F}_{CRS} to \mathcal{F}_{COM} . Several protocols that UC-realize \mathcal{F}_{COM} given access to \mathcal{F}_{CRS} are known. Here we briefly sketch the protocol of [CF01]. What “saves” the simulator in the CRS model from the above impossibility result is the following observation, which parallels the original CRS model of [BFM88]: When interacting with a commitment protocol that used \mathcal{F}_{CRS} , the environment learns about the value of the reference string only from the adversary. This means that, in the ideal process for \mathcal{F}_{COM} , the simulator can choose the reference string on its own. Consequently, the simulator can know some “trapdoor information” associated with the reference string, and even change its distribution slightly.

The [CF01] commitment protocol uses this observation as follows. The reference string consists of a public key e of an encryption scheme and a claw-free pair of permutations f_0, f_1 with trapdoor. (That is, given only the description f_0, f_1 it is infeasible to find x_0, x_1 such that $f_0(x_0) = f_1(x_1)$, but given a trapdoor t one can efficiently invert, say, f_0 .) Now, to commit to bit b , the committer chooses a random value r and sends the commitment message $(f_b(r), E_e(r_0, id), E_e(r_1, id))$ where $r_b = r$, $r_{1-b} = 0$, and id is an identifier for the session. (Typically, id would include the identities of the committer and receiver, plus additional commitment-specific information.) To open to bit b , the committer sends r and the randomness used for encrypting r ; this is the first or second encryption, depending on b .¹ Now, in a standard execution of the

¹The actual protocol is slightly different, to account for adaptive corruptions.

protocol the commitment is committing (due to the claw-freeness of f_0, f_1), and hiding (due to the security of the encryption scheme). However, in a simulated execution the simulator can know both t and the decryption key associated with e . It can thus easily generate commitment strings that can be opened both ways, and at the same time it can easily extract the hidden value committed in an honestly generated commitment. When the encryption scheme is secure against chosen ciphertext attacks, it can be shown that the simulator can successfully extract the hidden value even when the commitment string is chosen adversarially. This idea is at the basis of the proof of security of the protocol.

We note that the above protocol can generate multiple commitments using a single reference string. In other words, it actually realizes a “multi-session version” of \mathcal{F}_{COM} , where a single instance allows multiple parties to commit and open multiple commitments. (This multi-session version is called $\mathcal{F}_{\text{MCOM}}$ in the literature.) This somewhat alleviates the need to agree on a different reference string for each protocol instance, since a single instance of the above protocol suffices for generating commitments for an entire system. However, the solution is far from satisfying: First, strictly speaking, all protocol instances that use the same commitment protocol now have some joint state and can no longer be analyzed separately and be composed later. Second, no security guarantee is given with respect to other protocols that use the same reference string in other ways than via that global instance of the commitment protocol. The first issue is handled by the Universal Composition with Joint State (JUC) theorem of [CR03]. The second issue is more subtle and is addressed in Section 7.

5 Dealing With a “Defective” Reference String

The CRS model guarantees that the reference string is drawn from a pre-specified distribution. This is a very convenient abstraction for the purpose of designing protocols. Indeed, all existing protocols use this guarantee in a crucial sense: Security analyses quickly fall apart whenever the distribution of the reference string is changed even slightly.

This situation is quite limiting. In particular, it seems to rule out “physical implementations” where the reference string is taken to be the result of joint measurement of some physical phenomenon such as astronomic measurements, fluctuations of the stock market, or even network delays across the Internet. Indeed, while it is reasonable to believe that such phenomena are largely unpredictable and uncontrollable, namely they have “high entropy”, it is a stretch of the imagination to believe that they are taken from a distribution that is known to and useful for the protocol designer.

Can composable security be obtained if we only have an *imperfect* reference string, or alternatively a reference string that are adversarially controlled to some extent? More specifically, are there protocols that UC-realize, say, \mathcal{F}_{COM} in such a setting?

A first indication that this might not be an easy task is the result of Dodis et. al. [DOPS04] that demonstrates the impossibility of NIZK in a relaxed variant of the CRS model in which the distribution of the reference string can be arbitrary subject to having some minimal min-entropy. However, this result does not rule out composable protocols; more importantly, it does not consider the case where the reference string is guaranteed to be taken from an efficiently samplable distribution. Indeed, for such distributions deterministic extractors are known to exist (under computational assumptions) [TV00]. Thus, one might expect it to be possible to “compile” any protocol in the CRS model (or at least protocols that can do with a uniformly distributed reference string) into a protocol that uses a reference string that is taken from any efficiently samplable distribution that has sufficient min-entropy: First have the parties use a deterministic extractor to transform the reference string into a string that is almost uniformly distributed. Next, run the original protocol. Since the extracted string is almost uniform, one might expect the original analysis to work in the same way.

