Abstract. We present a method to compile Yao’s two-player garbled circuit protocol into one that is secure against malicious adversaries that relies on witness indistinguishability. Our approach can enjoy lower communication and computation overhead than methods based on cut-and-choose [13] and lower overhead than methods based on zero-knowledge proofs [8] (or Σ -protocols [14]). To do so, we develop and analyze new solutions to issues arising with this transformation:

- How to guarantee the generator’s input consistency
- How to support different outputs for each player *without* adding extra gates to the circuit of the function f being computed
- How the evaluator can retrieve input keys but avoid selective failure attacks
- Challenging 3/5 of the circuits is near optimal for cut-and-choose (and better than challenging 1/2)

Our protocols require the existence of secure-OT and claw-free functions that have a weak malleability property. We discuss an experimental implementation of our protocol to validate our efficiency claims.

Keywords: Witness indistinguishability, Yao garbled circuits, signature schemes

1 Introduction

Yao [23] proposed a method that allows two *honest-but-curious* players—a *generator* (denoted by P_1) with secret input x , and an *evaluator* (denoted by P_2) with secret input y —to jointly compute a function $f(x, y)$ such that P_1 receives nothing and P_2 receives $f(x, y)$.¹ In this paper, we propose an approach for transforming Yao’s garbled circuit protocol for honest-but-curious players into a protocol that is secure against *malicious* players. Our main goal is to improve the efficiency of this transformation and to do so using more general assumptions.

There are two well-known methods to achieve this transformation: the *commit-and-prove* and *cut-and-choose*. The commit-and-prove method suggested by Goldreich, Micali, and Wigderson [6] only requires the weak general assumption of zero-knowledge proofs of knowledge. However, this approach requires costly NP-reductions, which have never been implemented. On the other hand, an efficient

¹ A thorough description of this protocol can be found in Lindell and Pinkas [13].

transformation based on the cut-and-choose method was recently proposed by Lindell and Pinkas [13] and implemented by Pinkas et al. [20]. The general idea in cut-and-choose is for P_1 to prepare multiple copies of the circuit to be evaluated. A randomly selected set of the circuits (called *check-circuits*) are then opened to show if they were constructed correctly. Finally, the unopened circuits (called *evaluation-circuits*) are evaluated by P_2 and the majority of the results is taken as the final output. This approach has only constant round complexity, but the replication incurs both communicational and computational overhead.

The starting point for our work is the cut-and-choose method. *A natural question we aim to study is to understand the fundamental limitations (in terms of efficiency) of the cut-and-choose method.* This method does not require NP-reductions; however, it faces other efficiency problems stemming from the new security problems introduced by evaluating e out of s copies of the circuit. In this paper, we address several of these issues: (1) ensuring input consistency, (2) handling two-output functions, (3) preventing selective failure attacks, and (4) determining the optimal number of circuits to open versus evaluate. Moreover, we identify weak and generic properties that admit efficient solutions to these issues. In several of the cases, using witness indistinguishable protocols suffice. Thus, in the case of input consistency, we are able to use an extremely efficient protocol as long as claw-free functions with a minimal malleability property exist (they do under the standard algebraic assumptions). We will later demonstrate the benefits of our approach by both asymptotic analysis of complexity and experimental results from an implementation. We now give an overview of our contributions.

1.1 Generator’s input consistency

According to the cut-and-choose method, P_1 needs to send e copies of her garbled input to P_2 . Since the circuits are *garbled*, P_1 could cheat by sending different inputs for the e copies of the garbled circuit. For certain functions, there are simple ways for P_1 to extract information about P_2 ’s input (§ 3 of [13]). Therefore, the protocol must ensure that all e copies of P_1 ’s input are *consistent*.

Related work Let n be P_1 ’s and P_2 ’s input size, and let s be a statistical security parameter for the cut-and-choose method. Mohassel and Franklin [16] proposed the *equality-checker* scheme, which has $O(ns^2)$ computation and communication complexity. Woodruff [22] later suggested an *expander-graph* framework to give a sharper bound to P_1 ’s cheating probability. The asymptotic complexity is $O(ns)$, however, in practice, the constant needed to construct the expander graphs is prohibitively large. Lindell and Pinkas [13] develop an elegant cut-and-choose based construction that enjoys the simulation-based security against malicious players. This approach requires $O(ns^2)$ commitments to be computed and exchanged between the participants. Although these commitments can be implemented using lightweight primitives such as collision-resistant hash functions, communication complexity is still an issue. Jarecki and Shmatikov [8] presented an approach that is based on commit-and-prove method. Although only a single circuit is constructed, their protocol requires hundreds of heavy cryptographic

operations *per gate*, whereas approaches based on the cut-and-choose method require only such expensive operations for the *input gates*. Nielsen and Orlandi [18] proposed an approach with Lego-like garbled gates. Although it is also based on the cut-and-choose method, via an alignment technique only a single copy of P_1 's input keys is needed for all the e copies of the garbled circuit. However, similar to Jarecki and Shmatikov's approach, each gate needs several group elements as commitments resulting both computational and communicational overhead. Lindell and Pinkas propose a Diffie-Hellman pseudorandom synthesizer technique in [14]; their approach relies on finding efficient zero-knowledge proofs for specifically chosen complexity assumptions, which is of complexity $O(ns)$.

Our approach to consistency We solve this problem not by explicitly using zero-knowledge protocols (or Σ -protocols) but by communicating merely $O(ns)$ group elements. Our novel approach is to first observe that witness indistinguishable proofs suffice for consistency, and to then use *claw-free functions*² that have a weak malleability property to generate efficient instantiations of such proofs.

Intuitively, P_1 's input is encoded using elements from the domain of the claw-free collections which can later be used to prove their consistency among circuits. The elements are hashed into random bit-strings which P_1 uses to construct keys for garbled input gates. The rest of the gates in the circuit use fast symmetric operations as per prior work. A concrete example is to instantiate the claw-free functions under the Discrete Logarithm assumption by letting $f_b(m) = g^b h^m$ for some primes p and q such that $p = 2q + 1$, and distinct group elements g and h of \mathbb{Z}_p^* such that $\langle g \rangle = \langle h \rangle = q$. It is well-known that such a pair of functions have efficient zero-knowledge proofs. An example instantiation of our solution built on this pair of claw-free functions works as follows: P_1 samples $[m_{0,1}, \dots, m_{0,s}]$ and $[m_{1,1}, \dots, m_{1,s}]$ from f_0 and f_1 's domain \mathbb{Z}_q . The range elements $[h^{m_{0,1}}, \dots, h^{m_{0,s}}]$ and $[gh^{m_{1,1}}, \dots, gh^{m_{1,s}}]$ are then used to construct garbled circuits in the way that $g^b h^{m_{b,j}}$ is associated with P_1 's input bit value b in the j -th garbled circuit. The cut-and-choose method verifies that the majority of the evaluation-circuits are correctly constructed. Let $[j_1, \dots, j_e]$ be the indices of these evaluation-circuits. At the onset of the evaluation phase, P_1 with input bit x reveals $[g^x h^{m_{x,j_1}}, \dots, g^x h^{m_{x,j_e}}]$ to P_2 and then proves that these range elements are the commitments of the same bit x . Intuitively, by the identical range distribution property, P_2 with $f_x(m_{x,i})$ at hand has no information about x . Furthermore, after P_1 proves the knowledge of the pre-image of $[f_x(m_{x,j_1}), \dots, f_x(m_{x,j_e})]$ under the same f_x , by the claw-free property, P_1 proves the consistency of his input keys for all the evaluation-circuits.

Furthermore, in the course of developing our proof, we noticed that witness indistinguishable proofs suffice in place of zero-knowledge proofs. Even more generally, when the claw-free collection has a very weak malleability property

² Loosely speaking, a pair of functions (f_0, f_1) are said to be claw-free if they are (1) easy to evaluate, (2) identically distributed over the same range, and (3) hard to find a *claw*. A claw is a pair of elements, one from f_0 's domain and the other from f_1 's domain, that are mapped to the same range element.

(which holds for all known concrete instantiations), sending a simple function of the witness itself suffices. We will get into more details in §2.1.

It is noteworthy that both the committed-input scheme in [16] and Diffie-Hellman pseudorandom synthesizer technique in [14] are special cases of our approach, and thus, have similar complexity. However, the committed-input scheme is not known to enjoy simulation-based security, and the pseudorandom synthesizer technique requires zero-knowledge proofs that are unnecessary in our case, which means that our approach is faster by a constant factor in practice.

1.2 Two-output Functions

It is not uncommon that *both* P_1 and P_2 need to receive outputs from a secure computation, that is, the goal function is $f(x, y) = (f_1, f_2)$ such that P_1 with input x gets output f_1 , and P_2 with input y gets f_2 .³ In this case, the security requires that *both* the input and output are hidden from the other player. When both players are honest-but-curious, a straightforward solution is to let P_1 choose a random number c as an extra input, convert $f(x, y) = (f_1, f_2)$ into a new function $f^*((x, c), y) = (\lambda, (f_1 \oplus c, f_2))$, run the original Yao protocol for f^* , and instruct P_2 to pass the encrypted output $f_1 \oplus c$ back to P_1 , who can then retrieve her real output f_1 with the secret input c chosen in the first place. However, the situation gets complicated when either of the players could potentially be malicious. Note that the two-output protocols we consider are not *fair* since P_2 may always learn its own output and refuse to send P_1 's output. However, they can satisfy the notion that if P_1 accepts output, it will be correctly computed.

Related work One straightforward solution is for the players to run the single-output protocol twice with roles reversed. Care must be taken to ensure that the same inputs are used in both executions. Also, this approach doubles the computation and communication cost. Other simple methods to handle two-output functions also have subtle problems. Suppose, for example, P_1 encrypts all copies of her output and has P_2 send these s random strings (or encryptions) in the last message. In a cut-and-choose framework, however, a cheating P_1 can use these random strings to send back information about the internal state of the computation and thereby violate P_2 's privacy. As an example, the cheating P_1 can make one bad circuit in which P_1 's output bit is equal to P_2 's first input bit. If P_2 sends all copies of P_1 's output bit back to P_1 , then with noticeable probability, the cheating P_1 can learn P_2 's first input bit. The problem remains if instead of sending back all bits, only a randomly chosen output bit is sent. Besides, P_1 should not be convinced by a cheating P_2 with an arbitrary output.

As described in [13], the two-output case can be reduced to the single-output case as follows: (1) P_1 randomly samples $a, b, c \in \{0, 1\}^n$ as extra input; (2) the original function is converted into $f^*((x, a, b, c), y) = (\lambda, (\alpha, \beta, f_2))$ where $\alpha = f_1 \oplus c$ is an encryption of f_1 and $\beta = a \cdot \alpha + b$ is the Message Authentication code (MAC) of α , and (3) P_2 sends (α, β) back to P_1 , who can then check the

³ Here f_1 and f_2 are abbreviations of $f_1(x, y)$ and $f_2(x, y)$ for simplicity purpose.

authenticity of the output $\alpha = f_1 \oplus c$. However, this transformation increases the size of P_1 's input from n bits to $4n$ bits. As a result, the complexity of P_1 's input consistency check is also increased. A second drawback is that the circuit must also be modified to include extra gates for computing the encryption and MAC function. Although a recent technique [12] can be used to implement XOR gates “for free,” the MAC function $a \cdot \alpha + b$ still requires approximately $O(n^2)$ extra gates added to the circuit. Since all s copies of the circuit have to be modified, this results in additional communication of $O(sn^2)$ encrypted gates. Indeed, for simple functions, the size of this overhead exceeds the size of the original circuit.

Kiraz and Schoenmakers [11] present a fair two-party computation protocol in which a similar issue for two-output functions arises. In their approach, P_2 commits to P_1 's garbled output. Then P_1 reveals the two output keys for each of her output wires, and P_2 finds one circuit GC_r which agrees with “the majority output for P_1 .” The index r is then revealed to P_1 . However, informing P_1 the index of the majority circuit could possibly leak information about P_2 's input. As an anonymous reviewer has brought to our attention an unpublished follow-up work from Kiraz [9], which elaborated this issue (in § 6.6 of [9]) and further fixed the problem without affecting the overall performance. Particularly, in the new solution, the dominant computational overhead is an OR-proof of size $O(s)$, and the dominant communicational overhead is the commitments to P_1 output keys, where the number of such commitments is of order $O(ns)$. Their techniques favorably compare to our approach, but we do not have experimental data to make accurate comparisons with our implementation.

