ABSTRACT
The growing adoption of digital assets—including but not limited to cryptocurrencies, tokens, and even identities—calls for secure and robust digital assets custody. A common way to distribute the ownership of a digital asset is \((M, N)\)-threshold access structures. However, traditional access structures leave users with a painful choice. Setting \(M = N\) seems attractive as it offers maximum resistance to key compromise, but it also causes maximum brittleness: A single lost share renders the asset permanently frozen, inducing paralysis. Lowering \(M\) improves availability, but degrades security.

In this paper, we introduce techniques that address this impasse by making general cryptographic access structures dynamic. The core idea is what we call Paralysis Proofs, evidence that players or shares are provably unavailable. Using Paralysis Proofs, we show how to construct a Dynamic Access Structure System (DASS), which can securely and flexibly update target access structures without a trusted third party. We present DASS constructions that combine a trust anchor (a trusted execution environment or smart contract) with a censorship-resistant channel in the form of a blockchain. We offer a formal framework for specifying DASS policies, and show how to achieve critical security and usability properties (safety, liveness, and paralysis-freeness) in a DASS.

To illustrate the wide range of applications, we present three use cases of DASSes for improving digital asset custody: a multi-signature scheme that can “downgrade” the threshold should players become unavailable; a hybrid scheme where the centralized custodian can’t refuse service; and a smart-contract-based scheme that supports recovery from unexpected bugs.

CCS CONCEPTS
• Security and privacy → Key management; Access control.

1 INTRODUCTION
Nearly all key management and access control systems have an “always / never” requirement [65]: they should always provide availability when validly authorized, but never when not. Balancing availability against the potential for misuse is a pervasive challenge. Consider the task of securing a single private key. Replicate the key broadly across geography, machine architectures, and custodians, and the risk of key compromise increases. Store the key in a single location and the probability of loss increases, as do barriers to timely access.

Generally, this challenging trade-off is navigated by distributing control across a small number of parties by means of an access structure [37]. An access structure is a policy determining which players can control a resource. \((M, N)\)-access structures, as in, e.g., Shamir secret sharing [66], are a popular choice. They allow any \(M\) out of \(N\) players to access a target resource, e.g., to sign a cryptocurrency transaction. Varying \(M\) and \(N\) provides flexibility on the defensibility vs. availability spectrum. Unfortunately this flexibility is often still inadequate.

For example, in the setting of a cryptocurrency custodian, despite the availability of \((M, N)\)-multisig wallets (which require \(M\) of \(N\) players to sign), loss and theft of cryptocurrency have been rampant for years [15, 26, 57, 58, 73]. Over 980,000 Bitcoin (currently worth about $6.4 billion) [62] have been stolen from exchanges alone. An estimated 4,000,000 Bitcoin (currently worth around $26 billion), have vanished forever due to lost keys [63].

One of the primary concerns looming over the use of \((M, N)\)-multisig schemes is what we call a "shareholders’ dilemma": setting \(M = N\) is not only desirable for its maximum resilience to key compromise and collusion, but it could also be the only option to meet certain business requirements, e.g., when \(N\) people want a joint-account with equal ownership. However, setting \(M = N\) also causes maximum brittleness: a single lost key share renders the asset permanently frozen.

Fundamentally, the problem with traditional \((M, N)\)-access structures is that they are static. \(M\) cannot be lowered or \(N\) raised when funds become unavailable, so insecure choices are often made at system setup.

1.1 Our work
In this paper, we show how to achieve both good availability and good security, and to do so without trusted third parties (TTPs). Specifically, we show how to achieve a better trade-off than any static access structure alone can do. We accomplish this by means of access structures that are dynamic.

We introduce the idea of a Dynamic Access Structure System (DASS), which allows for secure conditional downgrading, e.g., changing \((3, 3)\)-multisig to a \((2, 3)\)-multisig if a player becomes unavailable. Consequently, the full security of a \((3, 3)\)-multisig is available in the general case. A \((2, 3)\)-multisig is instantiated in the critical case that funds would otherwise be lost. (If Alice has lost her key, it’s better to run the risk of Bob and Carol absconding with funds than to lose funds with certainty forever.) In other words, a DASS

\[ (M, N) \]

This an extended version of [83].
implements a policy of access-structure migrations (e.g., downgrades). Fig. 1 illustrates the idea by showing a three-player DASS that can withstand two key losses.

DASSes do not completely avoid security/availability trade-offs. They do however introduce new and desirable points on the security/availability spectrum, and thus new security management options for cryptocurrencies and a wide range of other cryptographic systems.

One major technical challenge in our work is ensuring that the downgrading of access structures only happens when a player is truly unavailable. Otherwise, players can cheat by simulating the disappearance of a live player. The tool we introduce for this purpose are strong proofs of player (or key-share) unavailability called Paralysis Proofs.

1.2 Approach overview and challenges

Proving that a player is available is easy: just have her sign a fresh message. Secure Paralysis Proofs, though, require that a player be able to signal liveness when other players collude and potentially try to block her network access. This is challenging even with a trusted third party (TTP).

Our constructions rely on a censorship-resistant stateful channel to detect and record the fact of an unavailable player. Such a channel has two properties: censorship-resistance, meaning players can freely send and receive messages with a bounded delay, and statefulness, meaning messages sent through the channel are recorded and can be retrieved later. These properties are strictly stronger than those of anonymous channels (e.g., Tor [70]), which lack statefulness.

We leverage public blockchains as censorship-resistant stateful channels in our work. The basic idea is that if a player, e.g., Alice, disappears, other players can post a challenge to her on chain. If Alice tries to post a response within a delay (for some suitable \( \Delta \)), she can do so with high probability even in the face of powerful network adversaries and her response will be world readable. Thanks to these properties, lack of response from Alice within \( \Delta \) blocks of a challenge constitutes a Paralysis Proof.

Building a DASS from Paralysis Proofs is easy given a TTP, which can simply manage all users’ keys. We report on implementations for both script-based cryptocurrencies (e.g., Bitcoin) and smart-contract-based ones (e.g., Ethereum).

1.3 Improved digital asset custody with DASS

We consider three use cases of Paralysis Proofs that illustrate our techniques’ wide range of application to improving digital asset custody and beyond:

- **Tolerate cryptocurrency key loss.** We present a \((M, N)\)-multisig wallet that can downgrade the threshold if players become unavailable. We report on implementations for both script-based cryptocurrencies (e.g., Bitcoin) and smart-contract-based ones (e.g., Ethereum).

- **Tolerate custodian failures.** Centralized custodians, e.g., Coinbase [55], help users manage keys, but are single points of failure. We present a DASS that migrates control of funds to their owners if and only if a custodian fails or refuses service. The “only if” part guarantees that as long as the centralized custodian is operational, a user’s key won’t breach the user’s account, which is desirable.

- **Tolerate software-induced paralysis.** Smart contract bugs can lead not just to theft, but paralyzed funds, as in the $150 million lost to the infamous (second) Parity Multisig Wallet bug [59]. We propose a continuous-integration framework that regularly applies a test suite to a smart contract to validate its correct functioning, including liveness of funds. Critical error conditions such as paralysis trigger an “escape hatch” [47], failover logic that refunds or moves a smart contract’s assets.

1.4 Contributions

In summary, our main contributions are as follows:

- **Paralysis Proofs.** We introduce Paralysis Proofs, and show how to achieve them using censorship-resistant stateful channels such as
blockchains. We also introduce Dynamic Access Structure Systems (DASSes), which offer security vs. availability trade-offs unachievable with conventional, static access structures.

**Formal definitions and framework.** We formally define key properties for a DASS (liveliness, safety) and its underlying migration policy (privilege-preserving, paralysis-free) (Section 3). We present an ideal functionality that formally specifies security properties required for a broad range of applications (Section 4).

**Improved digital asset custody with DASS.** We present three example applications of DASS to protect digital asset custody from: cryptocurrency key loss (Section 4), cryptocurrency custody failures (Section 5), and smart contract failures (Section 6).

**TEE compromise.** We explore alternative DASS designs that provide resilience to TEE compromise, such as through side-channel attacks demonstrated against SGX (Section 4.4).

**Implementation.** We present implementations in Ethereum and Bitcoin for the first application, using smart contracts and TEEs (Intel SGX, in particular) respectively. To illustrate the limitations of pure blockchain approaches for Bitcoin, we also explore script-based schemes in Appendix D.

**2 BACKGROUND**

In this section we provide some basic background on Trusted Execution Environments, Bitcoin, and smart contracts.