However, deterministic extractability turns out to be insufficient for this purpose. In fact, it turns out that if one relaxes \mathcal{F}_{CRS} so as to allow the distribution to be adversarially determined, then UC-realizing \mathcal{F}_{COM} becomes impossible [CPS07]. Impossibility holds even if the chosen distribution is guaranteed to have full min-entropy minus a polynomially vanishing fraction, even if the distribution is guaranteed to be sampled via an *algorithmic* process, namely via a sampling process that has a relatively succinct description, and even when this process is guaranteed to be computationally efficient.

As a recourse, one may restrict attention to the case where the algorithm for sampling the reference string is known to the adversaries involved. (Still, it is of course unknown to the protocol.) Here it turns out to be possible to UC-realize \mathcal{F}_{COM} , as long as the reference string is taken from a distribution that is guaranteed to have a polynomial time sampling algorithm, a short description, and super-logarithmic min-entropy. Furthermore, all three conditions are simultaneously necessary, in the sense that impossibility holds as soon as any one of the conditions is relaxed [CPS07].

It may appear over-optimistic to assume that the physical (or man-made) phenomena used to generate the reference string are governed by distributions where the sampling algorithm is computable in polynomial time. Indeed, why should Nature be governed by succinct and efficient algorithms? However, beyond the technical fact that these restrictions are necessary, one can view our analysis as a proof that any successful attack against the proposed protocols demonstrates that either the underlying hardness assumptions are violated, *or else that the process for choosing the reference string is not efficiently computable, or has long description*. This might be an interesting revelation in itself. Alternatively, the positive result may be interpreted as addressing situations where the process of choosing the reference string is influenced by an actual attacker. Here the guarantee that the distribution has some min-entropy represents the fact that the attacker’s influence on the sampling process is limited.

A more detailed description. We describe the results of [CPS07] in some more detail. Three relaxations of $\mathcal{F}_{\text{CRS}}^{\mathcal{P},D}$ are formulated. The first relaxation, called $\mathcal{F}_{\text{BBSUN}}$, proceeds as follows. (Here SUN stands for “sunspots”, which is the term used in the first works that propose the CRS model when referring to astronomic observations [BFM88, F88] and BB stands for “black-box”). Instead of treating the distribution D as a fixed, public parameter, let the environment determine the distribution by providing a description of a sampling algorithm for D . Then, $\mathcal{F}_{\text{BBSUN}}$ chooses a sufficiently long random string ρ and computes the reference string $r = D(\rho)$. In addition, $\mathcal{F}_{\text{BBSUN}}$ lets the adversary (and simulator) obtain additional independent samples from the distribution “on the side”. These samples are not seen by the environment or the parties running the protocol.

Three parameters of $\mathcal{F}_{\text{BBSUN}}$ turn out to be salient. First is the min-entropy, or “amount of randomness” of the reference string (measured over the random choices of both the environment and the sunspot functionality). Next is the runtime, or computational complexity of the sampling algorithm D . Last is the description-size of D (namely, the number of bits in its representation as a string); this quantity essentially measures the amount of randomness in the reference string that comes from the random choices of the environment. All quantities are measured as a function of the length n of the reference string; that is, we treat n as the security parameter. We have:

Theorem: There exist no two-party protocols that UC-realize \mathcal{F}_{COM} when given access to $\mathcal{F}_{\text{BBSUN}}$. This holds even if the distribution of the reference string is guaranteed to have min-entropy greater than $n - n^\epsilon$, and even if both the description size and the computational complexity of the provided sampling algorithm are guaranteed to be at most n^ϵ , for any $\epsilon > 0$. \square

Next a more restricted setting is considered, where the adversary has access to the “code”, or description of the sampling algorithm D . This is modeled by having the functionality that generates the reference string explicitly send the description of D to the adversary. (Note that this relaxation is meaningful only for sampling algorithms that can be described in $\text{poly}(n)$ bits, else the adversary cannot read the description.) Call this functionality $\mathcal{F}_{\text{GBSUN}}$ (the GB stands for “gray box”). The third variant, called \mathcal{F}_{SUN} , gives to the adversary also the local random choices used to generate the reference string. It turns out that this variant provides an incomparable setup guarantee to that of $\mathcal{F}_{\text{GBSUN}}$. (This is so since the setup functionality is invoked directly by the environment. Consequently, the functionality exists both in the real-life and in the ideal models.)