Our approach to two-output functions We present a method to evaluate two-output function f without adding non-XOR gates to the original circuit for f .

In order for P_2 to choose one output that agrees with the majority, similar to Kiraz and Schoenmakers' approach in [11], we add extra bits to P_1 's input as a one-time pad encryption key by changing the function from $f(x, y) = (f_1, f_2)$ to $f^*(c, x, y) = (\lambda, (f_1 \oplus c, f_2))$, where $x, c, y, f_1, f_2 \in \{0, 1\}^n$. With this extra random input c from P_1 , P_2 is able to do the majority function on the evaluation output $f_1 \oplus c$ without knowing P_1 's real output f_1 . Next, P_2 needs to prove the authenticity of the evaluation output $f_1 \oplus c$ that she has given to P_1 . Here, our idea is that P_1 's i -th output gate in the j -th garbled circuit is modified to output $0 \parallel \sigma_{sk}(0, i, j)$ or $1 \parallel \sigma_{sk}(1, i, j)$ instead of 0 or 1, where $\sigma_{sk}(b, i, j)$ is a signature of the message (b, i, j) signed by P_1 under the signing key sk . In other words, the garbled gate outputs P_1 's output bit b and a signature of b , bit index i , and circuit index j . Therefore, after the circuit evaluation, P_2 hands $f_1 \oplus c$ to P_1 and proves the knowledge of the signature of each bit under the condition that the j -index for all signatures are the same and valid (among the indices of the evaluation-circuits). Naively, this proof would have been a proof of $O(ns)$ group elements. However, we will show that a witness indistinguishable proof suffices, which reduces the complexity by a constant factor. Furthermore, by using the technique of Camenisch, Chaabouni, and Shelat for efficient set membership proof [4], we are able to reduce the complexity to $O(n + s)$ group elements.

1.3 The problem of Selective Failure

Another problem with compiling garbled circuits occurs during the Oblivious Transfer (OT) phase, when P_2 retrieves input keys for the garbled circuits. A malicious P_1 can attack the protocol with *selective failure*, where the keys used to construct the garbled circuit might not be the ones used in the OT so that P_2 's input can be inferred according to her reaction after OT. For example, a cheating P_1 could use (K_0, K_1) to construct a garbled circuit but use (K_0, K_1^*) instead in the corresponding OT, where $K_1 \neq K_1^*$. As a result, if P_2 's input bit is 1, she will get K_1^* after OT and cannot evaluate the garbled circuit properly. In contrast, if her input bit is 0, P_2 will get K_0 from OT and complete the evaluation without complaints. P_1 can therefore infer P_2 's input. This issue is identified by both Mohassel and Franklin [16] and Kiraz and Schoenmakers [10].

Related work Lindell and Pinkas [13] replace each of P_2 's input bits with s additional input bits. These s new bits are XOR'ed together, and the result is used as the input to the original circuit. Such an approach makes the probability that P_2 must abort due to selective failure independent of her input. This approach, however, increases the number of input bits for P_2 from n to ns . Woodruff later pointed out that the use of clever coding system can reduce the overhead to $\max(4n, 8s)$. To be sure, Lindell, Pinkas, and Smart [15] implement the method described in [13] and empirically confirm the extra overhead from this step. In particular, a 16-bit comparison circuit that originally needs fifteen 3-to-1 gates and one 2-to-1 gate will be inflated to a circuit of several thousand gates after increasing the number of inputs. Since the number of inputs determines the number of OT operations, an approach that keeps the number of extra inputs small is preferable. In fact, we show that increasing the number of inputs and number of gates in the circuit for this problem is unnecessary.

Independent of our work, Lindell and Pinkas [14] propose to solve this problem by *cut-and-choose OT*. This new solution indeed provides a great improvement over [13] and shares roughly the same complexity with our solution. Furthermore, both the cut-and-choose OT and our solution can be built upon the efficient OT proposed by Naor and Pinkas [17] or Peikert, Vaikuntanathan, and Waters [19]. However, the particular use the latter OT in [14] needs two independently chosen common reference strings, while our solution needs only one.

Our approach to selective failure Inspired by the idea of *committing Oblivious Transfer* proposed by Kiraz and Schoenmakers [10], we solve the problem of selective failure by having the sender (P_1 in Yao protocol) of the OT *post-facto* prove that she ran the OT correctly by revealing the randomness used in the OT. Normally, this would break the sender-security of the OT. However, in a cut-and-choose framework, the sender is already opening many circuits, so the keys used as inputs for the OT are no longer secret. Thus, the idea is that the sender can prove that he executed the OT correctly for all circuits that are opened by simply sending the random coins used in the OT protocol for those instances. We stress that not every OT can be used here. Intuitively, a committing OT

is the OT with the binding property so that it is hard for a cheating sender to produce random coins different from what she really used.

A critical point with this approach is that in order to simulate a malicious P_2 , we need to use a coin-flipping protocol to pick which circuits to open. Consequently, P_1 cannot open the circuits to P_2 until the coin-flipping is over; yet the OT must be done before the coin-flipping in order to guarantee a proper *cut*. So the order of operations of the protocol is critical to security. An efficient committing OT based on Decisional Diffie-Hellman problem is presented in §2.3.

1.4 Optimal Cut-and-Choose Strategy

We find that most cut-and-choose protocols open $s/2$ out of the s copies of the garbled circuit to reduce the probability that P_1 succeeds in cheating. We show that opening $3s/5$ -out-of- s is a better choice than $s/2$ -out-of- s . In particular, when s circuits are used, our strategy results in security level $2^{-0.32s}$ in contrast to $2^{-s/17}$ from [13] and $2^{-0.31s}$ from [14]. Although the difference with the latter work is only 1% less, we show the optimal parameters for the cut-and-choose method in Appendix A, thereby establishing a close characterization of the limits of the cut-and-choose method.

1.5 Comparison of Communication Complexity

We attempt to compare communication efficiency between protocols that use a mix of light cryptographic primitives (such as commitments instantiated with collision-resistant hash functions) and heavy ones (such as group operations that rely on algebraic assumptions like discrete logarithm). To meaningfully do so, we consider asymptotic security under reasonable assumptions about the growth of various primitives with respect to the security parameter k . We assume that:

1. light cryptographic primitives have size $\Theta(k)$;
2. heavy cryptographic operations that can be instantiated with elliptic curves or bilinear groups take size $\tilde{o}(k^2)$.
3. heavy cryptographic operations that require RSA or prime order groups over \mathbb{Z} take size $\tilde{o}(k^3)$.

The size assumption we make is quite conservative. It is based on the observation that in certain elliptic curve groups, known methods for computing discrete logarithms of size n run in time $L_n(1, 1/2)$. Thus, to achieve security of 2^k , it suffices to use operands of size $\tilde{o}(k^2)$ by which we mean a value that is asymptotically smaller than k^2 by factors of $\log(k)$. The computation bound follows from the running time analysis of point multiplication (or exponentiation in the case of \mathbb{Z}_p^*) algorithms. As we discuss below, for reasonable security parameters, however, the hidden constants in this notation make the difference much smaller. Let k be a security parameter for cryptographic operations, let s be a statistical security parameter, and let $|C|$ be the number of gates in the base circuit computing $f : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}^n \times \{0, 1\}^n$.

- Jarecki and Shmatikov [8]: For each gate, the number of the communicated group elements is at least 100, including the commitments of the garbled values for input wires, the commitments of the doubly-encrypted entries, and the ZK proof for the correctness of the gate. Moreover, for each input or output wires, a ZK proof for conjunction/disjunction is required. Each of the ZK proofs needs constant number of group elements. Finally, this protocol assumes the decisional composite residuosity problem in an RSA group; thus, each group element is of size $\tilde{o}(k^3)$.
- Kiraz [9]: This approach uses an equality-checker framework that requires $O(ns^2)$ commitments for checking P_1 's input consistency. They solve the selective failure attack with committing OT as we do. Moreover, to deal with two-output functions, they add n extra bits to P_1 's input, commit to all of P_1 's output keys, which include $2ns$ commitments and $2ns$ decommitments, and a zero-knowledge OR-proof of size $O(s)$.
- Lindell and Pinkas [13]: Each of the garbled gates requires $4k$ space for four doubly-encrypted entries. Thus, for this approach, the communication analysis is as follows: (1) s copies of the base circuit itself require $s|C|$ gates; (2) each of P_1 's n input bits requires s^2 light commitments for the consistency check; (3) P_2 's n input bits require $\max(4n, 8s)$ OT's. Also, the MAC-based two-output function computation add additional $O(n^2)$ gates to each of the s copies of the circuit and additional $3n$ bits to P_1 's input. Thus, the overall communication cost to handle two-output function is $O(n^2sk + ns^2k)$.

| | Base circuit | COMMUNICATION | | |
|----------|----------------------------|-----------------------------------|---------------------|--|
| | | P_1 's input | P_2 's input | Two-output |
| JS07 | $ C \cdot \tilde{o}(k^3)$ | $n \cdot \tilde{o}(k^3)$ | n OT's | $n \cdot \tilde{o}(k^3)$ |
| Ki08 | $\Theta(C \cdot sk)$ | $\Theta(ns^2k)$ | n OT's | $\Theta(nsk) + \Theta(s) \cdot \tilde{o}(k^2)$ |
| LP07 | $\Theta(C \cdot sk)$ | $\Theta(ns^2k)$ | $\max(4n, 8s)$ OT's | $\Theta(n^2sk + ns^2k)$ |
| LP11 | $\Theta(C \cdot sk)$ | $\Theta(ns) \cdot \tilde{o}(k^2)$ | n OT's | $\Theta(n^2sk + ns^2k)$ |
| Our work | $\Theta(C \cdot sk)$ | $\Theta(ns) \cdot \tilde{o}(k^2)$ | n OT's | $\Theta(ns) \cdot \tilde{o}(k^2)$ |

Table 1: Asymptotic Analysis of various two-party secure computation.

The recent work of [14] also considers a more efficient way to implement two-party computation based on cut-and-choose OT and specific security assumptions. They report $13sn$ exponentiations and communication of $5sn + 14k + 7n$ group elements. (Note we count bits above to compare commitments versus other primitives.) Concretely, these parameters are similar to our parameters but rely on more specific assumptions, and do not consider two-party outputs.

2 Building Blocks

For clarity purpose, the standard checks that are required for security have been omitted. For example, in many cases, it is necessary to verify that an element that has been sent is indeed a member of the right group. In some cases, it is implicit that if a player detectably cheats in a sub-protocol, then the other player would immediately abort execution of the entire protocol.

2.1 Consistency Check for the Generator’s Input

The cut-and-choose approach to compiling Yao circuits ensures that P_1 submits consistent input values for each copy of the evaluation-circuits. Recall that there are e copies of the circuit which must be evaluated. Thus, for each input wire, P_1 must send e keys corresponding to an input bit 0 or 1. It has been well-documented [16,10,22,13] that in some circumstances, P_1 can gain information about P_2 ’s input if P_1 is able to submit different input values for the e copies of this input wire. The main idea of our solution is inspired by the *claw-free collections*⁴ defined as follows:

Definition 1 (Claw-Free Collections in [7]). *A three-tuple of algorithms (G, D, F) is called a claw-free collection if the following conditions hold*

1. **Easy to evaluate:** *Both the index selecting algorithm G and the domain sampling algorithm D are probabilistic polynomial-time, while the evaluating algorithm F is a deterministic polynomial-time.*
2. **Identical range distribution:** *Let $f_I^b(x)$ denote the output of F on input (b, I, x) . For any I in the range of G , the random variable $f_I^0(D(0, I))$ and $f_I^1(D(1, I))$ are identically distributed.*
3. **Hard to form claws:** *For every non-uniform probabilistic polynomial-time algorithm A , every polynomial $p(\cdot)$, and every sufficiently large n ’s, it is true that $\Pr[I \leftarrow G(1^n); (x, y) \leftarrow A(I) : f_I^0(x) = f_I^1(y)] < 1/p(n)$.*

With the claw-free collections, our idea works as follows: P_2 first generates I by invoking the index generating algorithm $G(1^k)$, where k is a security parameter. For each of her input bits, P_1 invokes sampling algorithms $D(I, 0)$ and $D(I, 1)$ to pick $[m_{0,1}, \dots, m_{0,s}]$ and $[m_{1,1}, \dots, m_{1,s}]$, respectively. P_1 then constructs s copies of garbled circuit with range elements $[f_I^0(m_{0,1}), \dots, f_I^0(m_{0,s})]$ and $[f_I^1(m_{1,1}), \dots, f_I^1(m_{1,s})]$ by associating $f_I^b(m_{b,j})$ with P_1 ’s input wire of bit value b in the j -th garbled circuit. Let $[j_1, \dots, j_e]$ denote the indices of the garbled circuits not checked in the cut-and-choose (evaluation-circuits). During the evaluation, P_1 reveals $[f_I^b(m_{b,j_1}), \dots, f_I^b(m_{b,j_e})]$ to P_2 and proves in zero-knowledge that P_1 gets $f_I^b(m_{j_1}^b)$ and $f_I^b(m_{j_i}^b)$ via the same function f_I^b , for $2 \leq i \leq e$.