**2.1 Trusted Execution Environments and SGX**

A Trusted Execution Environment (TEE) is an execution environment that provides confidentiality and integrity for applications running on potentially malicious hosts.

Intel Software Guard Extensions (SGX) \[10, 35, 50\] is a CPU-based TEE implementation available in recent Intel CPUs. SGX allows processes to execute in an *enclave*, an environment that enforces application confidentiality and integrity against even a malicious operating system and some classes of hardware attacks. SGX also enables applications to emit third-party verifiable attestations to their origin and outputs.

**Limitations of TEEs.** Although powerful, TEEs have fundamental security limitations. TEEs generally don’t guarantee availability. Moreover, TEEs depend upon a potentially malicious operating system for I/O. A consequence is that TEEs cannot provide trusted sources of time. In the case of SGX, although a trusted relative timer is available in an off-CPU component, the communication between enclaves and the timer can be delayed by the malicious OS [1]. Thus SGX only enclaves can only ascertain a lower bound on the elapsed time. Server-grade Intel CPUs offer no support for timers at the time of writing. Moreover, unless with additional protection mechanisms (e.g., [48]), SGX doesn’t have trustworthy monotonic counters and therefore is susceptible to state rollback attack. These security limitations make Paralysis Proofs challenging even with TEE.

**2.2 Bitcoin**

Bitcoin is a decentralized electronic cash scheme in which transactions moving funds are recorded in an append-only log, a blockchain. Rather than storing funds in accounts whose balance is altered by transactions, Bitcoin uses transactions themselves to record both ownership and balance. Transactions consist of inputs and outputs. An output consists of an amount and a *scriptPubKey* that specifies how that amount can be spent. Inputs specify the transaction output which is the source of the funds and include a *scriptSig* showing authorization to use the funds. Thus transactions spend the outputs of previous transactions. Unconsumed outputs are known as Unspent Transaction Outputs (UTXOs). One can check if an output has been spent by seeing if it is in the set of UTXOs. By requiring that outputs can only be spent once and that the amount of money included in a transaction’s inputs is at least as much as its outputs, Bitcoin enforces the invariants of a monetary system and prevents forgery.

**Bitcoin Script.** When creating an output, users can specify an access control policy by embedding a script—called *scriptPubkey*—in the output. To spend an output, one must provide a witness—called *scriptSig*—such that running the script with the provided witness outputs true. For example, a typical scriptPubkey specifies the keys that must sign any transaction spending that output. This may be a single key or an arbitrary combination of keys, e.g., \((pk_1 \land pk_2) \lor pk_3\). An input consuming an output with such a scriptPubkey would then need a signature that satisfied that requirement, e.g., it would need to contain signatures under both \(pk_1\) and \(pk_2\). While in principle Bitcoin Script can represent complex logic, in practice limitations on supported instructions and the length of a script mean it is mainly used for simple authorization.

We use \((V, \phi)\) to denote an UTXO of \(V\) coins with a scriptPubkey \(\phi\). A Bitcoin transition (with the exception of coinbase transitions) consumes a set of UTXOs and creates one or more new ones. We use \((\{\text{In}_i\}_{i=1}^n \leftarrow \text{Witness}_i \rightarrow \text{Out}_j\}_{j=1}^m\) to denote a Bitcoin transaction with \(n\) inputs, \(m\) outputs, and \(n\) witnesses, one for each input, such that \(w_i\) satisfies the script of \(\text{In}_i\).

**Time-based opcodes.** An essential ingredient of \(\Pi_{\text{SGX}}\) is Bitcoin’s relative timeout script opcodes, also known as CheckSequenceVerify or CSV [20]. By putting the CSV instruction with parameter \(\tau\) in the script \(\phi\) of a UTXO \(u\), we assert that the transaction that spends \(u\) must reside in a block whose height (or timestamp) is more than \(\tau\) relative to \(u\).

**2.3 Smart contracts**

Smart contracts are executable objects stored in a blockchain. Users can send transactions with input data to the blockchain to trigger the execution of a smart contract. To process a transaction, the blockchain executes the code with the provided input data and potentially alters the blockchain state.

A key differentiator between such smart contracts and script-based systems (e.g., Bitcoin) is rich-statefulness [78]. In a smart contract system, all executing transactions have native access to persistent state stored across transactions, blocks, and time. Rich statefulness is particularly relevant to our system. It is Bitcoin’s lack of such that renders TEEs the only practical solution.

**2.4 Censorship-resistant stateful channels**

We use a blockchain to realize a censorship-resistant stateful channel, i.e., messages sent to the blockchain will be delivered within \(\Delta\) time, and items added to the blockchain cannot be removed. In
practice, a central goal of public blockchains such as Bitcoin is to prevent a malicious miner from dropping a user’s transactions [31]. Also thanks to the high redundancy of the underlying peer-to-peer network, as long as a user can connect to some network nodes, her transactions will be propagated and included in a block with high probability, thus offering censorship-resistant access.

Bitcoin and other public blockchains have been proposed as a means to facilitate an anonymous channel (e.g., in [4, 9]). We note, however, that public blockchains are more powerful than anonymous channels (such as Tor), because blockchain-based channels are also stateful, i.e., messages are persisted on-chain with strong availability guarantees. As statefulness is critical in Paralysis Proofs, anonymous channels such as Tor insufficient. The statefulness of blockchains is also used in [25] to enforce fairness in MPC, and in [39] to build stateful TEE execution.

3 Dynamic Access Structure Systems

In this section, we develop formal definitions and a framework for reasoning about the security of dynamic access structures.

A Dynamic Access Structure Policy (DASP) consists of a set of access structures and rules dictating migration conditions among them. For example, “this Bitcoin fund requires signatures from Alice, Bob and Carol to spend; if any of them disappears, signatures from the remaining two suffice to spend the fund” informally specifies a DASP. The access structure is the set of holders authorized to spend Bitcoin, and migration entails removing unresponsive signers.

We use the term Dynamic Access Structure System (DASS) to denote a system that enforces a DASP. Essential to our DASS constructions is the use of Paralysis Proofs to demonstrate conditions, e.g., party incapacitation, that justify migration from one access structure to another.

Motivating example. Getting dynamic access control policies right is hard and intuitive correctness often is not enough. There are subtle vulnerabilities that are missed without the formalism. For example, consider $s_1 = "at least a majority of \{1, 2, 3, 4\} is required to access", s_2 = "at least a majority of \{1, 2, 3\} is required to access". If the current access structure is $s_1$ and player 4 goes missing, it’s intuitive to permit migration to $s_2$. However this is not secure as it would deprive the privilege of one of the three players.

Looking forward, Definition 2 correctly prevents such a migration because $s_2 \notin S_{LP}(\{1, 2, 3\})$. (The only secure migration is to stay at $s_1$.) Capturing subtle vulnerabilities like this is critical and challenging, and motivates our exploration of the formal framework presented below.

3.1 Policy specification

3.1.1 Basic definitions. A Dynamic Access Structure Policy (DASP) comprises a tuple $(R, S, M)$ that specifies the resources $(R)$ being access-controlled, a set of access structures $(S)$, and a set of migration rules $(M)$ dictating conditions under which access-structure migrations are permitted.

Let $\{P_i\} = \{P_i\}_{i=1}^{N}$ denote the set of $N$ parties at beginning of the protocol, and $L_t$ the set of live (i.e. not incapacitated) parties at time $t$. As we shall see shortly, correctly determining $L_t$, i.e. which parties are actually live, is the main technical challenge in enforcing a DASP. We use $L_t$ to denote the ground truth. When generally referring to a single player, we drop the subscript and simply denote the player as $P$. We assume that if a party becomes incapacitated, it remains incapacitated throughout the protocol, i.e. $P \notin L_t$ implies $P \notin L_{t'}$ for all $t' > t$.

In this paper, an access structure $s$ is a function $s(L) \rightarrow \{true, false\}$ that determines whether a set of live parties $L \subseteq \{P_i\}$ is allowed to access the managed resource. Access structures are monotonic, i.e., $s(L) = true$ and $L \subseteq L'$ together imply that $s(L') = true$.

A migration rule $m_{s_1, s_2} \in M$ is a function $m_{s_1, s_2}(\omega) \rightarrow \{true, false\}$ that determines whether migrating from $s_1$ to $s_2$ is permitted given witness $\omega$. We use $s_1 \rightarrow s_2$ to denote $m_{s_1, s_2}(\omega) = true$. The exact form of $\omega$ depends on the migration rule. An example of $\omega$ is $L_1$, the set of live players.