Theorem: There exist no two-party protocols that UC-realize \mathcal{F}_{COM} when given access to either $\mathcal{F}_{\text{GBSUN}}$ or \mathcal{F}_{SUN} . This holds even if either one of the following holds

1. The computational complexity of the sampling algorithm can be super-polynomial in n , as long as the distribution of the reference string is guaranteed to have min-entropy $n - \text{poly} \log n$, and the description size of the provided sampling algorithm is guaranteed to be at most $\text{poly} \log n$ (assuming one-way functions with sub-exponential hardness).

2. The description size of the sampling algorithm is at least $\mu(n) - \log n$, as long as the distribution of the reference string is guaranteed to have min-entropy $\mu(n) = n$ and the computational complexity is guaranteed to be at most $O(n)$.
3. The distribution of the reference string has min-entropy at most $\log n$, as long as the description length is $O(1)$ and the computational complexity is $O(n)$. \square

On the other hand, we have:

Theorem: Assume there exist collision-resistant hash functions, dense crypto-systems and one-way functions with sub-exponential hardness. Then there exists a two-party protocol that UC-realizes $\mathcal{F}_{\text{MCOM}}$, when given access to $O(1)$ instances of either $\mathcal{F}_{\text{GBSUN}}$ or \mathcal{F}_{SUN} , as long as it is guaranteed that the min-entropy of the reference string is at least $\mu(n) = \text{poly log } n$ the computational complexity of the provided sampling algorithm is at most $\text{poly}(n)$ and its description size is at most $\mu(n) - \text{poly log } n$. \square

Furthermore, the protocol from Theorem 3 withstands even adaptive party corruptions, with no data erasure, whereas Theorems 1 and 2 apply even to protocols that only withstand static corruptions.

In other words, under computational assumptions, Theorem 2 and 3 provide an essentially tight characterization of the feasibility of UC protocols, in terms of the min-entropy, computational complexity and description length of the reference string. Informally,

UC-security of non-trivial tasks is possible if and only if the reference string has min-entropy at least $\mu(n) = \text{poly log } n$, and is generated by a computationally-efficient sampling algorithm with description length at most $\mu(n) - \text{poly log } n$.

Techniques for the impossibility results. The impossibility results combine the [CF01] proof of impossibility of UC-realizing \mathcal{F}_{COM} in the plain model with techniques from [GK89]. Recall that the model does not let the environment see the reference string directly, which in principle allows the simulator to present the environment with any string of its choosing and claim that this is the reference string chosen in the execution. To mitigate this freedom, the environment chooses a special distribution D that makes sure that the string presented by the simulator as the actual reference string can only be one of the strings that the simulator received as “extra samples” from the functionality. Since the simulator can only ask for a polynomial number of such samples, it can be seen that a dishonest verifier can still use the simulator to extract the committed bit from an honest committer, much as in the proof of [CF01], and with only polynomial degradation in success probability. All impossibility results use this idea, with different techniques or choosing the distribution D so as to obtain the desired effect.

Protocol techniques. To explain the main idea behind the protocol, it is useful to first sketch a simpler protocol that is only secure with respect to static corruptions. Also, the protocol aims to realize the zero-knowledge functionality, \mathcal{F}_{ZK} , rather than $\mathcal{F}_{\text{MCOM}}$. The idea is to use a variation on Barak’s protocol [B01]: Let L be an NP language and assume that a prover P wishes to prove to a verifier V that $x \in L$, having access to a reference string r that is taken from an unknown distribution with min-entropy at least $\mu = n^\epsilon$. Then, P and V will engage in a witness-indistinguishable proof that “either $x \in L$ or the reference string r has a description of size $\mu/2$ ”. (As in Barak’s protocol, the description size is measured in terms of the Kolmogorov complexity, namely existence of a Turing machine M with description size $\mu/2$ that outputs r on empty input. Also, in order to guarantee that the protocol is simulatable in polynomial-time M should be polynomial time.) Soundness holds because in a real execution of the protocol, r is taken from a distribution with min-entropy at least μ , so the second part of the “or” statement is false with high probability. To demonstrate zero-knowledge, the simulator generates a simulated reference string \tilde{r} by running the sampling algorithm D for the distribution on a pseudorandom random-input. That is, the simulator chooses a random string $\tilde{\rho}$ of length, say, $\mu/2 - |D|$ (where $|D|$ denotes the description size of D) and computes $\tilde{r} = D(G(\tilde{\rho}))$, where G is some length-tripling pseudo-random generator. Now, \tilde{r} indeed has description of size $\mu/2$ (namely, $\tilde{\rho}$ plus $|D|$ plus the constant-size description of G); furthermore, the simulator knows this description. Also, since both D and the environment are polynomial time, the simulated string \tilde{r} is indistinguishable from the real string r .