However, in the course of developing our solution, we noticed that witness indistinguishable proofs suffice in place of zero-knowledge proofs. For example,

⁴ It is well known that claw-free collections exist under either the Discrete Logarithm assumption or Integer Factorization assumption [7].

consider the claw-free collection instantiated from the Discrete Logarithm assumption, that is, let $f_I^b(m) = g^b h^m$, where $I = (g, h, p, q)$ includes two primes p and q such that $p = 2q + 1$, and distinct generators g and h of \mathbb{Z}_p^* such that $\langle g \rangle = \langle h \rangle = q$. After revealing $[g^b h^{m_{b,j_1}}, \dots, g^b h^{m_{b,j_e}}]$ to P_2 , it is a natural solution that P_1 proves in zero-knowledge to P_2 the knowledge of $(m_{b,j_i} - m_{b,j_1})$ given common input $g^b h^{m_{b,j_i}} (g^b h^{m_{b,j_1}})^{-1} = h^{m_{b,j_i} - m_{b,j_1}}$, for $2 \leq i \leq e$. The key insight here is that it is unnecessary for P_1 to hide $(m_{b,j_i} - m_{b,j_1})$ from P_2 since $[m_{b,j_1}, \dots, m_{b,j_e}]$ are new random variables introduced by P_1 and b is the only secret needed to be hidden from P_2 . Simply sending $(m_{b,j_i} - m_{b,j_1})$ to P_2 will suffice a proof of checking P_1 's input consistency without compromising P_1 's privacy. In other words, given $[g^b h^{m_{b,j_1}}, \dots, g^b h^{m_{b,j_e}}, m'_2, \dots, m'_e]$, if P_2 confirms that $g^b h^{m_{b,j_1}} = g^b h^{m_{b,j_i}} \cdot h^{m'_i}$ for $2 \leq i \leq e$, then either P_1 's input is consistent so that $m'_i = m_{b,j_i} - m_{b,j_1}$, or P_1 is able to come up with a claw.

Note that extra work is only done for the input gates—and moreover, only those of P_1 . All of the remaining gates in the circuit are generated as usual, that is, they do not incur extra commitments. So, unlike solutions with committed OT such as [8], asymmetric cryptography is only used for the input gates rather than the entire circuit. To generalize the idea, we introduce the following notion.

Definition 2 (Malleable Claw-Free Collections). *A four-tuple of algorithms (G, D, F, R) is a malleable claw-free collection if the following conditions hold.*

1. **A subset of claw-free collections:** (G, D, F) is a claw-free collection, and the range of D and F are groups, denoted by (\mathbb{G}_1, \star) and (\mathbb{G}_2, \diamond) respectively.
2. **Uniform domain sampling:** For any I in the range of G , random variable $D(0, I)$ and $D(1, I)$ are uniform over \mathbb{G}_1 , and denoted by $D(I)$ for simplicity.
3. **Malleability:** $R : \mathbb{G}_1 \rightarrow \mathbb{G}_2$ runs in polynomial time, and for $b \in \{0, 1\}$, any I in the range of G , and any $m_1, m_2 \in \mathbb{G}_1$, $f_I^b(m_1 \star m_2) = f_I^b(m_1) \diamond R_I(m_2)$.

Consider the claw-free collection constructed above under the Discrete Logarithm assumption, we know that it can become a malleable claw-free collection simply by letting $\mathbb{G}_1 = \mathbb{Z}_q$, $\mathbb{G}_2 = \mathbb{Z}_p^*$, and $R_I(m) = h^m$ for any $m \in \mathbb{G}_1$.

2.2 Two-Output Functions

To handle two-output functions, we want to satisfy the notion that it might be unfair in the sense that P_2 could abort prematurely after circuit evaluation and she gets her output. However, if P_1 accepts the output given from P_2 , our approach guarantees that this output is genuine. Namely, P_2 cannot provide an arbitrary value to be P_1 's output. In particular, P_2 cannot learn P_1 's output more than those deduced from P_2 's own input and output.

Recall that it is a well-accepted solution to convert the garbled circuit computing $f(x, y) = (f_1, f_2)$ into the one computing $g((x, p, a, b), y) = ((\alpha, \beta), f_2)$, where $\alpha = f_1 + p$ as a ciphertext of f_1 and $\beta = a \cdot \alpha + b$ as a MAC for the ciphertext. Since P_2 only gets the ciphertext of P_1 's output, she does not learn anything from the ciphertext. Also, given (α, β) , P_1 can easily verify the authenticity of her output. However, we are not satisfied with the additional $O(s^2)$

gates computing the MAC (s is the statistical security parameter) to each of the s copies of the garbled circuit, which results in $O(s^3)$ extra garbled gates in total. Indeed, the number of extra gates can easily exceed the size of the original circuit when f is a simple function. Hence, we propose another approach to authenticate P_1 's output without the extra gates computing the MAC function.

While our approach also converts the circuit to output the ciphertext of P_1 's output, that is, from $f(x, y) = (f_1, f_2)$ to $f^*((c, x), y) = (\lambda, (f_1 \oplus c, f_2))$, we solve the authentication problem by the use of the public-key signature scheme and its corresponding witness-indistinguishable proof. Each bit value of the output of P_1 's output gates is tied together with a signature specifying the value and the location of the bit. On one hand, P_2 can easily verify the signature during the cut-and-choose phase (to confirm that the circuits are correctly constructed). On the other hand, after the evaluation and giving P_1 the evaluation result $(f_1 \oplus c)$, P_2 can show the authenticity of each bit of the result by proving the knowledge of its signature, that is, the signature of the given bit value from the right bit location. Note that a bit location includes a bit index and a circuit index. In other words, a bit location (i, j) indicates P_1 's i -th output bit from the j -th garbled circuit. While the bit index is free to reveal (since P_1 and P_2 have to conduct the proof bit by bit anyway), the circuit index needs to be hidden from P_1 ; otherwise, P_1 can gain information about P_2 's input as we discussed above. We stress that it is critical for P_2 to provide a signature from the right location. Since during the cut-and-choose phase, many properly signed signatures are revealed from the check-circuits, if those signatures do not contain location information, they can be used to convince P_1 to accept arbitrary output.

Normally, an OR-proof will suffice the proof that the signature is from one of the evaluation-circuits. Nevertheless, an OR proof of size $O(s)$ for each bit of P_1 's n -bit output will result in a zero-knowledge proof of size $O(ns)$. We therefore adopt the technique from [4] in order to reduce the size of the proof to $O(n + s)$. Let $S = \{j_1, \dots, j_e\}$ be the indices of all the evaluation-circuits. The idea is for P_1 to send a signature of every element in S , denoted by $[\delta(j_1), \dots, \delta(j_e)]$. By reusing these signatures, P_2 is able to perform each OR proof in constant communication. More specifically, after the evaluation, P_2 chooses one evaluation-circuit, say the j_l -th circuit, the result of which conforms with the majority of all the evaluation-circuits. Let $\mathcal{M} = [M_1, \dots, M_n]$ be P_1 's output from the j_l -th circuit. Recall that P_2 has both M_i and the signature to (M_i, i, j_l) , denoted by $\sigma(M_i, i, j)$, due to the way the garbled circuits were constructed. To prove the authenticity of M_i , P_2 sends M_i to P_1 , blinds signature $\delta(j_l)$ and $\sigma(M_i, i, j_l)$, and proves the knowledge of " $\sigma(M_i, i, j)$ for some $j \in S$." In other words, P_2 needs to prove the knowledge of $\sigma(M_i, i, j)$ and $\delta(j^*)$ such that $j = j^*$ for $i = 1, \dots, n$. The complete proof is shown in Protocol 1. Due to the nonforgeability property of signature schemes, P_2 proves the knowledge of the signature and thus the authenticity of \mathcal{M} .

One particular implementation of our protocol can use the Boneh-Boyen short signature scheme [2] which is briefly summarized here. The Boneh-Boyen

signature scheme requires the q -SDH (*Strong Diffie-Hellman*) assumption⁵ and *bilinear maps*⁶. Based on these two objects, the Boneh-Boyen signature scheme includes a three-tuple of efficient algorithms (G, S, V) such that

1. $G(1^k)$ generates key pair (sk, vk) such that $sk = x \in \mathbb{Z}_p^*$ and $vk = (p, g, \mathbb{G}_1, X)$, where \mathbb{G}_1 is a group of prime order p , g is a generator of \mathbb{G}_1 , and $X = g^x$.
2. $S(sk, m)$ signs the message m with the signing key sk by $\sigma(m) = g^{1/(x+m)}$.
3. $V(vk, m, \sigma)$ verifies the signature σ with vk by calculating $e(\sigma, g^m X)$. If the result equals $e(g, g)$, V outputs **valid**; otherwise, V outputs **invalid**.

Protocol 1: Proof of P_1 's output authenticity

Common Input: ciphertext of P_1 's output $f_1 \oplus c = [M_1, \dots, M_n]$, the indices of the evaluation-circuits $S = \{j_1, \dots, j_e\}$ and the public key (p, \mathbb{G}, g, X, Y) of the Boneh-Boyen signature scheme. In particular, $X = g^x$, and $Y = g^y$.

P_1 **Input:** the corresponding private key (x, y) of the signature scheme.

P_2 **Input:** the signature vector $[\sigma(b_1, 1, j_1), \dots, \sigma(b_n, n, j_i)]$ such that $\sigma(b, i, j) = g^{1/(bx+iy+j)}$ and $j_i \in S$.

$P_1 \xrightarrow{Z, \{\delta(j)\}_{j \in S}} P_2$ P_1 picks another generator h of G and a random $z \in \mathbb{Z}_p^*$. Then P_1 sends $[Z, \delta(j_1), \dots, \delta(j_e)]$ to P_2 such that

$$Z = h^z \text{ and } \delta(j) = h^{1/(z+j)}.$$

$P_1 \xleftarrow{U_1, \dots, U_n, V} P_2$ P_2 picks $u_1, \dots, u_n, v \in \mathbb{Z}_p$ and computes $U_i \leftarrow \sigma(b_i, i, j_i)^{u_i}$ and $V \leftarrow \delta(j_i)^v$. Then $[U_1, \dots, U_n, V]$ is sent to P_1 .

$P_1 \xleftarrow{a_1, \dots, a_n, b} P_2$ P_2 picks $\alpha, \beta_1, \dots, \beta_n, \gamma \in \mathbb{Z}_p$ and sends $[a_1, \dots, a_n, b]$ to P_1 , where $a_i \leftarrow e(U_i, g)^\alpha e(g, g)^{\beta_i}$ and $b \leftarrow e(V, h)^\alpha e(h, h)^\gamma$.

$P_1 \xrightarrow{c} P_2$ P_1 picks $c \in \mathbb{Z}_p$ at random and sends it to P_2 .

$P_1 \xleftarrow{z_\alpha, \{z_{\beta_i}\}, z_\gamma} P_2$ P_2 sends $z_\alpha \leftarrow \alpha + c \cdot j_i$, $z_{\beta_i} \leftarrow \beta_i - c \cdot u_i$, and $z_\gamma \leftarrow \gamma - c \cdot v$ back to P_1 , who checks $a_i \stackrel{?}{=} e(U_i, X^{M_i} Y^i)^c \cdot e(U_i, g)^{z_\alpha} \cdot e(g, g)^{z_{\beta_i}}$ for $i = 1, \dots, n$ and $b \stackrel{?}{=} e(V, Z)^c \cdot e(V, h)^{z_\alpha} \cdot e(h, h)^{z_\gamma}$. P_1 aborts if any of the checks fails.