For a given DASP, the set of access structures $S$ and the associated migration rules $M$ may be represented as a directed graph $G = (S, M)$. Here we overload $S$ and $M$ to denote respectively the sets of nodes and edges. A node $s_1 \in S$ is an access structure and an enhanced edge $(s_1, s_2) \in M$ represents the migration rule $m_{s_1, s_2}$, which specifies the condition to migrate from access structure $s_1$ to $s_2$. Access structure $s_{\omega}$ is said reachable from $s_1$ by $\omega$, denoted $s_1 \xrightarrow{\omega} s_{\omega}$, if there exists a path $(s_1, s_2, \ldots, s_{\omega})$ in $G$ such that $s_i \rightarrow s_{i+1}$ for all $i \in [1, n - 1]$.

3.1.2 Security goals. A fundamental correctness requirement for any access structure is that migration between access structures does not eliminate the privilege of live parties. We capture this notion by stipulating that a DASP be privilege-preserving. To define this property, we first require two technical definitions.

Definition 1. The set of least permissive access structures for $L \subseteq \{P_i\}$, denoted by $S_{LP}(L)$, is defined as: $S_{LP}(L) = \{s \in S : s(L) = true \land (\forall L' \subseteq L, s(L') = false)\}$.

Intuitively, $S_{LP}(L)$ is the set of all access structures such that if the only possible live parties are in $L$, then all such parties must be live to access the resource. Given this, we define privilege-preserving:

Definition 2. (Privilege-preserving) Let $L_t$ be the set of live parties at time $t$. A DASP $(R, S, M)$ is privilege-preserving if $L_t$ can never migrate to an access structure that can be satisfied with a set $L'$ of parties such that $L_t \subseteq L' \land \exists s \in S \land s(L) = true$.

A DASP is paralysis-free if, when the current access structure cannot be satisfied, switching to another satisfiable access structure is permitted provided that the migration will not deprive the privilege of any live party.

Definition 3. (Paralysis-freeness) Let $L_t$ be the set of live parties at time $t$. A DASP $(R, S, M)$ is paralysis-free if at any time $t$, $\forall s \in S$ such that $s(L_t) = false$, it holds that:

$$S_{LP}(L_t) \neq \emptyset \implies \exists s', s' \in S_{LP}(L_t) \ s.t. \ s \xrightarrow{\omega} s'$$

Note that a paralysis-free DASP doesn’t imply the availability of the resource. What a paralysis-free policy can guarantee is the best possible availability: if there is a access structure $s'$ that can get the system out of paralysis, then the DASP should permit a transition to $s'$. However, if the set of live parties is too sparse to satisfy any of
the prescribed access structures (i.e., $S_{LP}(L_t) = \emptyset$), then the desired availability cannot be achieved.

**Example 1.** Let’s take the example of $N$ shareholders who wish to retain access to the resource $R$ should one party disappear. Let $\mathcal{P} = \{P_i\}_{i=1}^N$ denote the set of $N$ parties, and $\mathcal{P}_{i\rightarrow} = \mathcal{P} \setminus \{P_i\}$ denote the set of $N - 1$ parties that excludes $P_i$. Let $I()$ denote an indicator function. A DASS $(\mathcal{R}, \mathcal{S}, M)$ that realizes the aforementioned access control can be specified by $S = \{s_i\}_{i=1}^N$ where $s_0 \equiv \mathbb{I}_R$ and $s_i \equiv \mathbb{I}_{P_{i\rightarrow}}$, for $i \in [N]$, and the condition $m_{s_i}(\omega) \in \mathcal{M}$ outputs true if $\omega$ is a witness to $L_t = \mathcal{P}_{i\rightarrow}$.

One can examine that the DASS in Example 1 is privilege-preserving and paralysis-free.

### 3.2 Security definitions for a DASS

We use the term Dynamic Access Structure System (DASS) to denote a system that enforces a DASP. In this section, we define the security of a DASS with a Universal Composability (UC) [23] ideal functionality $\mathcal{F}_{\text{DASS}}$. Later in Section 4 we present a protocol $\Pi_{SGX}$ that UC-realizes $\mathcal{F}_{\text{DASS}}$.

#### 3.2.1 Adversarial model.

We assume an adversary that may corrupt an arbitrary number of parties. An honest party always follows the protocol, while a corrupted party controlled by the adversary may deviate arbitrarily (i.e., perform Byzantine corruption). In the realization of $\mathcal{F}_{\text{DASS}}$, we assume that the adversary has complete control of the network, with the exception that a censorship-resistant stateful channel is available to all parties, i.e., anyone can send and receive messages through the channel subject to bounded latency, and messages sent through the channel are persisted and can be retrieved later.

#### 3.2.2 Ideal functionality.

We specify security goals of a DASS in the ideal functionality $\mathcal{F}_{\text{DASS}}$ as defined in Fig. 2.

To reduce clutter, we omit the handling of session IDs (SIDs) in $\mathcal{F}_{\text{DASS}}$ but readers are advised that messages received and sent by $\mathcal{F}_{\text{DASS}}$ are implicitly associated with an SID. When $\mathcal{F}_{\text{DASS}}$ sends subroutine output to parties, we use the delayed output terminology from [23] to reflect the network adversary. Specifically, when $\mathcal{F}_{\text{DASS}}$ sends a public delayed output to party $P_i$, the output is first sent to $\mathcal{A}$ and then forwarded to $P_i$ after $\mathcal{A}$’s acknowledgement or delay time has past, whichever happens first.

$\mathcal{F}_{\text{DASS}}$ maintains internal states ($L_t$, $s$) for the set of live parties and currently enforced access structure respectively. To capture the paralysis explicitly, we extend the standard corruption model [23] with special “paralysis” corruption. Upon receipt of a paralysis message from $\mathcal{A}$, a party immediately announces its paralysis and halts until the end of the protocol. In the ideal protocol, $\mathcal{A}$ sends (paralysis, $P_i$) to $\mathcal{F}_{\text{DASS}}$ who removes $P_i$ from the set of live parties.

To access the resource, a set of parties $P$ send (access, inp), in which inp specifies the parameter of access, to $\mathcal{F}_{\text{DASS}}$. If $P$ is permitted to access by the current access structure, i.e., $\text{s}(P) = \text{true}$, $\mathcal{F}_{\text{DASS}}$ returns the result of accessing $\mathcal{R}$. A set of parties can initiate a migration to another access structure $s'$ by sending (migrate, $s'$) to $\mathcal{F}_{\text{DASS}}$. If the transition to $s'$ is permitted by the enforced DASP, $\mathcal{F}_{\text{DASS}}$ sets the current enforced access structure to $s'$.

#### 3.2.3 Security properties.

$\mathcal{F}_{\text{DASS}}[s_0, \mathcal{R}, \mathcal{S}, \mathcal{M}]$ encapsulates the following security properties of a Dynamic Access Structure System. Let $s$ denote the effective access structure of $\mathcal{F}_{\text{DASS}}$, and $L_t$ the set of live parties at time $t$. $\mathcal{F}_{\text{DASS}}$ guarantees both safety and liveness in all states $s \in \mathcal{S}$ at any time $t$:

**Safety:** A set of parties $L \subseteq L_t$ can access $\mathcal{R}$ only if $\text{s}(L) = \text{true}$. A transition to $s' \neq s$ occurs only if $m_{s_1}(L_t) = \text{false}$.

**Liveness:** If $\text{s}(L) = \text{true}$ for some $L \subseteq L_t$, then $L$ can access $\mathcal{R}$ at any point in time $t$.

**Examples.** Consider a DASS enforcing the DASP in Example 1, the Safety property ensures that access is enforced by the current access structure at any time, and that the access structure can be downgraded to allow access by $N - 1$ shareholders only if $|L_t| < N$, i.e., a collusion of $N - 1$ shareholders cannot maliciously accuse the $N^\text{th}$ shareholder of being incapacitated and thereby steal her share. The Liveness property ensures that access is granted if the structure is satisfied by a set of cooperating parties. Moreover, if allowed by the policy, the Liveness property ensures that the access structure will be downgraded within a bounded time should parties submit legitimate requests. Note that the Liveness property does not stipulate that access structure $s_1$ is automatically instantiated if $|L_t| < N$. This is because parties may not immediately activate an access-structure migration; in fact, if all parties are incapacitated, such migration cannot happen.
4 PARALYSIS PROOFS FOR CRYPTOCURRENCIES

In this section, we expand on the use of Paralysis Proofs to recover from cryptocurrency key loss (and related failures, e.g., player disappearance).