The above protocol allows for straight-line simulation. It is not yet straight-line extractable, but it can be modified to be so using the techniques of [BL04]. Still, it is only secure against *static* corruptions of parties.

In order to come up with a protocol that withstands *adaptive* corruptions a somewhat different technique is used, which combines the above idea with techniques from [CDPW07]. First, they move to realizing $\mathcal{F}_{\text{MCOM}}$. They then proceed in several steps: The first step is to construct a commitment scheme that is *equivocal* and adaptively secure. This is done using Feige and Shamir’s technique [FS89] for constructing equivocal commitments from Zero-Knowledge protocols such as the one described above. Next, the constructed equivocal commitment scheme is used in a special type of a coin-tossing protocol, and use the obtained coin tosses as a reference string for a standard UC commitment protocol such as [CF01].

The protocol allows *two* parties to perform *multiple* commitment and decommitment operations between them, using only *two* reference strings —one for the commitments by each party. This means that in a multi-party setting it is possible to realize any ideal functionality using one reference string for each (ordered) pair of parties, regardless of the number of commitments and decommitment performed. Furthermore, each reference string needs to be trusted only by the two parties who use it.

6 The Key Registration Model

The CRS model has the advantage that it only requires the parties to obtain a single short string. In particular, it does not require parties to identify themselves or to go through a registration process before participating in a protocol. Thus, in settings where it is reasonable to assume that such a reference string is physically available, this model is very attractive. However, when the reference string is being generated by a computational entity that may be corrupted or subverted, the CRS modeling is somewhat unsatisfactory, in that it puts complete trust in a single entity. In fact, this entity, if subverted, can completely undermine the security of the protocol by choosing the reference string from a different distribution, or alternatively by leaking to some parties some secret information related to the string. Furthermore, it may be able to do so without being detected.

The key registration functionality, \mathcal{F}_{KS} , formulated in [BCNP04] and presented in Figure 3, is written in a way that can be realized by real-world mechanisms that do not require all participants to put full trust in a single entity. We first describe the functionality and its use, and then discuss how it can be realized.

\mathcal{F}_{KS} is parameterized by a set \mathcal{P} of parties and a deterministic function $f : \{0, 1\}^* \rightarrow \{0, 1\}^*$, that represents a method for computing a public key given a secret (and supposedly random) key. The functionality allows parties to register their identities together with an associated “public key”. However, \mathcal{F}_{KS} provides only relatively weak guarantees regarding this public key, giving the adversary considerable freedom in determining this key. (This freedom is what makes \mathcal{F}_{KS} so relaxed.) Specifically, the “public key” to be associated with a party upon registration is determined as follows. The functionality keeps a set R of “good public keys”. Upon receiving a registration request from party $P \in \mathcal{P}$, the functionality first notifies the adversary that a request was made and gives the adversary the option to set the registered key to some key p that is already in R . If the adversary declines to set the registered key, then the functionality determines the key on its own, by choosing a random secret r from a given domain (say, $\{0, 1\}^k$ for a security parameter k) and letting $p = f(r)$. Once the registered key p is chosen, the functionality records (P, p) and returns p to P and to the adversary. Finally, if p was chosen by the functionality itself then p is added to R . If the registering party is corrupted, then the adversary can also specify, if it chooses, an arbitrary “secret key” r . In this case, P is registered with the value $f(r)$ (but r is not added to R).

A retrieval request, made by a party in \mathcal{P} , for the public key of party P is answered with either an error message \perp or one of the registered public keys of P , where the adversary chooses which registered public key, if any, is returned. (That is, the adversary can prevent a party from retrieving any of the registered keys of another party.)

Notice that the uncorrupted parties do not obtain any secret keys associated with their public keys, whereas the corrupted parties may know the secret keys of their public keys. This means that protocols designed in this model cannot use the secret keys. Still, security is guaranteed even if corrupted parties obtain their secret key. Furthermore, \mathcal{F}_{KS} gives the adversary a fair amount of freedom in choosing the registered keys. It can set the keys associated with corrupted parties to be any arbitrary value (as long as the functionality received the corresponding private key). The adversary can also cause the keys of both corrupted and uncorrupted parties to be identical to the keys of other (either corrupted or uncorrupted)

Functionality $\mathcal{F}_{\text{KS}}^{\mathcal{P},f}$

$\mathcal{F}_{\text{KS}}^f$ proceeds as follows, given set \mathcal{P} of identities, function f and security parameter k . At the first activation a set R of strings is initialized to be empty.

Registration: When receiving input (**Register**, sid) from a party P , verify that that $P \in \mathcal{P}$; else ignore the input. Next, send (**Register**, sid, P) to the adversary, and receive a value p' from the adversary. Then, if $p' \in R$ then let $p \leftarrow p'$. Else, choose $r \xleftarrow{\mathcal{R}} \{0, 1\}^k$, let $p \leftarrow f(r)$, and add p to R . Finally, record (P, p) and return (sid, p) to P and to the adversary.