2.3 Committing Oblivious Transfer

The oblivious transfer (OT) primitive, introduced by Rabin [21], and extended by Even, Goldreich, and Lempel [5] and Brassard, Crépeau and Robert [3] works

⁵ q -SDF assumption in a group G of prime order p states that given $g, g^x, g^{x^2}, \dots, g^{x^q}$, it is infeasible to output a pair $(c, g^{1/(x+c)})$ where $c \in \mathbb{Z}_p^*$.

⁶ Let \mathbb{G}_1 and \mathbb{G}_2 be two groups of prime order p . A bilinear map is a map $e : \mathbb{G}_1 \times \mathbb{G}_1 \mapsto \mathbb{G}_2$ with the following properties: (1) for any $u, v \in \mathbb{G}_1$ and $a, b \in \mathbb{Z}$, $e(u^a, v^b) = e(u, v)^{ab}$; (2) for any generator g of \mathbb{G}_1 , $e(g, g) \neq 1$; and (3) for any $u, v \in \mathbb{G}_1$, it is easy to compute $e(u, v)$.

as follows: there is a sender with messages $[m_1, \dots, m_n]$ and a receiver with a selection value $\sigma \in \{1, \dots, n\}$. The receiver wishes to retrieve m_σ from the sender in such a way that (1) the sender does not “learn” anything about the receiver’s choice σ and (2) the receiver “learns” only m_σ and nothing about any other message m_i for $i \neq \sigma$. Kiraz and Schoenmakers [10] introduced another notion of OT called *committing OT* in which the receiver also receives a perfectly-hiding and computationally-binding commitment to the sender’s input messages, and the sender receives as output the values to open the commitment. Indeed, Kiraz and Schoenmakers introduced this notion specifically for use in a Yao circuit evaluation context. We adopt the idea behind their construction.

Formally, a one-out-of-two committing oblivious transfer OT_1^2 is a pair of interactive probabilistic polynomial-time algorithms sender and receiver. During the protocol, the sender runs with input messages $((m_0, r_0), (m_1, r_1))$, while the receiver runs with input the index $\sigma \in \{0, 1\}$ of the message it wishes to receive. At the end of the protocol, the receiver outputs the retrieved message m'_σ and two commitments $\text{com}_H(m_0; r_0), \text{com}_H(m_1; r_1)$, and the sender outputs the openings (r_0, r_1) to these commitments. Correctness requires that $m'_\sigma = m_\sigma$ for all messages m_0, m_1 , for all selections $\sigma \in \{0, 1\}$ and for all coin tosses of the algorithms. Here, we use the standard notion of simulation security.

Theorem 1. [19] *If the Decisional Diffie-Hellman assumption holds in group G , there exists a protocol that securely computes the committing OT_1^2 .*

Protocol 2 constructively proves Theorem 1. This protocol is a simple modification of the OT protocols designed by Peikert, Vaikuntanathan, and Waters [19] and later Lindell and Pinkas [14]. We simply add a ZK proof of knowledge in intermediate steps. Intuitively, the receiver-security is achieved due to the Decisional Diffie-Hellman assumption and the fact that the ZK proof of knowledge is independent of the receiver’s input. On the other hand, the sender security comes from the uniform distributions of $X_{i,j}$ and $Y_{i,j}$ over G given that $r_{i,j}$ and $s_{i,j}$ are uniformly chosen and that the ZK proof has an ideal-world simulator for the verifier (or the receiver in the OT). As described in [15], it is possible to batch the oblivious transfer operations so that all n input keys (one for each bit) to s copies of the garbled circuit are transferred in one execution.

3 Main Protocol

Here we put all the pieces together to form the complete protocol. Note that $\text{com}_H(K; t)$ denotes a perfectly-hiding commitment to K with opening t , and $\text{com}_B(K; t)$ denotes a perfectly-binding commitment to K with opening t .

Common input: a security parameters k , a statistical security parameter s , a malleable claw-free collection $(G_{\text{CLW}}, D_{\text{CLW}}, F_{\text{CLW}}, R_{\text{CLW}})$, a signature scheme $(G_{\text{SIG}}, S_{\text{SIG}}, V_{\text{SIG}})$, a two-universal hash function $H : \{0, 1\}^* \rightarrow \{0, 1\}^k$, and the description of a boolean circuit C computing $f(x, y) = (f_1, f_2)$, where $|x| = 2n$ (including the extra n -bit random input) and $|y| = |f_1| = |f_2| = n$.

Protocol 2: Oblivious transfer for retrieving P_2 's input keys [14]

| | |
|--|---|
| Common: | A statistical security parameter s , a group G of prime order p , and G 's generator g_0 |
| P_1 Input: | Two s -tuples $[K_{0,1}, \dots, K_{0,s}]$ and $[K_{1,1}, \dots, K_{1,s}]$. |
| P_2 Input: | $\sigma \in \{0, 1\}$ |
| P_1 Output: | Commitment openings $\{K_{i,j}, r_{i,j}, s_{i,j}\}_{i \in \{0,1\}, 1 \leq j \leq s}$ |
| P_2 Output: | $[K_{\sigma,1}, \dots, K_{\sigma,s}]$ and $\{\text{com}_H(K_{i,j}; r_{i,j}, s_{i,j})\}_{i \in \{0,1\}, 1 \leq j \leq s}$ |
| $P_1 \xleftarrow{h_0, g_1, h_1} P_2$ | P_2 picks $y, a \in \mathbb{Z}_p$ and sends $(g_1, h_0, h_1) \leftarrow (g_0^y, g_0^a, g_1^{a+1})$ to P_1 . |
| $P_1 \xleftrightarrow{\text{ZK PoK}} P_2$ | P_2 proves that (h_0, g_1, h_1) satisfies $(h_0 = g_0^a) \wedge (\frac{h_1}{g_1} = g_1^a)$. |
| $P_1 \xleftarrow{g, h} P_2$ | P_2 picks $r \in \mathbb{Z}_p$ and sends $g \leftarrow g_\sigma^r$ and $h \leftarrow h_\sigma^r$ to P_1 . |
| $P_1 \xrightarrow{\{X_{i,j}, Y_{i,j}\}} P_2$ | For $i \in \{0, 1\}, 1 \leq j \leq s$, P_1 picks $r_{i,j}, s_{i,j} \in \mathbb{Z}_p$ and sends $X_{i,j}$ and $Y_{i,j}$ to P_1 , where $X_{i,j} = g_i^{r_{i,j}} h_i^{s_{i,j}}$ and $Y_{i,j} = g^{r_{i,j}} h^{s_{i,j}} \cdot K_{i,j}$. P_2 gets $\text{com}_H(K_{i,j}; r_{i,j}, s_{i,j}) = (X_{i,j}, Y_{i,j})$ and computes key $K_{\sigma,j} \leftarrow Y_{\sigma,j} \cdot X_{\sigma,j}^{-r}$. |

Private input: P_1 has the original input $x_1 \dots x_n$ and the extra random input $x = x_{n+1} \dots x_{2n}$, while P_2 has input $y = y_1 y_2 \dots y_n$.

Private output: P_1 receives output $f_1(x, y)$, while P_2 receives output $f_2(x, y)$.

1. P_2 runs the index selecting algorithm $I \leftarrow G_{\text{CLW}}(1^k)$ and sends I to P_1 .
2. **Committing OT for P_2 's input:** For every $1 \leq i \leq n$ and every $1 \leq j \leq s$, P_1 picks a random pair of k -bit strings $(K_{i,j}^0, K_{i,j}^1)$, which is associated with P_2 's i -th input wire in the j -th circuit. Both parties then conduct n instances of committing OT in parallel. In the i -th instance,
 - (a) P_1 uses input $([K_{i,1}^0, \dots, K_{i,s}^0], [K_{i,1}^1, \dots, K_{i,s}^1])$, whereas P_2 uses input y_i .
 - (b) P_1 gets the openings $([t_{i,1}^0, \dots, t_{i,s}^0], [t_{i,1}^1, \dots, t_{i,s}^1])$ to both commitment vectors, whereas P_2 gets the vector of her choice $[K_{i,1}^{y_i}, \dots, K_{i,s}^{y_i}]$ and the commitments to both vectors, ie., $[\text{com}_H(K_{i,1}^0; t_{i,1}^0), \dots, \text{com}_H(K_{i,s}^0; t_{i,s}^0)]$ and $[\text{com}_H(K_{i,1}^1; t_{i,1}^1), \dots, \text{com}_H(K_{i,s}^1; t_{i,s}^1)]$.
3. **Garbled circuit construction:** P_1 runs the key generating algorithm $G_{\text{SIG}}(1^k)$ to generate a signature key pair (sk_1, pk_1) and the domain sampling algorithm $D_{\text{CLW}}(I)$ to generate domain element $m_{i,j}^b$, for $b \in \{0, 1\}, 1 \leq i \leq 2n, 1 \leq j \leq s$. Next, P_1 constructs s independent copies of garbled version of C , denoted by GC_1, \dots, GC_s . In addition to Yao's construction, circuit GC_j also satisfies the following:
 - (a) $J_{i,j}^b$ is associated with value b to P_1 's i -th input wire, where $J_{i,j}^b$ is extracted from group element $F_{\text{CLW}}(b, I, m_{i,j}^b)$, ie., $J_{i,j}^b = H(F_{\text{CLW}}(b, I, m_{i,j}^b))$.
 - (b) $K_{i,j}^b$ chosen in Step 2 is associated with value b to P_2 's i -th input wire.
 - (c) $b || S_{\text{SIG}}(sk_1, (b, i, j))$ is associated with bit value b to P_1 's i -th output wire.
4. For $b \in \{0, 1\}, 1 \leq i \leq 2n, 1 \leq j \leq s$, P_1 sends circuits GC_1, \dots, GC_s and the commitments to $F_{\text{CLW}}(b, I, m_{i,j}^b)$, denoted by $\text{com}_B(F_{\text{CLW}}(b, I, m_{i,j}^b); r_{i,j}^b)$ to P_2 .

5. **Cut-and-choose:** P_1 and P_2 conduct the coin flipping protocol to generate a random tape, by which they agree on a set of check-circuits. Let T be the resulting set, that is, $T \subset \{1, \dots, s\}$ and $|T| = 3s/5$. For every $j \in T$, P_1 sends to P_2 P_1 's of garbled circuit GC_j , including $[K_{1,j}^b, \dots, K_{n,j}^b]$, $[t_{1,j}^b, \dots, t_{n,j}^b]$, $[m_{1,j}^b, \dots, m_{2n,j}^b]$, $[r_{1,j}^b, \dots, r_{2n,j}^b]$, for $b \in \{0, 1\}$, and the random keys associated with each wire of GC_j . P_2 check the following:
- (a) The commitment from Step 2 is revealed to $K_{i,j}^b$ with $t_{i,j}^b$.
 - (b) The commitment from Step 4 is revealed to $F_{\text{CLW}}(b, I, m_{i,j}^b)$ with $r_{i,j}^b$.
 - (c) GC_j is a garbled version of C^* that is correctly built. In particular,
 - $H(F_{\text{CLW}}(b, I, m_{i,j}^b))$ is associated with value b to P_1 's i -th input wire;
 - $K_{i,j}^b$ is associated with bit value b to P_2 's i -th input wire;
 - $V_{\text{SIG}}(pk_1, (b, i, j), \sigma(b, i, j)) = \text{valid}$, where $\sigma(b, i, j)$ is the signature comes along with bit value b from P_1 's i -th output wire;
 - the truth table of each boolean gate is correctly converted to the doubly-encrypted entries of the corresponding garbled gate.

If any of the above checks fails, P_2 aborts.