Bitcoin, the most popular cryptocurrency with a market cap of $110B at the time of writing, is an important application target for Paralysis Proofs. Implementing secure Paralysis Proofs for the current Bitcoin protocol, however, is challenging because of the limited expressiveness of Bitcoin scripts. Were a proposed enhancement called “covenants” available [53], we show in Appendix C that Paralysis Proofs can be constructed, though with significantly higher complexity. Moreover, it is unclear when or whether covenants will be adopted in Bitcoin. Thus we explore an alternative approach involves the use of TEEs—specifically, Intel SGX—in this section. In Appendix D we give a similar Paralysis Proof construction compatible with the current Bitcoin protocol without using SGX, but it only provides a weaker security guarantee and incurs more than exponential overhead, making it impractical.

Realizing Paralysis Proofs is challenging even with TEEs, due to their inherent security limitations: they can’t maintain persistent states, their I/O can be censored by the malicious OS and they don’t have an accurate sense of time. We use the following strawman protocol to illustrate why these limitations lead to design challenges.

A strawman protocol. Suppose there are N players. On initialization, the enclave generates a key pair (sk, pk) and outputs pk. Players move the fund to the address of pk. The enclave also initializes the access structure as an (N, N)-multisig scheme, i.e., signatures from all N players are required to spend the fund controlled by sk. To attempt to remove a player P, the enclave sends a challenge to P and starts the timer. If P doesn’t respond within Δ time, the enclave removes P from the access structure.

This strawman protocol is insecure for three reasons. First, unless additional mechanisms (e.g., [14, 48]) are employed, an SGX enclave is susceptible to state rollback. A malicious player could restore the enclave to a state before she’s removed from the access structure, defeating the basic security requirement. Second, since the enclave’s network is censored by the network adversary, she can cause a live player to be removed by delaying the response.

Note that these two problems can be solved by using a blockchain as a censorship-resistant stateful channel between players and the enclave. Nonetheless, the strawman protocol is still insecure. The issue is that the enclave—lacking a trusted timer—cannot establish an update-to-date view of the blockchain. For example, the adversary could present the enclave with a fork without P’s response. Thanks to the lack of a trusted timer—in the case of SGX, an enclave can only ascertain an lower bound on the elapsed time—even an adversary with a low computational power can mount such attacks.

Solutions. Instead of patching TEEs to make the above strawman protocol work, we took a different path that does not rely on TEE for keeping track of time or maintaining the current access structure. It is important to emphasize that the security of our protocol doesn’t require the enclave to have an update-to-date view of the blockchain—in fact, the enclave need not any view of the blockchain state. Moreover, a challenged player does not communicate with the enclave to signal her liveness. Finally, the enclave doesn’t maintain any state, except for a secret key. Since the state is static, our protocol is immune from state rollback.

The high-level idea behind our solution is to use Bitcoin’s time-based opcodes to track time, and to condition the output of the enclave on the state of the blockchain that is presented to the enclave. For example, if the TEE is presented with a forked blockchain, then the enclave output would only be valid on that fork. We achieve this using “life signal” transactions with time-based opcodes.

4.1 System model and trust assumptions

In this section we setup the formal model in which we specify the protocol, and discuss trust assumptions.

SGX and attested execution. Throughout the paper, we use SGX as a building block, although the protocol can be realized by any TEE capable of attested execution.

In our formal specification, we adopt the (local) ideal functionality $\mathcal{F}_{SGX}$ based on Pass et al [60] to model TEEs with attested execution. Informally, a party first loads a program $\text{prog}_{\text{encl}}$ into an SGX enclave with an install message. On a resume call, the program is run on the given input inp, generating an output along with an attestation $\sigma_{\text{SGX}} = \Sigma_{\text{SGX}}, \text{Sig}(\text{sk}_{\text{att}}, (\text{prog}_{\text{encl}}, \text{out}))$, a signature under the hardware key $\text{sk}_{\text{att}}$. The public key $\text{pk}_{\text{att}}$ is can be obtained from $\mathcal{F}_{SGX}\text{-getpk}$. We refer readers to [60] for details.

An ideal blockchain. Our protocol uses an ideal blockchain defined in Fig. 7 as a censorship-resistant stateful channel. $\mathcal{F}_{\text{chain}}[\text{succ}]$ generalizes the bulletin board model because it also captures the notion of item validity. $\text{succ}(\text{history}, \text{item}) \rightarrow \{0, 1\}$ is a function that specifies the criteria for a new item to be appended to history. We retain the append-only property of blockchains but abstract away the inclusion of items in blocks. As reflected in $\mathcal{F}_{\text{chain}}$, we assume items are timestamped when added. In practice, block numbers can serve as such timestamps.

Trust assumptions. Our protocol relies on TEE with attestation that protects the confidentiality and integrity of computation, and an censorship-resistant stateful channel. Concretely, we assume SGX is correctly implemented and that the Bitcoin blockchain is secure and available to all parties. Let us stress that the trust assumptions in SGX is local, i.e., only the parties in the protocol will be affected should SGX properties be broken. We discuss ways to minimize trust in SGX in Section 4.4.

4.2 Protocol details

We denote our DASS for Bitcoin by $\Pi_{SGX}$. $\Pi_{SGX}$ is formally specified in Fig. 8 and Fig. 9. We give text descriptions below of the steps involved in $\Pi_{SGX}$, so formal protocol or ideal-functionality specifications are not required for understanding.

Recall that we use $N$ to denote the number of players at the start of $\Pi_{SGX}$, and $P_i$ for $i \in \{1, 2, \ldots, N\}$ to denote each player. Each $P_i$ is associated with a Bitcoin public key $\text{pk}_i$, whose corresponding secret key is only known to $P_i$. For simplicity, $\{P_i\}$ is used to refer to the complete set of all players.

Initialization. To start the protocol, some honest party needs to load an SGX instance with $\text{prog}_{\text{encl}}$ (Fig. 9) and invoke the init procedure. For now we assume a single SGX available to all honest...
parties; thus any honest party can initiate the enclave (once initialized, sequential initialization will be ignored). In Section 4.4 we present an expanded distributed setup procedure that avoids this assumption and provides stronger guarantees.

After the setup procedure is completed, the parties send a small fund of δB (e.g., δ = 0.00001) to a new output that can be spent by pkSGX. Then the parties launch the protocol by sending their unspent output of V coins (denoted UTXOfund) to a new output of V coins with a script spendable by \{pk_i\}_{i=1}^N or pkSGX.

**Spending funds.** There are two ways to spend the funds that are managed in \(\PiSGX\). At any time, the players can spend the money via a Bitcoin transaction that embeds their N signatures (per \(\phi_{all}\) in Fig. 8). Hence, even in the case that all N SGX CPUs are destroyed, the players are still able to spend the funds just as they could before the execution of \(\PiSGX\). However, a better way to spend the funds is by sending \(N\) requests to an enclave, letting the enclave create a Bitcoin transaction with a single signature (signed by \(skSGX\)). This reduces the on-chain complexity and the transaction fee.

**Migrating to another access structure.** The migrate procedure of \(\PiSGX\) resolves system paralysis by letting the live shareholders spend the money if one or more shareholders is incapacitated. Intuitively, the role of SGX is to be an arbitrator: when any shareholder alleges that the money is stuck due to an unresponsive party, SGX first gives the accused party Δ time to appeal. The set of shareholders that controls the fund will be reduced only if no appeal is observed on the blockchain within this sufficiently large Δ (meaning that such an appeal did not occur, assuming censorship resistance [31] holds on the underlying blockchain).

The core idea of implementing an "appeal" in Bitcoin is to use what we call **life signals**. A life signal for party \(P_k\) is a UTXO of negligible Bitcoin amount \(\epsilon_B\), that can be spent either by \(P_k\) — thereby signaling her liveness—or by \(pkSGX\), but only after a delay. \(\PiSGX\) makes use of life signals to securely migrate to remove a party from the current access structure. Specifically, suppose the current set of shareholders is \(P = \{P_i\}_{i=1}^N\), to (propose to) remove party \(P_k\) from \(P\), any live players can send a message (migrate, UTXOfund, \(P \setminus \{P_k\}\)) to prog SGX. Then prog SGX will generate two signed transactions, \(t_1\) and \(t_2\) (defined in Fig. 9 and illustrated in Fig. 3), as follows:

- \(t_1\): a life signal for \(P_k\),
- \(t_2\): spends both the life signal UTXOfundsignal in \(t_1\) and the escrowed fund UTXOfund to a script that is spendable without \(P_k\) (i.e., by \(\{pk_i\}_{i=1}^N \setminus \{pk_k\}\) or \(pkSGX\)).