Registration by a corrupted party: When receiving input (**Register**, sid, r) from a corrupted party $P \in \mathcal{P}$, record $(P, f(r))$. In this case, $f(r)$ is *not* added to R .

Retrieval: When receiving a message (**Retrieve**, sid, P) from party $P' \in \mathcal{P}$, send (**Retrieve**, sid, P, P') to the adversary and obtain a value p in return. If (P, p) is recorded then return (sid, P, p) to P' . Else, return (sid, P, \perp) to P' .

Figure 3: The Key Registration functionality

parties. Still, \mathcal{F}_{KS} guarantees two basic properties: **(a)** the public keys of good parties are “safe” (in the sense that their secret keys were chosen at random and kept secret from the adversary), and **(b)** the public keys of the corrupted parties are “well-formed”, in the sense that the functionality received the corresponding private keys.

In [BCNP04] it is shown how to UC-realize $\mathcal{F}_{\text{MCOM}}$ given access to \mathcal{F}_{KS} . A non-interactive protocol for realizing \mathcal{F}_{ZK} given access to \mathcal{F}_{KS} is also shown. The protocol for realizing $\mathcal{F}_{\text{MCOM}}$ is essentially identical to the [CF01] protocol described in section 4; the only difference is that the claw-free pair f_0, f_1 is now the public key of the receiver, whereas the encryption key e is now the public key of the committer. Intuitively, this works since the committer is only concerned that the secret decryption key associated with e remains unknown, whereas the receiver is only concerned that the trapdoor t of f_0, f_1 remains unknown. We note, however, that this protocol remains secure only for non-adaptive party corruption.

Realizing \mathcal{F}_{KS} . \mathcal{F}_{KS} can be realized in a number of different ways. First, we observe that $\mathcal{F}_{\text{KS}}^{\mathcal{P},f}$ can be realized in the $\mathcal{F}_{\text{CRS}}^{\mathcal{P},D}$ -hybrid model, where $D = D_k$ is the distribution of $f(r)$ for r that is uniform in $\{0, 1\}^k$. The protocol is straightforward: On input either (**Register**, sid) or (**Retrieve**, sid, P), party P sends (CRS, sid) to \mathcal{F}_{CRS} and returns the obtained value.

Realizing \mathcal{F}_{KS} given a distributed registration service. Consider a setting where the parties have access to registration servers where parties can register and obtain public keys that were chosen at random according to a given distribution (i.e., the public key is $f(r)$ for an $r \xleftarrow{\mathcal{R}} \{0, 1\}^k$). Alternatively, parties can choose their keys themselves and provide them to the server. Note that here each party needs to put full trust (to keep its key secret) only in the server it registers with. The trust put in other servers is much lower - it only needs to be trusted that the public keys obtained from these servers are “well formed”.

Realizing \mathcal{F}_{KS} using traditional proofs of knowledge. Finally, it is possible to realize $\mathcal{F}_{\text{KS}}^f$ via traditional (non-UC) proofs of knowledge of the private key, under the assumption that the proofs of knowledge occur when there is no related network activity. (Intuitively, in this case it is ok to “rewind” the environment, as necessary to prove security of the traditional proof of knowledge. A more formal treatment might assume access to the non-concurrent functionality in [C01].)

7 Globally Available Trusted Information

All the trust models considered so far model the trusted information as information that’s available only to the participants of a single protocol instance. This means that, in order to implement such a model, one has to generate a fresh reference string (or fresh public keys) for each instance of a protocol that uses it. Furthermore, this has to be done in a way that makes the reference string available only to the protocol participants. While such implementations are possible (say, via joint measurements of physical phenomena

at the onset of an execution), this is a severe limitation. In particular, this modeling stands in contrast with the prevalent intuitive perception of the reference string (or public key infrastructure) as a “global” construct that is chosen in advance and made available to all throughout the lifetime of the system.

To exemplify this point, consider the “non-transferability” (or, “deniability”) concern, namely allowing party A to interact with party B in a way that prevents B from later “convincing” a third party, C , that the interaction took place. Indeed, if A and B interact via an idealized “trusted party” that communicates only with A and B then deniability is guaranteed in a perfect, idealized way. Thus, intuitively, if A and B interact via a protocol that emulates the trusted party, then deniability should hold just the same. When the protocol in question uses no trusted information, or alternatively trusted information that’s local to each protocol instance, this intuition works, in the sense that UC-realizing such a trusted party automatically implies non-transferability. However, when the trusted information is available globally, this is no longer the case: There are protocols that emulate such a trusted party but do *not* guarantee non-transferability.