6. **Consistency check for P_1 's inputs:** Let $e = 2s/5$ and $\{j_1, \dots, j_e\}$ be the indices of evaluation-circuits. P_1 then decommits to her input keys for the evaluation-circuits by sending $([r_{1,j_1}^{x_1}, \dots, r_{2n,j_1}^{x_{2n}}], \dots, [r_{1,j_e}^{x_1}, \dots, r_{2n,j_e}^{x_{2n}}])$ to P_2 . Let $[M_{1,j_1}, \dots, M_{2n,j_1}], \dots, [M_{1,j_e}, \dots, M_{2n,j_e}]$ be the resulting decommitments. Next, P_1 proves the consistency of her i -th input bit by sending $[m_{i,j_2}^{x_i} \star (m_{i,j_1}^{x_i})^{-1}, \dots, m_{i,j_e}^{x_i} \star (m_{i,j_1}^{x_i})^{-1}]$ to P_2 , who then checks if

$$M_{i,j_l} = M_{i,j_1} \diamond R_{\text{CLW}}(I, m_{i,j_l}^{x_i} \star (m_{i,j_1}^{x_i})^{-1}), \text{ for } l = 2, \dots, e.$$

P_2 aborts if any of the checks fails. Otherwise, let $J_{i,j_l}^{x_i} = H(M_{i,j_l})$.

7. **Circuit evaluation:** For every $j \in \{j_1, \dots, j_e\}$, P_2 now has key vectors $[J_{1,j}^{x_1}, \dots, J_{2n,j}^{x_{2n}}]$ (from Step 6) representing P_1 's input x and $[K_{1,j}^{y_1}, \dots, K_{n,j}^{y_n}]$ (from Step 2) representing P_2 's input y . So P_2 is able to do the evaluation on circuit GC_j and get P_1 's output $[M_{1,j} \parallel \sigma(M_{1,j}), \dots, M_{n,j} \parallel \sigma(M_{n,j})]$ and P_2 's output $[N_{1,j}, \dots, N_{n,j}]$, where $M_{i,j}, N_{i,j} \in \{0, 1\}$. Let $\mathcal{M}_j = [M_{1,j}, \dots, M_{n,j}]$ and $\mathcal{N}_j = [N_{1,j}, \dots, N_{n,j}]$ be the n -bit outputs for P_1 and P_2 , respectively. P_2 then chooses index j_l such that \mathcal{M}_{j_l} and \mathcal{N}_{j_l} appear more than $e/2$ times in vectors $[\mathcal{M}_{j_1}, \dots, \mathcal{M}_{j_e}]$ and $[\mathcal{N}_{j_1}, \dots, \mathcal{N}_{j_e}]$, respectively. P_2 sends \mathcal{M}_{j_l} to P_1 and takes \mathcal{N}_{j_l} as her final output. If no such j_l exists, P_2 aborts.
8. **Verification to P_1 's output:** To convince P_1 the authenticity of \mathcal{M}_{j_l} without revealing j_l , P_1 generates another signature key pair (sk_2, pk_2) . Then P_1 signs the indices of all the evaluation-circuits and sends the results to P_2 . In particular, P_1 sends to P_2 the public key pk_2 and a signature vector $[\delta(j_1), \dots, \delta(j_e)]$, where $\delta(j) = S_{\text{SIG}}(sk_2, j)$. The signature is verified by P_2 by checking $V_{\text{SIG}}(pk_2, j, \delta(j)) = \text{valid}$, for every $j \in \{j_1, \dots, j_e\}$. Next, P_2 proves to P_1 in witness-indistinguishable sense the knowledge of $\sigma(M_{i,j_l}, i, j)$ (a signature signed with sk_1) and $\delta(j^*)$ (a signature signed with sk_2) such that j and j^* are equivalent, for $1 \leq i \leq n$. P_1 aborts if the proof is not valid; otherwise, P_1 takes $\mathcal{M}_{j_l} \oplus (x_{n+1}, \dots, x_{2n})$ as her final output.

Theorem 2. *Let $f : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}^n \times \{0, 1\}^n$ be any function. Given a secure committing oblivious transfer protocol, a perfectly-hiding commitment scheme, a perfectly-binding commitment scheme, a malleable claw-free family, and a pseudo-random function family, the Main protocol securely computes f .*

We have omitted the standard simulation-based definition of “securely computes f ” for space. Roughly, this definition requires a simulator for the corrupted evaluator, and a simulator for the corrupted generator that is able to generate transcripts given only oracle access to either the evaluator or generator (respectively) that are indistinguishable from the transcripts produced in real interactions between the corrupted generator and honest evaluator or honest generator and corrupted evaluator. (A simulator for when both parties are corrupted is also required but trivial.) The proof of Theorem 2 is omitted for space.

4 Experimental Results

We produced an implementation of our protocol to demonstrate its practical benefits. Our implementation takes the boolean circuit generated by Fairplay compiler as input. The encryption function used to construct garbled gates is defined as $\text{Enc}_{J,K}(m) = (m \oplus \text{SHA-256}(J) \oplus \text{SHA-256}(K))_{1\dots k}$, where $|J| = |K| = |m| = k$, and $S_{1\dots k}$ denotes the least significant k bits of S . Here SHA-256 is modeled as a pseudorandom function. The choice of SHA-256 is to make a fair comparison as it is used in [20].

Table 2: The performance comparison with [20].

Following Pinkas et. al [20], we set the security level to 2^{-40} and the security parameter k (key length) to 128-bit. In the first experiment, P_1 and P_2 hold a 32-bit input $x = (x_{31}x_{30} \dots x_0)_2$ and $y = (y_{31}y_{30} \dots y_0)_2$, respectively. They want to compute $f(x, y) = (f_1, f_2)$ such that after the secure computation, P_1 receives $f_1 = \sum_{i=0}^{31} x_i \oplus y_i$, and P_2 receives f_2 as the result of comparison between x and y . The 6 gates of overhead we incur in the first experiment relate to our method for two-output functions. In the second experiment, P_2 has a 128-bit message block while P_1 has a 128-bit encryption key. They want to securely compute the AES encryption, and only P_2 gets the ciphertext.

We ran our experiments on two machines: `slower` and `fast`, where `slower` runs OS X 10.5 with Intel Core 2 Duo 2.8 GHz and 2GB RAM, and `fast` runs CentOS with Intel Xeon Quad Core E5506 2.13 GHz and 8GB RAM. `slower` is not as powerful as the machine used in [20] (Intel Core 2 Duo 3.0 GHz, 4GB RAM), and `fast` is the next closest machine that we have.

Table 2 reports the *best* numbers from [20]. We note that [20] applies the Garbled Row Reduction technique so that even non-XOR gates can save 25% of the communication overhead. A future version of our protocol can also reap this 25% reduction since the technique is compatible with our protocol.

Our implementation involves a program for P_1 and one for P_2 . For the purpose of timing, we wrote another program that encapsulates both of these programs and feeds the output of one as the input of the other and vice versa. Timing routines are added around each major step of the protocol and tabulated in Table 3. This timing method eliminates any overhead due to network transmission, which we cannot reliably compare. The reported values are the averages from 5 runs.

We implemented our solution with the PBC (Pairing Based Cryptography) library [1] for testing. The components of our protocol, including the claw-free collections, the generator’s input consistency check, and the generator’s output validity check, are built on top of the elliptic curve $y^2 = x^3 + 3$ over the field \mathbb{F}_q for some 80-bit prime q . We have made systems-level modifications to the random bit sampling function of the PBC library (essentially to cache file handles and eliminate unnecessary systems calls).

In Table 4, we list the results of the MAC-based two-output function handling and ours. The MAC approach introduces extra 16,384 (128^2) non-XOR gates to the AES circuit, whereas the original AES circuit has only 11,286 non-XOR gates. Since the number of non-XOR gates is almost doubled in the MAC-based approach, their circuit construction and evaluation need time about twice as much as ours. Moreover, the MAC-based approach has twice as many input bits as ours so that the time for P_1 ’s input consistency has doubled.

A Optimal Choice in Cut-and-Choose Strategy

According to the cut-and-choose strategy, P_2 chooses e copies of the garbled circuits and asks P_1 to open the rest ($s - e$). After the verification, P_2 evaluates the rest e copies of the circuits and takes the majority output as her output. A natural question is: *Under the assumption that P_1 's inputs are consistent, how many circuits does P_2 evaluate in order to minimize the probability for P_1 's best cheating strategy to succeed?*

The assumption is valid due to the consistency check on P_1 's input. Given that s and e are fixed and known to P_1 , let b be the number of bad circuits created by P_1 . A circuit is *bad* if either the circuit is wrongly constructed or P_2 's inputs are selectively failed via OT. The goal is to find e and b such that the probability that P_1 cheats without getting caught $\binom{s-b}{s-e} / \binom{s}{s-e}$ is minimized.

We first claim that P_1 's best cheating strategy is to produce $b = \lfloor e/2 \rfloor + 1$ bad circuits. Indeed, if $b \leq \lfloor e/2 \rfloor$, P_2 's output will not get affected since the faulty outputs will be overwhelmed by majority good ones. Also, the more bad circuits, the more likely that P_1 will get caught since $\binom{s-(b-1)}{s-e} > \binom{s-b}{s-e}$. So the best strategy for P_1 to succeed in cheating is to construct as few bad circuits as possible while the majority of evaluation circuits are bad, which justifies the choice of b .

Our next goal is to find the e that minimizes $\Pr(e) = \binom{s-\lfloor \frac{e}{2} \rfloor - 1}{s-e} / \binom{s}{s-e}$. To get rid of the troublesome floor function, we will consider the case when e is even and odd separately. When $e = 2k$ for some $k \in \mathbb{N}$ such that $k \leq \frac{s}{2}$, let $\Pr_{\text{even}}(k) = \binom{s-k-1}{s-2k} / \binom{s}{s-2k}$. Observe that $\frac{\Pr_{\text{even}}(k+1)}{\Pr_{\text{even}}(k)} = \frac{(2k+1)(2k+2)}{(s-k-1)k}$. It is not hard to solve the quadratic inequality and come to the result that

$$\frac{\Pr_{\text{even}}(k+1)}{\Pr_{\text{even}}(k)} \leq 1 \text{ when } 0 < k \leq \frac{1}{10} \left(s - 7 + \sqrt{(s-7)^2 - 40} \right) \stackrel{\text{def}}{=} \alpha.$$

In other words, $\Pr_{\text{even}}(k) \geq \Pr_{\text{even}}(k+1)$ when $0 < k \leq \alpha$; and $\Pr_{\text{even}}(k) < \Pr_{\text{even}}(k+1)$ when $\alpha < k \leq \frac{s}{2}$. Therefore, \Pr_{even} is minimal when $k = \lceil \alpha \rceil$. Similarly, when $e = 2k + 1$, the probability $\Pr_{\text{odd}}(k) = \binom{s-k-1}{s-2k-1} / \binom{s}{s-2k-1}$ is minimal when $k = \lceil \beta \rceil$, where $\beta = \frac{1}{5}(s-7)$. In summary,

$$\begin{cases} \Pr_{\text{even}}(e) \text{ is minimal when } e = 2\lceil \alpha \rceil; \\ \Pr_{\text{odd}}(e) \text{ is minimal when } e = 2\lceil \beta \rceil + 1, \end{cases}$$

and $\Pr(e)$'s minimum is one of them.

B Security Proof for Theorem 2

Malicious evaluator P_2^*

Recall that in this case P_1 follows the Main protocol faithfully. To prove that

$$\mathbf{Real}(P_1(x), P_2^*(y), 1^k) \approx_c \mathbf{Ideal}(P_1(x), S_2^{P_2^*(y)})$$

for all $x, y \in \{0, 1\}^n$, consider the following hybrid experiments and lemmas.

Hybrid₁($P_1(x), P_2^*(y), 1^k$): This hybrid experiment is the same as the real experiment **Real** except the oblivious transfers. During the OT, the experiment runs the OT simulator S_{OT} , the existence of which comes from Theorem 1. Let y_i^* be the query that S_{OT} requests to the OT oracle in the i -th OT instance. The experiment generates key vectors ($[K_{i,1}^0, \dots, K_{i,s}^0], [K_{i,1}^1, \dots, K_{i,s}^1]$), and uses these key vectors to answer S_{OT} 's query so that P_2^* gets

$$[K_{i,1}^{y_i^*}, \dots, K_{i,s}^{y_i^*}], \text{ for } 1 \leq i \leq n.$$

Lemma 1. $\mathbf{Real}(P_1(x), P_2^*(y), 1^k) \approx \mathbf{Hybrid}_1(P_1(x), P_2^*(y), 1^k)$

Proof. The only difference between **Hybrid₁** and **Real** is that S_{OT} is invoked in **Hybrid₁**. After this step, both experiments are identical since the experiment acts exactly the same as P_1 does in **Real**. So this lemma follows from the simulation property of the secure OT protocol in Theorem 1. In particular, the identical distribution of key vectors and commitments is being used by S_{OT} . \square

Hybrid₂($P_1(x), P_2^*(y), 1^k$): This is the same as **Hybrid₁** except the coin-flipping phase. In particular, instead of running the coin-flipping protocol like what P_1 and P_2^* would do in the Main protocol, the experiment chooses a random string ρ , and runs the coin-flipping simulator $S_{\text{CF}}(\rho, 1^k)$ to generate the protocol transcript whose output is ρ .