The SGX enclave gives both \(t_1\) and \(t_2\) together as output. If \(t_1\) is sent to the Bitcoin blockchain, \(P_k\) can cancel her removal by spending \(t_1\). Otherwise, \(t_2\) will become valid after the Δ delay and can be sent to the blockchain, thereby removing \(P_k\)’s control over the fund. Fig. 3 demonstrates an example with three players.

Notice that prog SGX parses UTXOfund and obtains the list of current shareholders, so that prog SGX does not have to keep track of current live shareholders locally, nor does it need to have an up-to-date view of the blockchain. As we will discuss shortly, this is an important security feature.

### 4.3 Security of \(\PiSGX\)

Intuitively, the security of \(\PiSGX\) stems from the use of SGX and the relative timeout feature of Bitcoin. We discuss the security of \(\PiSGX\) informally, then present a formal proof.

#### 4.3.1 Security arguments

The core security property of \(\PiSGX\) is that a live party cannot be falsely removed from the access structure, no matter how many of parties are malicious. This is achieved by the use of the relative timeout feature of Bitcoin [20] in the fresh \(t_1\), and the atomicity of the signed transaction \(t_2\).

To elaborate, \(t_2\) will be valid only if the witness of both inputs (UTXOfund and UTXOfundsignal) is correct. The witness that the SGX enclave produced for spending the UTXOfund is immediately valid, but the witness for spending UTXOfundsignal becomes valid only after \(t_1\) has been incorporated into a Bitcoin block that has been extended by Δ additional blocks (due to the CSV condition). The shareholder \(P_i\) that accused \(P_k\) of being incapacitated should therefore broadcast \(t_1\) to the Bitcoin network, wait until \(t_1\) is added to the blockchain, then wait for the next Δ blocks, and then broadcast \(t_2\) to the Bitcoin network. However, while these Δ blocks are being generated, \(P_k\) has the opportunity to appeal by spending \(t_1\) with the secret key \(sk_k\), that is known only to her (the script of \(t_1\) does not require the CSV condition for spending with \(sk_k\)). Δ is set to a large enough value for two purposes: (1) to give \(P_k\) enough time to respond, and (2) to ensure that it is infeasible for an attacker to create a secretive chain of Δ blocks faster than the Bitcoin miners, and then broadcast this chain (in which \(t_2\) is valid) to overtake the public blockchain.

A fresh, ephemeral key pair \((skR, pkR)\) is generated for each life signal to ensure that \(t_1\) is unique and hence does not already reside on the blockchain (e.g., \(P_k\) may have failed to respond to an earlier life signal but luckily another shareholder \(P_j\) was removed at that time). The SGX enclave does not need to store ephemeral keys, as they are consumed right after generation.

#### 4.3.2 Strawman attacks

To illustrate the security properties of \(\PiSGX\), we discuss a few strawman attacks in which \(N - 1\) malicious players (collectively referred to as the attacker) attempt to remove the \(N\)th player (i.e., \(P_N\)) from the access structure and why they
are prevented by $\Pi_{\text{SGX}}$. The attacker’s goal is to somehow get $t_2$—the transaction that changes the access structure—included in the blockchain. Recall that we assume players can reliable connect to the blockchain (when the enclave may not).

**Withholding transactions.** Clearly, withholding $t_2$ is only to the disadvantage of the attacker. On the other hand, withholding $t_1$ doesn’t gain the attacker any advantage either. Due to the relative timeout in $t_1$, $P_N$ always gets the $\Delta$ blocks worth of time to respond regardless when $t_1$ is included in the blockchain.

**Manipulating the I/O of the enclave.** In $\Pi_{\text{SGX}}$, the enclave receives as input $(\text{migrate}, \text{UTXO}_{\text{fund}}, P \setminus \{P_N\})$ and outputs signed transactions $(t_1, t_2)$ as specified. The enclave doesn’t (and generally can’t) check the validity of the input UTXO, nor does it check that the output transactions are sent to the blockchain correctly. This is, however, not a security problem.

The attacker may feed the enclave with an invalid (e.g., spent or non-existent) UTXO. However, since the output transaction $t_2$ spends UTXO$_{\text{fund}}$—providing the enclave with an invalid UTXO$_{\text{fund}}$—would result in an invalid $t_2$ that can’t change the access structure, making the attack a no-op.

The attacker may also send the output transactions to secretive forks as opposed to the main chain. Note that since $t_2$ spends $t_1$, in order for $t_2$ to be valid, both must be in the same fork. If both are sent to the main chain, then $P_N$ would notice and respond normally. However, if both are sent to a secretive fork, the access structure would indeed be changed on that fork. Nonetheless, unless the attacker can overtake the main chain with that fork, which is at least as difficult as double spending attack assuming a large enough $\Delta$, the fund on the main chain remains intact.

4.3.3 **Security proofs.** The security of $\Pi_{\text{SGX}}$ is proven using the framework developed in Section 3, as summarized in Theorem 1. See Appendix B for a proof sketch.

**Theorem 1 (The Security of $\Pi_{\text{SGX}}$).** Assume $\mathcal{T}_{\text{SGX}}$’s attestation scheme and the digital signature used in $\Pi_{\text{SGX}}$ are existentially unforgeable under chosen message attacks (EU-CMA). Then $\Pi_{\text{SGX}}$ UC-realizes $\mathcal{T}_{\text{DASS}}[\mathcal{F}, R, S, M]$ in the $(\mathcal{F}_{\text{SGX}}, \mathcal{F}_{\text{chain}})$-hybrid model, for static adversaries.

4.4 **Minimizing trust in TEEs**

We now briefly consider some ways to minimize the trust placed in the TEE employed in our protocol.

**Avoiding a single point of failure.** Trusted hardware in general cannot ensure availability. In the case of SGX, a malicious host can terminate enclaves, and even an honest host could lose enclaves to outages. To avoid reliance on a centralized SGX server, each party in $\Pi_{\text{SGX}}$ can run her own SGX enclave with an identical program. This way, any individual party (or set of parties) can always use all the capabilities of the protocol without being dependent on others.

Specifically, the initialization procedure of $\Pi_{\text{SGX}}$ can be replaced with the following procedure that distributes the master key $sk_{\text{SGX}}$ across multiple hosts. First, each enclave first generates a fresh key pair $(pk_{\text{SGX}}, sk_{\text{SGX}})$ and outputs $pk_{\text{SGX}}$, while keeping $sk_{\text{SGX}}$, secret. Then, each player uses her identity $P_i$ to endorse $pk_{\text{SGX}}$, and all the players reach agreement on the list of SGX identities $\{pk_{\text{SGX}}\}_{i=1}^N$. Finally, the enclaves then use $\{sk_{\text{SGX}}\}_{i=1}^N$ to establish secure channels (TLS) with each other, and create a fresh shared secret key $sk_{\text{SGX}}$ that is associated with $\{pk_{\text{SGX}}\}_{i=1}^N$ (i.e., another invocation of the setup procedure will generate a different shared key). Given use of the secure hardware random number generator (RDRAND), secret keys generated by SGX are known only to the enclaves, not to any of the players. From now on, no inter-enclave communication is needed in the course of the protocol. Each enclave then seals its state (which mainly consists of $sk_{\text{SGX}}$) by encrypting it using the hardware key (unique to each CPU) and storing the ciphertext to persistent storage. Hence, the enclave program does not have to run persistently, and each players can run the backup on-demand when needed.

**Side-channel resistance.** Although SGX aims to provide confidentiality, recent work has uncovered data leakage via side-channel attacks (e.g. [76, 80]). Admittedly $\Pi_{\text{SGX}}$ is not side-channel-free, but it has a relatively small and controlled attack surface. The only secret in SGX is $sk_{\text{SGX}}$ and only operation involving $sk_{\text{SGX}}$ is signature generation (besides key generation)—this makes $\Pi_{\text{SGX}}$ amenable to software-level side-channel mitigations, such as constant-time ECDSA implementation (e.g. [28]).