For instance, consider the case of Zero-Knowledge protocols, namely protocol that emulate the trusted party for the “Zero-Knowledge functionality”: Zero-Knowledge protocols in the plain model are inherently deniable, but all existing Zero-Knowledge protocols in the CRS model are completely *undeniable* whenever the reference string is public knowledge (see [P03]).

Non-transferability is not the only concern that remains un-captured in the present formulation of security in the CRS model. For instance, the protocol in [CF01] for realizing the single-instance commitment functionality becomes malleable as soon as *two* instances use the same reference string; indeed, to avoid this weakness a more involved protocol was developed, where multiple commitments can explicitly use the same reference string in a specific way. Other demonstrations of this point are given in [YYZ07A].

The global CRS model. Taking a second look at the way we modeled trusted information so far, the main reason for the inability to capture globally available trusted information is the fact that so far the trusted information is modeled as coming from a subroutine of the given protocol execution and is made available only to the participants of that execution. In particular, the trusted information does not formally exist in the ideal process. A natural way to capture globally available trusted information is thus to model this information as coming from an entity that interacts not only with the participants in a specific execution of the analyzed protocol, but also with other parties (or, in other words, with the external environment). This in particular means that the trusted information is available not only as part of the protocol execution, but also in the *ideal process*, where the protocol is replaced by the trusted party.

More precisely, modify the CRS functionality, \mathcal{F}_{CRS} , as follows: Instead of giving the reference string only to the adversary and the parties running the actual protocol instance, the new “global CRS” functionality, $\mathcal{F}_{\text{GCRS}}$, will give the reference string to all parties and in particular to the environment. (Technically, in order to model $\mathcal{F}_{\text{GCRS}}$ one has to use the generalized UC security notion, as sketched in Section 2.2. Indeed, it is for this reason that the generalized model was first formulated.)

Technically, the effect of this modeling is that now the simulator (namely, the adversary in the ideal process) cannot choose the reference string or know related trapdoor information. In a way, proofs of security in the new modeling, even with trusted set-up, are reminiscent of the proofs of security without trusted set-up, in the sense that the only freedom enjoyed by the simulator is to control the local random choices of the uncorrupted parties. Indeed, as shown in [CDPW07], the impossibility result of [CF01] extends to show that no two-party protocol can UC-realize \mathcal{F}_{COM} even when having access to a variant of \mathcal{F}_{CRS} that gives the reference string to the environment. The proof further extends to rule out any trusted set-up functionality that makes all of its inputs and outputs available to the environment.

New trust assumptions and constructions. Still, it turns out to be possible to come up with models of globally available trusted information that lend to reasonable implementation in practice, and at the same time are sufficient for UC-realizing \mathcal{F}_{COM} . We briefly sketch three such models.

The first such model lets parties have access to the “globally available version” of the key registration functionality, \mathcal{F}_{KS} , from Section 6. That is, the only difference from \mathcal{F}_{KS} is that in the global variant, \mathcal{F}_{GKS} , the registration is done once per party throughout the lifetime of the system, and the public key can be used in all instances of all the protocols that the party might run. In particular, public keys are directly accessible by the environment, even in the ideal process. It turns out that one of the [BCNP04] protocols for UC-realizing \mathcal{F}_{COM} given \mathcal{F}_{KS} continues to work even when \mathcal{F}_{KS} is replaced by \mathcal{F}_{GKS} , as long as party

corruptions are *non-adaptive* and *party-wise* (namely, for each PID, either all the parties with that PID are corrupted, or none are.) However, when party corruptions can be adaptive, and the adversary can observe the past internal data of corrupted parties, this protocol becomes insecure. To address this concern, a more sophisticated protocol is constructed in [CDPW07].

A second model assumes that the parties have access to a global functionality, called $\mathcal{F}_{\text{ACRS}}$ for “augmented CRS (ACRS)”, that is reminiscent of the CRS model, but is somewhat augmented so as to circumvent the impossibility result for plain CRS. That is, as in the case of $\mathcal{F}_{\text{GCRS}}$, all parties and the environment have access to a short reference string that is taken from a pre-determined distribution. In addition, the ACRS model allows corrupted parties to obtain “personalized” secret keys that are derived from the reference string, their public identities, and some “global secret” that’s related to the public string and remains unknown. It is stressed that in the formal model *only corrupted parties* may obtain their secret keys. This effect of this modeling is that protocol may not include instructions that require knowledge of the secret keys, and yet corrupted parties are assumed to have access to their secret keys. A protocol for UC-realizing \mathcal{F}_{COM} given $\mathcal{F}_{\text{ACRS}}$ is constructed in [CDPW07]. (in fact, this protocol UC-realizes even the multi-commitment functionality, $\mathcal{F}_{\text{MCOM}}$) The main additional technique on top of the protocol using \mathcal{F}_{GKS} is a new *identity-based trapdoor commitment (IBTC)* protocol. (IBTC protocols in the Random Oracle model appear in [ZSS 03, AM04].)