Lemma 2. $\mathbf{Hybrid}_1(P_1(x), P_2^*(y), 1^k) \approx_c \mathbf{Hybrid}_2(P_1(x), P_2^*(y), 1^k)$

Proof. **Hybrid₁** and **Hybrid₂** differ only in the way that transcripts of coin-flipping protocol are generated. Intuitively, the lemma follows from property (3) of Theorem ?? because the coin-flipping simulator S_{CF} is given black-box access to P_2^* and input ρ . More formally, suppose that there exists a distinguisher D that for infinitely many k , distinguishes **Hybrid₁** from **Hybrid₂** with probability $\Pr(k)$. We use D to construct D' that distinguishes $\mathbf{tran}(P_1, S_{\text{CF}}(\rho, 1^k))$ from $\mathbf{tran}(P_1, P_2^*)$ as follows:

Let x, y be inputs for which D has the greatest probability of distinguishing **Hybrid₁** and **Hybrid₂**. (These values are given as non-uniform advice for security parameter k .) On input a transcript \mathbf{tran} , D' first runs **Hybrid₁**($P_1(x), P_2^*(y), 1^k$) until the point that the coin-flipping protocol occurs. Recall that \mathbf{tran} consists of the view of both parties of the coin-flipping protocol. This includes the random coins of both parties and the messages exchanged. At this point, D' extracts the

random tapes r_1, r_2 of both parties from **tran**, and splices these into the random tapes for P_1 and for P_2^* (without loss of generality, we can assume that neither P_1 nor P_2^* has accessed these coins yet). D' then feeds the messages from the transcript **tran** to both parties until the coin-flipping protocol completes. At this point, D' continues the rest of **Hybrid**₂ to completion. Then D' runs D on the final transcript and echoes the result. Notice that when **tran** is generated by the real coin-flipping protocol, D' outputs **Hybrid**₁; and when **tran** is generated by the coin-flipping simulator, D' outputs **Hybrid**₂. Thus, D' distinguishes the coin-flipping simulator with probability $\Pr(k)$, which implies that $\Pr(k)$ must be negligible and therefore establishes the lemma. \square

Hybrid₃($P_1(x), P_2^*(y), 1^k$): This is the same experiment as **Hybrid**₂ except that the garbled circuits sent to P_2^* are modified as follows: The experiment generates a challenge set $T \subset \{1, \dots, s\}$ where $|T| = 3s/5$ based on the random tape ρ . If $j \in T$, then GC_j is the garbled version of C^* as per Step 3 of the Main protocol; otherwise, GC_j is constructed as per Claim 8 of [13] computing the constant function, which outputs \mathcal{N} for all input $x, y \in \{0, 1\}^n$. Recall that \mathcal{N} is P_2^* 's output returned from the external oracle after the experiment sends y^* to it.

Lemma 3. $\text{Hybrid}_2(P_1(x), P_2^*(y), 1^k) \approx_c \text{Hybrid}_3(P_1(x), P_2^*(y), 1^k)$

Proof. Note that the two hybrid experiments differ only in the way the garbled circuits are constructed. Intuitively, assuming perfectly binding/hiding commitments and secure symmetric encryption, this lemma follows from Claim 8 given in [13] and copied below for convenience.

Lemma 4 (Claim 8 of [13]). *Given a boolean circuit C computing function f and an output value z , it is possible to efficiently construct a garbled circuit GC' such that*

1. *For all inputs, the output of GC' is always z ,*
2. *If $z = f(x, y)$ for some x and y , then no non-uniform probabilistic polynomial-time adversary can distinguish between the distribution ensemble consisting of $\{GC', K_{x'}, K_{y'}\}$ where $K_{x'}, K_{y'}$ are the garbled keys for arbitrary x', y' , and the ensemble consisting of $\{GC, K_x, K_y\}$ where GC is a real garbled version of C , and K_x, K_y are the garbled keys representing inputs x, y .*

Formally, let $[GC_1, \dots, GC_s]$ be the garbled circuits in **Hybrid**₂ and $[GC'_1, \dots, GC'_s]$ be the fake garbled circuits in **Hybrid**₃. (Technically, only 40% among $[GC'_1, \dots, GC'_s]$ are fake. In each fake circuit, only P_2^* 's output gates are modified to output the constant \mathcal{N} .) Let **Hybrid**_{2, i} be the same as **Hybrid**₂ except that for the first i elements j_1, \dots, j_i in the challenge set T , circuit GC'_{j_i} is used instead of GC_{j_i} . Observe that **Hybrid**_{2,0} = **Hybrid**₂ and **Hybrid**_{2, s} = **Hybrid**₃. Suppose that there exists some x, y and some probabilistic polynomial-time distinguisher D such that for infinitely many k , D distinguishes **Hybrid**₂ from **Hybrid**₃ with

probability $\Pr(k)$. Then by averaging, there must be some i such that D distinguishes **Hybrid** $_{2,i}$ from **Hybrid** $_{2,i+1}$ with probability $\Pr(k)/s$. With such distinguisher D , an algorithm D' distinguishing $\{GC', K_x, K_{y^*}\}$ from $\{GC, K_x, K_{y^*}\}$ can be constructed as follows: On input either $\{GC', K_x, K_{y^*}\}$ or $\{GC, K_x, K_{y^*}\}$, D' first simulates **Hybrid** $_{2,i}$ except that D' uses its input for the $(i+1)$ st garbled circuit, and completes the rest of experiment **Hybrid** $_{2,i}$. Then D' runs D on the resulting transcript and echo D 's output. D' does a perfect simulation of either **Hybrid** $_{2,i}$ or **Hybrid** $_{2,i+1}$, and therefore distinguishes garbled circuits with probability $\Pr(k)/s$. By Lemma 4, $\Pr(k)$ must be negligible and we complete the proof. Note that both **Hybrid** $_2$ and **Hybrid** $_3$ still use the real input keys $\{K_x\}$. \square

Hybrid $_4(P_1(x), P_2^*(y))$: This is the same as hybrid experiment **Hybrid** $_3$ with the exception that in the consistency check the experiment uses input 0^{2n} instead of input (x, c) .

Lemma 5. $\text{Hybrid}_3(P_1(x), P_2^*(y), 1^k) \approx_s \text{Hybrid}_4(P_1(x), P_2^*(y), 1^k)$

Proof. Intuitively, the idea is to substitute P_1 's input (x, c) with 0^{2n} bit by bit. Each of the substitutions is indistinguishable from the previous one due to the witness indistinguishable property of the consistency check protocol. Formally, let **Hybrid** $_{3,i}$ be the same experiment as **Hybrid** $_3$ except 0's are used for the first i bits instead of x_1, \dots, x_i . Recall that x_i is the i -th bit of P_1 's input (x, c) , where $|x| = |c| = n$. In other words, experiment **Hybrid** $_{3,i}$ uses $(0, \dots, 0, x_{i+1}, \dots, x_{2n})$ rather than $(x_1, \dots, x_i, x_{i+1}, \dots, x_{2n})$ used by **Hybrid** $_3$. Note that **Hybrid** $_{3,0} = \text{Hybrid}_3$ and **Hybrid** $_{3,2n} = \text{Hybrid}_4$. To prove that **Hybrid** $_{3,i-1}$ and **Hybrid** $_{3,i}$ are statistically indistinguishable for $i = 1, \dots, 2n$, observe that the only difference between these two experiments are the messages for the i -th input bit consistency check. More specifically, in **Hybrid** $_{3,i-1}$, P_2^* receives

$$([F(x_i, I, m_{i,j_1}^{x_i}), \dots, F(x_i, I, m_{i,j_e}^{x_i})], [m_{i,j_2}^{x_i} \star (m_{i,j_1}^{x_i})^{-1}, \dots, m_{i,j_e}^{x_i} \star (m_{i,j_1}^{x_i})^{-1}],$$

whereas in **Hybrid** $_{3,i}$, P_2^* receives

$$([F(0, I, m_{i,j_1}^0), \dots, F(0, I, m_{i,j_e}^0)], [m_{i,j_2}^0 \star (m_{i,j_1}^0)^{-1}, \dots, m_{i,j_e}^0 \star (m_{i,j_1}^0)^{-1}]).$$

By the identical range (for the first halves of both messages) and the uniform domain (for the second halves) properties of the malleable claw-free collections, the two tuples are statistically indistinguishable. Thus, the lemma holds. \square

Hybrid $_5(P_1(x), P_2^*(y), 1^k)$: This is the same as experiment **Hybrid** $_4$ with the exception that experiment **Hybrid** $_5$ sends abort to the external oracle if the last proof protocol is invalid. Afterwards, S_2 outputs whatever P_2^* outputs.

Lemma 6. $\text{Hybrid}_4(P_1(x), P_2^*(y), 1^k) \approx_c \text{Hybrid}_5(P_1(x), P_2^*(y), 1^k)$

This follows immediately from the soundness of the WI proof in the last step.

Lemma 7. *The simulator $S_2^{P_2^*}$ runs in expected polynomial time.*

Proof. Since P_2^* is a strict polynomial-time adversary, most of the steps of the simulation are also strictly polynomial-time except the running of OT simulator S_{OT} , and the running of coin-flipping simulator S_{CF} . Thus, the running time of simulator S_2 can be expressed as $p(k) + r_{\text{OT}} + r_{\text{CF}}$ where r_{OT} and r_{CF} are random variables denoting the running time of S_{OT} and S_{CF} . This lemma follows because both S_{OT} and S_{CF} occur only once, i.e., they are never rewound or part of a loop. Thus, the overall running time is expected polynomial time by linearity of expectations. \square

Finally, since $\mathbf{Ideal}(P_1(x), S_2^{P_2^*}(y), 1^k)$ and \mathbf{Hybrid}_5 are syntactically similar, by Lemma 1–7, we prove the security of the Main protocol when P_2 is malicious.

Malicious generator P_1^* :

In this case, P_2 follows the Main protocol faithfully. Let $\mathbf{Real}(P_1^*(x), P_2(y), 1^k)$ be P_1^* 's and P_2 's outputs from the Main protocol with P_1^* using x and P_2 using y . To prove that $\mathbf{Real}(P_1^*(x), P_2(y), 1^k)$ and $\mathbf{Ideal}(S_1^{P_1^*}(x), P_2(y), 1^k)$ are indistinguishable for all $x, y \in \{0, 1\}^n$, consider the following hybrid experiments.

Hybrid₁($P_1^*(x), P_2(y), 1^k$): This is the same as $\mathbf{Real}(P_1^*(x), P_2(y), 1^k)$ except that if P_1^* passes the first cut-and-choose test, the experiment repeatedly rewinds P_1^* over the cut-and-choose process, including the coin-flipping protocol and the verification of the chosen circuits, until P_1^* passes for the second time. Let T_i be the challenge set of the i -th successful cut-and-choose, and $T = T_1 \setminus T_2$. If over the course of these two successful cut-and-choose test $|T| = 0$, then the experiment aborts.

Lemma 8. $\mathbf{Real}(P_1^*(x), P_2(y), 1^k) \approx_s \mathbf{Hybrid}_1(P_1^*(x), P_2(y), 1^k)$

Proof. The main idea behind the indistinguishability between these two experiment is if P_1^* never passes the cut-and-choose test, both \mathbf{Real} and \mathbf{Hybrid}_1 abort right after the cut-and-choose stage. Once P_1^* passes the test for the first time (even with small probability), experiment \mathbf{Hybrid}_1 is able to have P_1^* pass another cut-and-choose test after expected polynomially many rewinds. The goal here is to prove that $\Pr[|T| = 0]$ is negligible.