A more powerful and somewhat more interesting approach is to design side-channel-free Paralysis Proofs. We claim that no side-channel-free construction of Paralysis Proofs exists given the current trust assumptions. However, if we relax the assumptions slightly, for example, by assuming a trusted relative clock in SGX (which is not available now [1]), or assuming certain stationarity properties of the blockchain (e.g. difficulty), a side-channel-free Paralysis Proofs can be constructed by establishing an up-to-date view of blockchain in SGX (e.g., using techniques in [24]). Specifically, SGX will only be activated when paralysis happens (which requires an up-to-date view of the blockchain to detect), and will generate a new key $sk_{\text{SGX}}$ for every new UTXO$_{\text{fund}}$. Since the enclave secret is used only once, such a construction is side-channel-free.

**Least-privileged SGX.** In $\Pi_{\text{SGX}}$ and the examples above the fund can be spent by $pk_{\text{SGX}}$ alone, but it’s important to note that is not the only option. In fact, one can tune the knob between security and paralysis-tolerance to the best fit their needs. Specifically, for a desired level of paralysis-tolerance, one can design a DASP such that the SGX is least-privileged. For example, if the three shareholders only desire to tolerate up to one missing key share, what they can do is to move the funds into 3-out-of-4 multisig wallet where the 4th share is only known to the SGX enclave. If all of the parties are alive, then they can spend without use of the SGX node. If one of them is incapacitated, the enclave will release its share upon presentation of a Paralysis Proof. Therefore, even if the secret state of the SGX node (i.e., the fourth share) is leaked via a successful side-channel attack, the attacker cannot spend the fund unless two malicious parties collude. It can be shown that the SGX in the above DASP is least-privileged, in the sense that compromise of its secret state imparts minimal capabilities to an adversary. Intuitively, since we want to retain access even one player is incapacitated, the enclave must store a credential equivalent to that of the lost player. We leave formal specification of least-privileged SGXs for future work.
Figure 4: Execution time of $P^2W$ when accusing one user.

4.5 Implementation

4.5.1 Paralysis Proofs for Bitcoin. We implemented $\Pi_{\text{SGX}}$ as a Paralysis-Proof Wallet (called $P^2W$) for Bitcoin based on Intel SGX SDK and Bitcoin Core. The source code of $P^2W$ is published at [2]. The same code works for Bitcoin and compatible systems, e.g., Litecoin.

To minimize the Trusted Computing Base (TCB), we ported only the necessary part of Bitcoin Core v0.14.0 to SGX, resulting in only using $\sim 9.5\%$ of it. The entire TCB includes 734 lines of C++ code written by us, $\sim 9.5\%$ of the Bitcoin Core and its Elliptic Curve library (libsecp256k1).

In the normal case, $P^2W$ is essentially a $(N, N)$-multisig wallet. Users can spend the coins by either send $N$ signatures to the blockchain, or to $P^2W$ which then generates a single signature. The latter method reduces the transaction size and saves transaction fees, while the former ensures the availability of the fund. When a user is suspected to be unavailable, others can accuse her using $P^2W$, which sends transactions $t_1$ and $t_2$ (c.f. Section 4.2) to the blockchain. The accused user can appeal by spending the life signal UTXO in $t_1$ (a standard P2PKH output) using $P^2W$ or any standard Bitcoin wallet.

We evaluated $P^2W$'s performance by simulating $N$ users and measuring the execution time of accusing one of them. As summarized in Fig. 4, $P^2W$ is very fast. For example, for 100 users, it only takes about 10 ms to generate accusation transactions. $t_1$ is of constant size (224 bytes) which means the cost of a malicious accusation is about as high as dismissing it. $t_2$ is roughly $(443 + 34N)$ bytes. With a suggested fee rate of 20 Satoshi/byte\(^1\) at the time of writing, the transaction fee of $t_2$ would be about $0.02N$, which is a very reasonable cost for such an infrequent and security-critical operation.

We validated $P^2W$'s compatibility with Bitcoin by deploying it on the testnet. We set $\Delta = 144$ blocks (roughly 24 hours in Bitcoin) and simulated the following two scenarios: a) a user is falsely accused, but she appeals within $\Delta$ and maintains the ownership of the wallet, and b) a disappeared user is challenged and removed from the wallet after $\Delta$. Accepted Bitcoin transactions can be found at [5, 6] (for scenario A) and [7, 8] (for scenario B). Note that in the latter scenario, $t_2$ is not accepted until 24 hours after $t_1$ is included, enforced by the CSV opcode.

4.5.2 Paralysis Proofs for Ethereum. For assets that can be controlled by smart contracts, an implementation of the ideal functionality $\mathcal{F}_{\text{DASS}}$ is straightforward. Our reference implementation of a paralysis-free multisig wallet for Ethereum [78] consists of 156 lines of commented Solidity code. Fully tested contract code, including logic for pruning incapacitated signers and updating the signature threshold is at [3].

This implementation differs from the ideal functionality only in minor engineering changes and optimizations. There is no way to asynchronously prune keyholders that fail to respond to a challenge in time in Ethereum, where all contract calls must be initiated by some user. We instead check and prune any signers that did not respond to a challenge at the beginning of each on-chain operation that requires checking or manipulating only valid signers. This ensures that the state of unparalyzed signers is correct, reflecting $L_t$ in $\mathcal{F}_{\text{DASS}}$, before any contract action is processed.

A final caveat is that block timestamps are used to measure time; while this can be trivially replaced with block numbers, which are less susceptible to miner manipulation (timestamps are miner set), the bounded degree of manipulation and monotonically increasing timestamp constraints on Ethereum provide some assurance that the timestamps are reasonably accurate for our purposes.

One useful property of the Ethereum-based realization is that the multisignature key holders need not necessarily run archival nodes: because a log is emitted whenever a user is accused, users can simply watch transaction receipts for an accusation against them, using any Ethereum full or lite client to respond by calling the respond function (guaranteed to work as long as an adversary cannot censor a user’s connection to the blockchain, given that the user accepts the relevant trust assumptions surrounding their choice of node software, hardware, and connectivity).

5 EXTENDED PARALYSIS PROOFS: THE CASE OF CUSTODIAN PARALYSIS

5.1 Motivation

A (digital asset) custodian is a centralized service that secures or helps secure a user’s digital asset (or other key-controlled resource). Use of custodians is common as they offer better usability and security, compared to having end users managing secrets on their own. Coinbase recently indicated that it was holding 10% of all Bitcoin in circulation [12].

An obvious concern with centralized custodians is theft, in which a custodian (or hacker that has compromised a custodian) steals funds from users’ accounts. In addition to theft, Denial-of-Service (DoS) is another major concern. If a custodian refuses to respond to a user’s transaction requests, the user effectively loses her funds.

In this section, we show how DASSes enable an interesting new architecture for digital assets custodians—a hybrid custodian—to address both concerns.

To achieve these properties, we refine the definition of paralysis. In addition to unavailability, a party (i.e., a custodian here) is considered paralyzed if it exhibits a certain behavior (e.g., maliciously rejects users’ withdrawal requests). This definition refines the previous ones, as it such cases, the custodian may be “available” in the sense of responding to clients, but exhibits paralysis by failing to process certain legitimate transaction requests.

\(^1\)See, e.g., https://statoshi.info/dashboard/db/fee-estimates
In addition to realizing a new and appealing custody architecture, this example also illustrates how Paralysis Proofs can embody rich and precise conditions beyond mere unavailability. Specifically, we show that a publicly verifiable proof can be constructed if a custodian rejects valid authentication attempts. Generally, Paralysis Proofs can be a condition predicated on user and/or system secrets (passwords and/or keys for two-factor authentication), in addition to mere absence of response.

5.2 Protocol

Setup. In our hybrid custodian scheme, a user stores her funds in a (2, 2)-paralysis-proof-multisig wallet (using techniques in Section 4), of which one key is held by a TEE operated by the centralized custodian. The custodian is responsible for authenticating the user (e.g., via a password, SMS code, etc.) before authorizing a transaction. Both signatures from the user and the custodian are required to spend funds.

Such a setup has two security benefits. First, it prevents the custodian from stealing the funds, as the custodian only possesses one of the secret keys. Second, it offers the user stronger security than if she managed her own keys, given the general weakness of endpoint security and the fact that an institutional custodian is usually much better at managing and securing keys than an ordinary user is.

Dealing with malicious DoS. As mentioned, we add additional rules to basic Paralysis Proofs so that a party (i.e., the custodian) is considered paralyzed unless a predicate \( \phi \) is met. In other words, when the custodian is accused (see Section 4 for terminology), it can only appeal if \( \phi \) is true.