“Real world implementations” of \mathcal{F}_{GKS} and $\mathcal{F}_{\text{ACRS}}$ can involve trusted entities (say, “post offices”) that only publicize the public values. These entities will also agree to provide the secret keys to the corresponding parties upon request, with the understanding that once a party gets hold of its key then it alone is responsible to safeguard it and use it appropriately (much as in the case of standard PKI). In light of the insufficiency of a only public and globally available trusted information, this seems to be a minimal requirement from the trusted module.

8 The Hardware Token Model

All the trust models considered so far model situations where the parties have access to information that is provided by trusted external entities, or by observing external physical phenomena. This section describes a model, introduced by Katz in [K07], that represents a different type of trust: The model assumes that there exist computing devices that can be programmed by one party and then handed over to another party to be executed in a “tamper-proof” way, and without a direct communication link with external entities. No other trust assumptions are made; in particular, the protocol participants need not obtain any trusted information from external entities.

Formally, the model is captured via an ideal functionality, $\mathcal{F}_{\text{WRAP}}$, that allows one party to specify code that is then executed by another party. $\mathcal{F}_{\text{WRAP}}$ is presented in Figure 4.

Functionality $\mathcal{F}_{\text{WRAP}}$
<ol style="list-style-type: none"> 1. Upon receiving an input (Create-Token, SID, M, B) from party A, initialize a local instance of ITM M, and generate a delayed output (Token, A) to B. Ignore any subsequent (Create-Token, SID, \dots) inputs. 2. Upon receiving an input (Run, SID, x) from party B, run M on input x from its current local state, record the updated local state, and return (Output, SID, y) to party B, where y is the current local output of M.

Figure 4: The Hardware Token functionality, $\mathcal{F}_{\text{WRAP}}$

Note that $\mathcal{F}_{\text{WRAP}}$ does not provide the executing party, B , with any information about the code M that it is running, nor can B influence that code. Furthermore, M can maintain local state between calls and make private random choices. These features represent the “tamper-proofness”, or “virtual black box” guarantees that are given to party A . On the other hand, $\mathcal{F}_{\text{WRAP}}$ does not provide any information to party A . This guarantees to party B that M communicates only with B and has no “side channels” for communicating with A or other parties.

It is stressed again that $\mathcal{F}_{\text{WRAP}}$ can be realized in reality without requiring the parties to trust any third parties. Still, Katz shows that it suffices for realizing \mathcal{F}_{COM} :

Theorem: [k07] Under the Decisional Diffie-Hellman assumption, there exists a protocol that realizes \mathcal{F}_{COM} having access to $\mathcal{F}_{\text{WRAP}}$. \square

Some interesting remaining questions include obtaining the result of the theorem based under more general assumptions, and extending the modeling and construction to capture a “globally available token” that can be used for multiple protocols.

The “signature card” model. Another trust model, formulated in Hofheinz et. al [HMU06], represents a situation where each party is equipped with a “tamper proof signature card” that runs some secure signature algorithm in a trusted way. In addition, the public key associated with each card is globally known. In [HMU06] it is shown how to realize \mathcal{F}_{COM} in this model. We note however that these results are subsumed by the modeling and results in [k07]. The main difference being that in the [HMU06] model all parties need to trust that the hardware token is running some pre-specified program. In contrast, in the [k07] model parties need not trust the program of the hardware they are running.

9 A Timing Assumption

Yet another approach for putting trust in some parts of the system in order to guarantee composable security is to make assumptions on the relative delays of messages in the network. More precisely, it is assumed that all messages sent are eventually delivered unmodified within some time bound, and in addition there is a bound on the amount of relative “drift” between local clocks of parties in the system. In [LPT04] it is shown how to UC-realize \mathcal{F}_{CRS} and \mathcal{F}_{COM} in such a setting. Also here, the parties need not trust any piece of information that comes from external parties or sources.

The fact that a timing assumption suffices for UC-realizing, say, \mathcal{F}_{CRS} , is not surprising in of itself: Assume for instance that the network is completely synchronous, and furthermore no party (not even corrupted ones) receives messages sent in round i before the last chance to send out its messages for round i . Then a simple, unconditionally secure two-party protocol for UC-realizing \mathcal{F}_{CRS} would be to simply have each of the two parties send a random string of the appropriate length at a certain round, and then let the reference string be the bitwise xor of the two strings. In [LPT04] it is shown, via a sophisticated protocol and under standard hardness assumptions, how to obtain a similar effect while making (much) weaker synchronization assumptions on the system.