Let \mathcal{T} be the collection of all the possible challenge sets in the cut-and-choose test, that is, $\mathcal{T} = \{A \mid A \subset \{1, \dots, s\} \text{ and } |A| = 3s/5\}$. Next, let X be a random variable over \mathcal{T} representing the chosen challenge set and **success** be the event that P_1^* passes the cut-and-choose. Since the coin-flipping protocol always produces independently and uniformly distribution random bits, each rewind is independent. Moreover, between the first and the second successful

cut-and-choose tests, there might be many rewinds when P_1^* fails the test. Thus,

$$\begin{aligned} \Pr[|T| = 0] &= \sum_{t \in \mathcal{T}} \Pr[X = t \ \& \ \text{success}] \left(\sum_{i=0}^{\infty} (1 - \Pr[\text{success}])^i \cdot \Pr[X = t \ \& \ \text{success}] \right) \\ &= \sum_{t \in \mathcal{T}} \Pr[X = t \ \& \ \text{success}] \left(\frac{1}{\Pr[\text{success}]} \cdot \Pr[X = t \ \& \ \text{success}] \right) \\ &= \sum_{t \in \mathcal{T}} \frac{\Pr[X = t \ \& \ \text{success}]}{\Pr[\text{success}]} (\Pr[X = t] \Pr[X = t \ \& \ \text{success} | X = t]). \end{aligned}$$

Since X distributes uniformly over \mathcal{T} and $\Pr[X = t \ \& \ \text{success} | X = t] \leq 1$, we have

$$\Pr[|T| = 0] \leq \sum_{t \in \mathcal{T}} \frac{\Pr[X = t \ \& \ \text{success}]}{\Pr[\text{success}]} \cdot \frac{1}{|\mathcal{T}|} = \frac{1}{|\mathcal{T}|} = \frac{1}{\binom{s}{3s/5}} < 2^{-0.4s}.$$

Therefore, the lemma holds. \square

Hybrid₂($P_1^*(x), P_2(y), 1^k$): This is the same as **Hybrid₁** except the experiment aborts if P_1^* 's input cannot be extracted correctly. More specifically, recall that for all $j \in T$, garbled circuit GC_j has been *opened* during the first successful cut-and-choose. However, at this step P_1^* expects circuit GC_j to be evaluated and is supposed to reveal $[M_{1,j}, \dots, M_{2n,j}]$. So the experiment is able to extract P_1^* 's i -th bit x_i^* by comparing $M_{i,j}$ with the range elements associated with P_1^* 's i -th bit in GC_j . In particular, for $j \in T$, if $M_{i,j}$ is the range element associated with bit value 0 in GC_j , then $x_{i,j}^* \leftarrow 0$; else if $M_{i,j}$ is the range element associated with bit value 1 in GC_j , then $x_{i,j}^* \leftarrow 1$; otherwise, the experiment aborts (Fail₁). Since $|T| > 0$, the experiment has $|T|$ possible $2n$ -bit input for P_1 . The experiment aborts (Fail₂) if these inputs are inconsistent, that is, $x_{i,j}^* \neq x_{i,j'}^*$, for $j \neq j'$.

Lemma 9. $\text{Hybrid}_1(P_1^*(x), P_2(y), 1^k) \approx_c \text{Hybrid}_2(P_1^*(x), P_2(y), 1^k)$

Proof. **Hybrid₁** and **Hybrid₂** differ only when the experiment continues in **Hybrid₁** but aborts in **Hybrid₂**, that is, either Fail₁ or Fail₂ happens. Recall that for $j \in T$ garbled circuit GC_j passes the check in the first successful cut-and-choose, and thus, the commitments to $F_{\text{CLW}}(0, I, m_{i,j}^0)$ and $F_{\text{CLW}}(1, I, m_{i,j}^1)$ are correctly constructed. By the perfectly-binding commitment scheme P_1^* is using, the revealed $M_{i,j}$ must be either $F_{\text{CLW}}(0, I, m_{i,j}^0)$ or $F_{\text{CLW}}(1, I, m_{i,j}^1)$. So Fail₁ cannot happen.

Next, we need to bound the probability of Fail₂. If $|T| = 1$, then Fail₂ does not happen. On the other hand, if $|T| > 1$, without loss of generality, Fail₂ happens when $M_{i,j} = F_{\text{CLW}}(0, I, m_{i,j}^0)$ and $M_{i,j'} = F_{\text{CLW}}(1, I, m_{i,j'}^1)$ for some $j \neq j'$. Recall that it was checked that $M_{i,j'} = M_{i,j} \diamond R_{\text{CLW}}(I, m)$ for some m . In other words, $M_{i,j'} = F_{\text{CLW}}(0, I, m_{i,j}^0) \diamond R_{\text{CLW}}(I, m) = F_{\text{CLW}}(0, I, m_{i,j}^0 \star m)$. Hence, Fail₂ happens implies that P_1^* found a claw $(m_{i,j'}^1, m_{i,j}^0 \star m)$, which by the claw-free property of the malleable claw-free collections happens only with negligible probability. \square

Hybrid₃($P_1^*(x), P_2(y), 1^k$): This is the same as **Hybrid₂** except that the experiment aborts if the output from the external oracle for f does not coincide with the output from the majority of the results from garbled circuit evaluation. More specifically, let (x^*, c^*) be the $2n$ bits extracted from P_1^* , where $|x^*| = |c^*| = n$. The experiment sends x^* to the external oracle and gets $f_1(x^*, y)$ in return. Then $\mathcal{M} = f_1(x^*, y) \oplus c^*$ is the result from the external oracle. Then the experiment continues to evaluate the garbled circuits and get \mathcal{M}' as the majority of the results from the circuit evaluation. The experiment aborts if $\mathcal{M} \neq \mathcal{M}'$.

Lemma 10. $\text{Hybrid}_2(P_1^*(x), P_2(y), 1^k) \approx_c \text{Hybrid}_3(P_1^*(x), P_2(y), 1^k)$.

Proof. Note that after the input consistency check, P_1^* 's input is consistent among evaluation-circuits with very high probability (as long as P_1^* does not find a claw). Hence, \mathcal{M} and \mathcal{M}' differ only when more than half of the evaluation-circuits are corrupted. Recall that a circuit is corrupted if either P_2 's input from the committing OT is corrupted or the circuit itself is faulty. Since P_1^* has passed the cut-and-choose process, the event that \mathcal{M} and \mathcal{M}' differ implies that P_1^* has corrupted more than $s/5$ circuits and all of them are used in the evaluation stage, the probability of which is at most $\binom{4s/5}{3s/5} / \binom{s}{3s/5} < 2^{-0.32s}$. Hence, the lemma holds. It is worth mentioning that $\binom{4s/5}{3s/5} / \binom{s}{3s/5} < 2^{-0.32s} < \binom{3s/4}{s/2} / \binom{s}{s/2}$, which shows that our $2s/5$ -out-of- s approach for cut-and-choose has a better bound than the conventional $s/2$ -out-of- s approach. Also note that $2^{-0.32s}$ is also the upper bound of the probability that P_1^* cheats in our approach, which is better than any of the prior work. \square

Hybrid₄($P_1^*(x), P_2(y), 1^k$): This is the same as **Hybrid₃** except that the experiment actually uses \mathcal{M} , the output from the external oracle, instead of \mathcal{M}' , the output from circuit evaluation, to conduct the output authenticity proof. More specifically, after the circuit evaluation, if the experiment could not find a result that conforms with the majority, the experiment aborts. If the experiment does get the result \mathcal{M}' from evaluating circuits, it sends \mathcal{M}' to P_1^* . Next, the experiment randomly chooses an element j_l from T . Recall that garbled circuit GC_{j_l} is opened in the first successful cut-and-choose, and thus, the experiment has the knowledge of $[W_{1,j_l}^0, \dots, W_{n,j_l}^0, W_{1,j_l}^1, \dots, W_{n,j_l}^1]$.

Lemma 11. $\text{Hybrid}_3(P_1^*(x), P_2(y), 1^k) \approx_c \text{Hybrid}_4(P_1^*(x), P_2(y), 1^k)$.

Proof. Recall that in **Hybrid₃** the output \mathcal{M}' of P_1^* comes from the circuit $GC_{j'_l}$, the output of which conforms with the majority of the $2s/5$ evaluation-circuits, whereas in **Hybrid₄** the output \mathcal{M} of P_1^* comes from the external oracle for f and j_l is randomly chosen from T . Note that T is a subset of $\{1, \dots, s\} \setminus T_2$, the set of evaluation-circuits. Hence, both j_l and j'_l are valid indices of evaluation-circuits. Since $\mathcal{M}' = \mathcal{M}$, by the witness-indistinguishability property of the final proof, **Hybrid₃** and **Hybrid₄** are indistinguishable despite the possibility that j_l may not equal j'_l . \square

Hybrid₅($P_1^*(x), P_2(y), 1^k$): This is the same as **Hybrid₄** except that the experiment does not evaluate any of the garbled circuits.

Lemma 12. $\text{Hybrid}_4(P_1^*(x), P_2(y), 1^k) \approx_c \text{Hybrid}_5(P_1^*(x), P_2(y'), 1^k)$

Proof. The only concern here is that **Hybrid₄** might abort because of not evaluating circuits successfully (no output appears more than $s/5$ times and referred by event Fail_3), whereas **Hybrid₅** does not evaluate the circuits, and thus, never abort for the same reason. In other words, we need to argue that $\Pr(\text{Fail}_3)$ is negligible, which is straightforward as claimed in Lemma 10.

Hybrid₆($P_1^*(x), P_2(y), 1^k$): This is the same as **Hybrid₅** except that the experiment uses a random input y' instead of y in the OT protocol.

Lemma 13. $\text{Hybrid}_5(P_1^*(x), P_2(y), 1^k) \approx_c \text{Hybrid}_6(P_1^*(x), P_2(y'), 1^k)$

Proof. By the receiver-security property of the OT protocol (Theorem 1), these two experiments are indistinguishable during the OT phase. We then need to argue that after the OT phase, the probability experiment **Hybrid₅** using y aborts is statistically close to the probability experiment **Hybrid₆** using y' aborts. In particular, the probability of abort is independent of the choice of y .

Recall that when the key received from OT does not match the key used to construct the corresponding input gate, the garbled circuit is not *evaluable*. The issue is that garbled circuit GC_j may be evaluable in **Hybrid₅** but not in **Hybrid₆**. Without loss of generality, consider a specific input bit where $y_i = 0$ and $y'_i = 1$. Let $\{K_{i,j}^0, K_{i,j}^1\}$ be the input keys that P_1^* uses to construct GC_j . If both keys are corrupted, GC_j is not evaluable in both experiments, and thus, **Hybrid₅** and **Hybrid₆** react in exactly the same way as per Main protocol. In particular, a corrupt key in OT could be trash \perp so that the receiver detects P_1^* 's cheating right after OT. Next, consider the case that P_1^* only corrupts one of the keys. Namely, P_1^* uses $\{K_{i,j}^0, K_{i,j}^1\}$ to construct circuit GC_j while uses $\{K_{i,j}^*, K_{i,j}^1\}$ in the OT, where $K_{i,j}^* \neq K_{i,j}^0$. After the OT phase, by the correctness implied by the existence of the simulator for OT sender, **Hybrid₅** gets $\{K_{i,j}^*, \text{com}_{\mathbb{H}}(K_{i,j}^*), \text{com}_{\mathbb{H}}(K_{i,j}^1)\}$, whereas **Hybrid₆** gets $\{K_{i,j}^1, \text{com}_{\mathbb{H}}(K_{i,j}^*), \text{com}_{\mathbb{H}}(K_{i,j}^1)\}$. If GC_j is a check-circuit during the cut-and-choose phase, by the computationally-binding property of the committing OT, P_1^* has to decommit $\text{com}_{\mathbb{H}}(K_{i,j}^*)$ to $K_{i,j}^*$. Hence, both experiments will detect that $K_{i,j}^*$ is not the right key used to construct garble circuit GC_j , and thus, both abort. On the other hand, GC_j could be one of the evaluation-circuits. Recall that **Hybrid₅** does not evaluate any garbled circuits, and neither does **Hybrid₆**. In other words, whether GC_j is corrupted or not does not cause **Hybrid₅** and **Hybrid₆** to abort during the circuit evaluation phase or after. Therefore, we conclude that the case **Hybrid₅** aborts and the case **Hybrid₆** aborts are exactly the same despite the choice of y . \square

Lemma 14. *The simulator $S_1^{P_1^*}$ runs in expected polynomial time.*

Proof. Every step of the simulator except the rewinding step finishes in expected polynomial time. Thus, it remains to analyze the time spent during the rewinding. Let p_1 be the probability that P_1^* succeeds in opening circuits the first time (that is, P_1^* successfully opens the circuits specified by the result of the coin-flipping protocol, and each circuit passes the verification checks run by P_2). With probability p_1 , simulator S_1 will then proceed to re-execute the coin-flipping protocol and the open step until it completes one more openings. Since S_1 uses completely random coins when re-running these steps that are independent of all prior executions, it is expected that after $O(\frac{1}{p_1})$ executions, S_1 produces another successful opening with high probability. Thus, the expected number of the rewinding is $p_1 \cdot O(\frac{1}{p_1}) = O(1)$. Since each rewinding requires polynomial time in k , the total time spent for this step is polynomial in k . \square

Finally, note that $\mathbf{Hybrid}_4(P_1^*(x), P_2(y), 1^k)$ and $\mathbf{Ideal}(S_1^{P_1^*(x)}, P_2(y), 1^k)$ are syntactically similar. In particular, P_2 's input is no longer used. By Lemma 8–14, we prove the security of the Main protocol when P_1 is malicious.