Specifically, \( \phi \) will ensure an “appeal” is issued if and only if the custodian’s TEE faithfully attempted and failed to authenticate the user (e.g., the user inputs a wrong password). In other words, the custodian is honest but the accusation is invalid. Without this predicate, a malicious custodian can always appeal to dismiss honest users’ accusations. With the predicate, however, the custodian can only appeal against invalid accusations. Thus, we reduce the case of a malicious custodian actively refusing to accept authenticated transactions to that of a simple paralyzed party who cannot appeal.

Fig. 5 illustrates the idea of conditioning the issuance of response on the predicate of “the challenge contains valid authentication information.” The exact details of this predicate can vary depending on the authentication mechanism, as explored by example below.

Example: Password-based authentication. Consider a simple scenario where the user authenticates to the custodian with a password. The user submits her password (encrypted under the TEE’s public key) along with a partially signed transaction, and a signature over her full request. The custodian’s TEE verifies the signature on the request and checks if the password is correct. If so, it signs the transaction with its key. Otherwise, the request is discarded. If the signature is correct but the password is wrong, then the custodian may advance a counter which can be used to trigger rate limiting or lock the account. Here the custodian’s role would be to store a hashed version of the password securely, check it against the submitted password, and rate limit password attempts. Assuming that rollback attacks against TEs are prevented using, e.g., distributed state [48], authenticating the password request with a signature prevents the custodian itself from submitting false authentication attempts in an effort to deny service by locking a user’s account.

If the custodian is available but refuses to accept the password, we can now enter into an on-chain dispute resolution process, as shown in Fig. 5. The user posts a challenge containing the encryption of her password under a key known to the custodian’s TEE. If the custodian doesn’t respond within \( \Delta \), the standard Paralysis Proofs mechanism can kick in and remove the custodian from the access structure. To appeal with a response, the custodian’s TEE must decrypt the submitted password and test if it is correct. If the password is correct, the TEE refuses to issue a response, which is equivalent to the first case where no response is issued.

5.3 Extensions

For the ease of exposition the above protocol description uses simple password-based authentication. Various extensions are discussed below, including authentication via a third party (e.g., 2FA), user account recovery, and a general approach to use any interactive authentication protocol.

Third-party authentication. Another option is for the TEE to contact third parties directly to provide a primary or secondary authentication factor. Town Crier [82] demonstrated that it is possible to make a TLS request from an enclave to a third-party service and condition behavior on the response. Combined with input from the user via the blockchain, this can be used to directly authenticate a user, to provide a second factor via services such as Authy or Twillo, or to ensure that a user still has an account with some service. Many of these mechanisms depend on trusting a third party, but in the case of established and widely used services this may be more palatable than trusting any specific custodian. Multiple services can of course be combined to further distribute trust—with a trade-off against availability.

User account recovery. Using the same mechanisms for interactive protocols or authenticating via third parties, the custodian can provide a mechanism for account recovery in the case of lost credentials. Given a Paralysis Proof for the user, control can be transferred to a fresh multisig address. Indeed, if the custodian relies on third parties for authentication, then it inherits the account recovery mechanism automatically. This is, of course, a double-edged sword: the same mechanisms that are used for account recovery can be used to hijack the account. We are not limited, however, to simple password recovery mechanisms. If the custodian only controls one of two keys necessary to spend the funds, we can realize account recovery by requiring a Paralysis Proof against the user to migrate access control to another key.

More complex protocols. Following the techniques of [39], any interactive authentication protocol can be realized by posting encrypted messages between the client and the custodian to the blockchain. A Paralysis Proof then is simply an on-chain execution of the protocol where messages are delivered and logged via the blockchain. Indeed, the password example is a simple one-round version of this. The same idea can be applied to \( n \)-round protocols through repetition and extended to, for example, integrating federated authentication protocols or challenge-response-based two-factor authentication.
6 PARALYSIS WITHIN SMART CONTRACTS

6.1 Motivation
We’ve explored the use of smart contracts in Paralysis Proofs in Section 4. In the broader smart contract community, it is well known that paralysis can occur within smart contracts themselves. A classic example is the second of two well-publicized and related Parity multisignature vulnerabilities [18] [67] which permanently and irrecoverably froze hundreds of millions of US dollars in smart contracts. The Parity multisignature vulnerabilities are far from the only high-profile failures that resulted in paralysis; early analysis of Ethereum smart contract vulnerabilities [22] enumerated a number of vulnerable contracts with stuck funds and DoS vulnerabilities. Some vulnerabilities are subtle, involving low-level platform details like the “gas” model for pricing computation [78].

Most smart contract vulnerabilities, despite their different manifestations, have a fundamental commonality: in each case, a smart contract was operating as intended until some unexpected change to the state of the contract, the network, or the computation model under which the contract was operating. These changes then caused subsequent executions of previously working functionality to fail, leaving the funds in a contract potentially “paralyzed,” and stuck indefinitely. This problem is so widespread and severe on Ethereum, that hard-fork-based manual remediation of affected contracts has been suggested as a major governance issue and debate [21] [34].

We find a natural way to capture to this class of failure in Paralysis Proofs using software engineering tradition. When integrating various system components which may potentially be faulty, developers often create and run integration tests [38], often continuously as software is developed, in a process known as “continuous integration” [29, 69]. We can naturally extend Paralysis Proofs using continuous integration: if a full integration test suite is available, a provable test failure constitutes a Paralysis Proof and triggers a “downgrading of access control”, authorizing transfer of funds to a simpler recovery contract.

6.2 Protocols

Smart-contract based implementation. Two variant implementations of this idea are possible. The first is smart-contract based, with a protocol specification for the smart contract given in Fig. 6. (We omit user entry points from this specification.) In this protocol, there is a static, hardcoded set of tests T, with each test τj containing some storage locations to initialize that are required for correct operation of the test. (These locations are not necessarily comprehensive; tests can and should can pull storage variables from the environment.) For example, static state στ might contain an initialization of a special testing account with some balance available to be transferred that is not present in the real token contract, with the remainder of state required for the test sourced from the global stateful environment.

If a smart contract is paralyzed, it must be failing some unit test at block b. A user who notices this submits a proof by sending migrate, including Merkle proofs-of-inclusion for all state items consumed by the test from the environment at block b in the global Ethereum state trie [78]. The implementation proceeds checks that submitted Merkle proofs are all from the same block, that the block is recent (to prevent DoS via stale proofs), and that all proofs are valid.

For this check, proceed instantiates a temporary state. First all the validated state entries from the environment are added, then updated with the hardcoded static initialization state in στ. If observed test output differs from expected, paralysis is detected and proceed migrates any access to a recovery contract that returns user
funds, preventing paralysis of contract funds (assuming the test set is sufficiently rich and recovery operational). The test set is nulled to prevent further migrations.

Both users of the target contract and companies interested in maintaining availability of the contract (like the developers, for example Parity Technologies in [59]) are strongly incentivized to submit such proofs when they detect paralysis. Contracts desiring economic robustness can also incentivize a market of test executors by adding a substantial cryptocurrency bounty, paid to any user who successfully executes migrate.

The smart-contract based scheme has important advantages. Primarily, any user can prove paralysis using only on-chain data at any time, minimizing the trust surface required to just the code governing proof verification and recovery (and excluding complex attestation schemes and trust in enclave confidentiality). The scheme is also practical and optimistically efficient. We tested an example implementation provided at [44] of a Merkle-Patricia state item proof checker in a smart contract, usable for the is_valid function referenced in prog_{\text{att}}. In the optimistic case where funds are not paralyzed, our scheme adds no on-chain overhead or additional cost to contract operation. In the exceptional case of paralysis, our scheme’s cost is justified by the potential recovery of funds. Our initial exploration suggests a cost of about 1.36 million gas per invocation of the functionality required by is_valid; this is approximately 1/6 of a full Ethereum block, or $12 per storage location proof at the time of writing: expensive but not prohibitive.

**SGX-based implementation.** Several issues are however present with this SGX-free smart contract scheme. The on-chain Merkle proof verification is still somewhat costly, and a transaction/test can potentially access many storage locations. This may be acceptable in smart contract form, as tests can be potentially broken up into small/short pieces. This scheme financially incentivizes short tests, however, which may limit expressiveness of developers’ tests. Developers may choose to optimize against worst-case verification cost, which is difficult in a volatile and unpredictable transaction fee market. By making the cost of executing a test less dependent on the size of the test using SGX and off-chain computation, longer and more expressive tests become tractable. Such a scheme can optionally be operated in the Sealed-Glass Proof model in [72], enabling resilience against unbounded side channel leakage and removing confidentiality requirements, relying only on attestations for security.