It is interesting to note that the timing assumptions have to hold only during the execution of the protocol for UC-realizing \mathcal{F}_{CRS} . Once the reference string is fixed, no timing assumptions are needed. Also, since there is no trusted piece of information to be passed around, this approach bypasses the issue of whether this information is available globally or only locally. In particular it has no “transferability” issues and provides complete “deniability”.

10 Realizing authenticated communication

The treatment of Sections 3 through 9 concentrates on the case of ideally authenticated networks, where messages are not modified en route and arrive with an authentic sender identity. More precisely, the parties are assumed to have access to multiple copies of an ideal functionality, $\mathcal{F}_{\text{AUTH}}$, that, roughly, takes input (sid, B, m) from party A , and provides output (sid, A, m) to B , where sid is a session identifier.

As observed in [c04], it is impossible to UC-realize $\mathcal{F}_{\text{AUTH}}$ in the “bare” model with no trust assumptions. Still, $\mathcal{F}_{\text{AUTH}}$ can be UC-realized, via standard authentication mechanisms, when given access to an ideal functionality that allows parties to register public values associated with their identities [c04]. It is stressed that this functionality, \mathcal{F}_{REG} , does not verify knowledge of any secret information associated with the registered value; it merely provides a registration (or, “bulletin-board”) service.

Akin to the formulation of the traditional CRS model, the formulation of \mathcal{F}_{REG} in [c04] makes the registered keys available only to the parties that run the specific protocol instance. Implementing \mathcal{F}_{REG} is thus susceptible to the same limitations that apply to implementing \mathcal{F}_{CRS} (see Section 7): Essentially, a

new instance of the registration service is needed for each new protocol instance. In particular, similarly to the case of \mathcal{F}_{CRS} , when the [C04] protocol for UC-realizing $\mathcal{F}_{\text{AUTH}}$ uses a “global” registration service that’s available to arbitrary protocols, authentication becomes “transferable”. (In fact, a publicly verifiable signature by the sender on the transmitted information becomes available.) This stands in contrast to the fact that ideal authentication using $\mathcal{F}_{\text{AUTH}}$ does *not* allow for such “transferability”.

Modeling authenticated communication in the presence of registration services that make the registered keys available globally in the system is an interesting challenge. One direction is to model the security guarantees provided by standard authentication mechanisms (such as the simple signature-based mechanism studied in [C04]) in the presence of globally available public keys. These guarantees are naturally described by means of an ideal authentication functionality that allows for transferability *even in ideal process*. Another direction is to study protocols that UC-realize the original, non-transferable version of $\mathcal{F}_{\text{AUTH}}$ even when the public keys are made globally available. This is an interesting venue for current and future research.

11 Conclusion and open problems

We have exemplified the need for modeling situations with “trusted set-up”, namely where some parts of the system are trusted in certain respects. We have also studied a variety of such models. These models differ both from the point of view of the guarantees provided to protocols designed in these models, and from the point of view of the requirements from actual implementations.

While some progress has been made in the past few years towards understanding how to formulate models that allow bypassing the strong impossibility results regarding composable security, how to develop protocols in these models, and how to implement such models in reality, much remains to be understood. Some specific questions include:

1. Finding protocols that use current trust models more efficiently. Finding easier and more secure ways to implement existing trust models in practice. Finding new trust models that allow for more efficient protocols and/or easier implementations.
2. Finding a characterization of the trust models that allow for UC-realizing, say, \mathcal{F}_{COM} (or any other ideal functionality that allows for UC-realizing general ideal functionalities). We’ve seen that trust models can have very different flavors and characteristics. Are there some salient properties that are common to all and are necessary and/or sufficient for UC-realizing \mathcal{F}_{COM} ?
3. Are there trust models where the provided information is globally available, that still allow for UC-realizing \mathcal{F}_{COM} , and also allow for adversarial control over the provided information, akin to \mathcal{F}_{SUN} ? Are there trust models that allow for adversarial control over the trusted information, and at the same time allow for UC-realizing authenticated communication?
4. Are there general relationships between trust models that allow for UC-realizing authenticated communication and trust models that allow for UC-realizing \mathcal{F}_{COM} ?
5. More generally, how can we better model the information shared between protocol instances in arbitrary systems? Is globally available information the only information that can be shared, or are there other ways to share state and information? How to capture these? An indication that in some situations protocols indeliberately (but inevitably) share more information than just the public information is given in [YYZ07B].