Simulator 5: For P_2^*

| | |
|--|---|
| Common input: | <p>a security parameters k, a statistical security parameter s, a malleable claw-free collection $(G_{\text{CLW}}, D_{\text{CLW}}, F_{\text{CLW}}, R_{\text{CLW}})$, a signature scheme $(G_{\text{SIG}}, S_{\text{SIG}}, V_{\text{SIG}})$, a two-universal hash function $H : \{0, 1\}^* \rightarrow \{0, 1\}^k$, and a description of boolean circuit C computing function $f(x, y) = (f_1(x, y), f_2(x, y))$, where $x = y = f_1(x, y) = f_2(x, y) = n$.</p> |
| $S_2 \xleftarrow{I} P_2^*$ | Wait for the index I to malleable claw-free collections from P_2^* . |
| $S_2 \xleftrightarrow{\text{OT}} P_2^*$ | <p>Committing OT for P_2^*'s input: Randomly pick $K_{i,j}^0, K_{i,j}^1 \in \{0, 1\}^k$ for $1 \leq i \leq n, 1 \leq j \leq s$. Run the ideal-world OT simulator S_{OT} that corresponds to the real-world adversary represented by P_2^* (restricted to this step of the protocol). When S_{OT} queries the OT oracle for input y_i^*, record y_i^* and respond with $[K_{i,1}^{y_i^*}, \dots, K_{i,s}^{y_i^*}]$ and the commitments to both input vectors $([K_{i,1}^0, \dots, K_{i,s}^0], [K_{i,1}^1, \dots, K_{i,s}^1])$, for $1 \leq i \leq n$. Send input $y^* = y_1^* \dots y_n^*$ to the external oracle for f, and receive output $\mathcal{N} = f_2(x, y^*)$.</p> |
| S_2 | <p>Garbled circuit construction: Transform C into a circuit C^* computing $f^*((x, c), y) = (f_1(x, y) \oplus c, f_2(x, y))$, where $x = c = y = n$. Invoke $G_{\text{SIG}}(1^k)$ to generate a signature key pair (sk_1, vk_1) and $D_{\text{CLW}}(I)$ to generate $m_{i,j}^b$, for $b \in \{0, 1\}, 1 \leq i \leq n, 1 \leq j \leq s$. Pick a random tape ρ, based on which generate a challenge set $T \subset \{1, \dots, s\}$ such that $T = 3s/5$. With input keys $J_{i,j}^b = H(F_{\text{CLW}}(b, I, m_{i,j}^b))$ and $K_{i,j}^b$, generate GC_j as follows: if $j \in T$, GC_j is a garbled version of C^* as described in the Main protocol; otherwise, GC_j is a garbled circuit that always outputs \mathcal{N} as described in [13].</p> |
| $S_2 \xrightarrow{\{GC_j\}_{j=1}^s} P_2^*$ | Send P_2^* all the garbled circuits GC_1, \dots, GC_s and the commitments to $F_{\text{CLW}}(b, I, m_{i,j}^b)$. |
| $S_2 \xleftrightarrow{\text{COIN-FLIP}} P_2^*$ | <p>Cut-and-Choose: Run coin-flipping simulator $S_{\text{CF}}(\rho)$. Recall that by Theorem ??, $S_{\text{CF}}(\rho)$ forces the output of the coin-flipping protocol to be ρ, with which T is determined.</p> |
| $S_2 \xrightarrow{\{GC_j\}_{j \in T}} P_2^*$ | For every $j \in T$, reveal circuit GC_j by sending P_2^* all the openings to GC_j and decommitting to $(F_{\text{CLW}}(0, I, m_{i,j}^0), F_{\text{CLW}}(1, I, m_{i,j}^1))$, for $1 \leq i \leq 2n$. |
| $S_2 \xrightarrow{\text{P1 INPUT}} P_2^*$ | <p>Consistency check for P_1's input: Let $e = 2s/5$ and $[j_1, \dots, j_e]$ be the indices of evaluation-circuits. Fix inputs to 0 by decommitting to $F_{\text{CLW}}(0, I, m_{i,j}^0)$ for $1 \leq i \leq 2n, j \in \{j_1, \dots, j_e\}$. Next, send to P_2^* the vector $[m_{i,j_2}^0 \star (m_{i,j_1}^0)^{-1}, \dots, m_{i,j_e}^0 \star (m_{i,j_1}^0)^{-1}]$, for $1 \leq i \leq 2n$, to complete the input consistency check.</p> |
| $S_2 \xleftarrow{\mathcal{M}} P_2^*$ | <p>Circuit evaluation: Wait for $\mathcal{M} = \{M_1, \dots, M_n\} \in \{0, 1\}^n$ from P_2^*.</p> |
| $S_2 \xleftrightarrow{\text{P1 OUPUT}} P_2^*$ | <p>Verification to P_1's output: Invoke $G_{\text{SIG}}(1^k)$ to generate another signature key pair (sk_2, vk_2). Send to P_2^* the public key and the signature of $[j_1, \dots, j_e]$, that is, vk_2 and $[\delta(j_1), \dots, \delta(j_e)]$, where $\delta(j_i) = S_{\text{SIG}}(sk_2, j_i)$. Next, for every $1 \leq i \leq n$, verify P_2^*'s witness-indistinguishable proof of knowledge that P_2^* has M_i's signature, the j-index of which coincides with some $j \in \{j_1, \dots, j_e\}$. If P_2^* fails the proof, sent 0 to the external oracle for f indicating “do not deliver P_1's output”; otherwise, send 1 indicating “deliver P_1's output” and output whatever P_2^* outputs.</p> |

Simulator for P_1^*

| | | |
|--|--|--|
| Common input: | | a security parameters k , a statistical security parameter s , a mal- leable claw-free collection $(G_{\text{CLW}}, D_{\text{CLW}}, F_{\text{CLW}}, R_{\text{CLW}})$, a signature scheme $(G_{\text{SIG}}, S_{\text{SIG}}, V_{\text{SIG}})$, a two-universal hash function $H : \{0, 1\}^* \rightarrow \{0, 1\}^k$, and a description of boolean circuit C computing function $f(x, y) =$ $(f_1(x, y), f_2(x, y))$, where $ x = y = f_1(x, y) = f_2(x, y) = n$. |
| $P_1^* \xleftarrow{I} S_1$ | | Runs the index selecting algorithm $I \leftarrow G_{\text{CLW}}(1^k)$ and sends the result I to P_1^* . |
| $P_1^* \xleftrightarrow{\text{OT}} S_1$ | | Committing OT for P_1^*'s input: Pick random $y' = y'_1 \dots y'_n \in$ $\{0, 1\}^n$ and use y'_i as the input in the i -th committing OT instance with P_1^* . |
| $P_1^* \xrightarrow{\{GC_j\}_{j=1}^s} S_1$ | | Garbled circuit construction: Wait for garbled circuits $[GC_1, \dots, GC_s]$ and the commitment $\text{com}_B(M_{i,j}^b)$ from P_1^* , for $b \in$ $\{0, 1\}, 1 \leq i \leq 2n, 1 \leq j \leq s$. Note that $M_{i,j}^b$ will be a range ele- ment of $F_{\text{CLW}}(b, I, \cdot)$ if P_1^* is honest. Since P_1^* could be an arbitrary adversary, there is no assumption on $M_{i,i}^b$ here. |
| $P_1^* \xleftrightarrow{\text{COIN-FLIP}} S_1$ | | Cut-and-choose (1st time): Run the coin-flipping protocol with P_1^* in order to generate a challenge set $T_1 \subset \{1, \dots, s\}$ such that $ T_1 = 3s/5$. |
| $P_1^* \xrightarrow{\{GC_j\}_{j \in T_1}} S_1$ | | For every $j \in T_1$, receive from P_1^* the openings to garbled circuits GC_j and the decommitments to $([\text{com}_B(M_{1,j}^0), \dots, \text{com}_B(M_{2n,j}^0)], [\text{com}_B(M_{1,j}^1), \dots, \text{com}_B(M_{2n,j}^1)])$. Run all the checks like P_2 does in Step 5 of the Main protocol, and abort if any of the checks fails. |
| $P_1^* \xrightarrow{\{GC_j\}_{j \in T_2}} S_1$ | | Cut-and-choose (2nd time): Rewind P_1^* to run the cut-and-choose process (coin-flipping plus the checking of the $3s/5$ chosen circuits) until P_1^* passes the process for the second time. Let T_2 be the challenge set of the second successful cut-and-choose and let $T = T_1 \setminus T_2$. Abort if $ T = 0$. Note that for $j \in T$, garbled circuit GC_j is a check-circuit in the first successful cut-and-choose but an evaluation-circuit hereafter. |
| $P_1^* \xrightarrow{P_1^* \text{ INPUT}} S_1$ | | Consistency check for P_1^*'s input: Let $e = 2s/5$ and $\{j_1, \dots, j_e\}$ be the indices of evaluation-circuit. Note that $\{j_1, \dots, j_e\} =$ $\{1, \dots, s\} \setminus T_2$. Receive the decommitments to P_1^* 's input keys $[M_{1,j_1}, \dots, M_{2n,j_1}], \dots, [M_{1,j_e}, \dots, M_{2n,j_e}]$. Note that $M_{i,j}$ denotes the decommitment to either $\text{com}_B(M_{i,j}^0)$ or $\text{com}_B(M_{i,j}^1)$. Next, for ev- ery $1 \leq i \leq e$, receive the domain elements $[m_{i,2 \rightarrow 1}, \dots, m_{i,e \rightarrow 1}]$ and confirm the consistency of P_1^* 's i -th input bit by checking $M_{i,j_1} =$ $M_{i,j_l} \diamond R_{\text{CLW}}(I, m_{i,l \rightarrow 1})$, for $2 \leq j \leq e$. Abort if any of these checks fails. |
| $P_1^* \xleftarrow{\mathcal{M}} S_1$ | | Circuit evaluation: Extract P_1^* 's input by comparing $[M_{1,j}, \dots, M_{2n,j}]$ with the openings of GC_j , for all $j \in T$. Abort if for any $1 \leq i \leq 2n, j \in T$, $M_{i,j}$ do not match the group elements associated with P_1^* 's i -th input bit in garbled circuit GC_j (Fail ₁) or these $ T $ extracted $2n$ -bit inputs are inconsistent (Fail ₂). Let (x^*, \bar{x}^*) be the extracted result, where $ x^* = \bar{x}^* = n$. Send x^* to the external oracle and get $f_1(x^*, y)$ in return. Then $\mathcal{M} = f_1(x^*, y) \oplus \bar{x}^*$ is sent to P_1^* . |
| $P_1^* \xleftrightarrow{P_1 \text{ OUTPUT}} S_1$ | | Wait for the public signature key vk_2 and a signature vector $[\delta(j_1), \dots, \delta(j_e)]$. Confirm the validity of these signatures by checking $V_{\text{SIG}}(vk_2, j_l, \delta(j_l)) = \text{valid}$, for $1 \leq l \leq e$. Let j_l be an element from T and $\mathcal{M} = [M_1, \dots, M_n]$. Prove to P_1^* in witness-indistinguishable sense the knowledge of the signature of (M_i, i, j_l) (from GC_{j_l}) with- out revealing j_l . |