An SGX-based solution can also leverage attestations and confidentiality execution. For example, if any off-chain or legacy systems are required in the integration test (e.g., when an oracle such as Town Crier [82] is used), they can be queried or emulated by SGX, or can use a trusted off-chain oracle. Also, confidential tests may be useful for some contracts. While unsuitable in a public network due to their ability to hide backdoors, one could imagine a contract between parties with neutrally-agreed-on third parties or arbitrers responsible for maintaining independent anti-paralysis test suites. This approach can also be applied within a modified version of N-of-N version programming (NNVP) as described in the Hydra framework [19]. To reduce on-chain gas costs, one or more heads can be executed off-chain within an enclave, which can issue an attestation when a bug (divergence in component outputs) is identified. Unfortunately, off-chain execution does not harmonize well with the Hydra bug-bounty system, as it leaves on-chain logic exposed to exploitation. But it does provide an objective means for identifying vulnerabilities, creating a Paralysis Proof and triggering fault logic within a paralyzed smart contract.

### 7 RELATED WORK

**Static access-structures for cryptocurrencies.** Bitcoin had built-in support for threshold signatures at launch, and access-structure scripts for Bitcoin have been discussed since at least 2012 (e.g. [61]). However the built-in implementation (CHECKMULTISIG) simply takes a list of individual signatures and check if the threshold are met, which increases the on-chain verification complexity (this is undesirable, cf. [45]).

[33] presented a novel ECDSA threshold signature construction that reduces on-chain complexity. However, this construction requires a rather complex setup using ZK proofs, and does not support arbitrary access structures. Threshold Schnorr signatures are far more efficient [68], with support planned for Bitcoin [79].

Ethereum wallets such as Mist [52] and Gnosis [77] support multi-signature access structures, along with other features such as daily limits. However, these wallets are implemented via on-chain code, which implies that users will incur higher costs when the complexity of the access structure is greater. New versions of the Gnosis wallet [51] allow for arbitrary, unrestricted challenge-based policy migration, but do not formalize security or suggest secure policies.

**Access-control policies with dynamic access-structures.** Secret sharing schemes with revocation support do not provide the same guarantees as a Paralysis Proof system, since such schemes require actions by at least a threshold of players to update the access structure (see [27, 81]). By contrast, a Paralysis Proof system enables any player to remove incapacitated players. Privacy-preserving cloud services can allow remote administrators to modify access-control policies dynamically, via cryptographic constructions (see, e.g., [36, 40]). Dynamic access-control policies for non-confidential cloud service may also benefit from dynamic access-control polici [34]. All of these constructions requires a static set of administrator set authorized to perform modifications.

**Credential-recovery.** Password systems allow recovery from secret loss but require a TTP. See [16] for a survey.

### 8 PARALYSIS PROOF SYSTEMS BEYOND CRYPTOCURRENCIES

The techniques we have introduced for Paralysis Proof Systems in combining SGX with blockchains can be applied to settings other than Paralysis Proofs and even to settings other than cryptocurrencies. We give some examples here:

**Daily spending limits.** It is possible to enforce limits on the amount of BTC that set of players can spend in a given interval of time. For example, players might be able to spend no more than 0.5 BTC per day. We explore this objective, and technical limitations in efficient solutions in Appendix F.

**Decryption.** The credentials controlled by a Paralysis Proof System need not be signing keys, but instead can be decryption keys.
is possible then, for example, to create a deadman’s switch. For example, a document can be decrypted by any of a set of journalists should its author be incapacitated.

Event-driven policies. Using an oracle, e.g., [82], it is possible to condition access-control policies on real-world events. For example, daily expiration limits might be denominated in USD by accessing oracle rates on exchange rates. Similarly, decryption delays for a document might be released for situations other than incapacitation, e.g., if a document’s author is prosecuted by a government. (This latter example would in all likelihood require natural language processing, but this is not beyond the capabilities of an enclaved application.)

The last example involving prosecution does not require use of a blockchain, of course. Many interesting SGX-enforceable access-control policies do not. But use of a blockchain as a censorship-resistant stateful channel can help ensure that policies are enforced. For example, release of a decryption key might be entangled with the spending of cryptocurrency. A certain amount of cryptocurrency, say, 10 BTC, might be spendable on condition that an oracle is recently queried and the result consumed by an enclave application. This approach provides an economic assurance of a censorship-resistant stateful channel from the blockchain to the enclave.

9 CONCLUSION

We have shown how Paralysis Proofs can enrich existing access-control policies in a way that was previously unachievable without a trusted third party. By leveraging Paralysis Proofs, DASSes allow an access structure to be securely migrated—typically downgraded—given the incapacitation of a player, the inability of a set of players to act in concert, or the functional paralysis of a smart contract.

Our formalisms include a formal DASP framework, and security and functionality definitions for DASSes and DASPs, as well as UC-type ideal functionality for a DASS. Our ideal functionality suggests a natural proof sketch for security.

Paralysis Proofs and DASSes can be applied in many settings, and we showcase three in the paper: cryptocurrency key loss, cryptocurrency custody failures, and smart contract failures, proposing practical schemes for all three. We report on a simple DASS for cryptocurrency key loss in Ethereum, and on a detailed exploration concluding that DASS for Bitcoin is only practical using a TEE.

In summary, we believe that the combination of the advent of two pivotal technologies, blockchains and trusted hardware (specifically SGX), is a powerful one. It enables a powerful new range of access-control regimes without the need for trusted third parties and, we believe, will stimulate exploration of a broader spectrum of other novel capabilities with applications beyond cryptocurrencies.

For simplicity, we write $\mathcal{F}_{\text{DASS}}[P_h, \mathcal{R}, S, M]$ as $\mathcal{F}_{\text{DASS}}$ from now on. To prove Theorem 1, it suffices to show that for the "dummy adversary" $\mathcal{A}$, there exists a PPT adversary $\text{Sim}$ such that for any PPT environment $\mathcal{Z}$

$$\text{EXEC}_{\Pi_{\text{SGX}}, \mathcal{A}, \mathcal{Z}} \approx \text{EXEC}_{\mathcal{F}_{\text{DASS}}, \text{Sim}, \mathcal{Z}}.$$  

(1)
We show that no environment can distinguish an interaction with 
\( P \) as if from \( H \) attacks against the signature scheme.

\( \Sigma \) out the forgery attacks against \( \Pi \).

Similarly, the indistinguishability between \( H_2 \) and \( H_3 \) can be shown by a reduction to the EU-CMA property of signature scheme.

It remains to observe that \( H_3 \) is identical to the ideal protocol with Sim.

C PARALYSIS PROOFS FOR BITCOIN VIA COVENANTS

In the context of Bitcoin scripts, the notion of a covenant allows to put restrictions on the way that an output can be spent. Coveneans were introduced by Moser, Eyal and Sirer [53], following an early idea by Maxwell [49]. Another generic method for coveneans was given by O’Connor and Piekarska [56], and an efficient implementation of coveneans (OP_PUSHTXDATA) was created by Lau [43]. So far, coveneans support has not been enabled on the Bitcoin mainnet.

The mechanism of [53] supports a recursive covenean by letting the interpreter replace the Pattern keyword with the covenean itself. The recursion is required in our paralysis use-case, because the funds must be restored back to the original covenean whenever an accusation attempt fails. However, the single Pattern capability of [53] is inadequate for the paralysis covenean, because we wish to move the funds between different coveneans that depend on the subset of remaining shareholders. Fortunately, the implementation of [43] supports multiple recursive patterns, by hashing fixed and variable data and then comparing the result to the output.

An exemplary paralysis covenean is illustrated in Fig. 10, using syntax that is similar to that of [53]. In this example, three shareholders can spend the entire amount \( V \) with no restrictions, by using the 3-out-of-3 multisig condition of the Pattern123 covenean. Any two shareholders can accuse the third shareholder of being paralyzed, by moving the entire fund of \( V \) coins into an Pattern1 covenean that lets them spend the coins after a relative timeout of 150 blocks. While the 150 blocks are still being created, the third shareholder can move the funds back into the initial covenean Pattern123. Similarly, any single shareholder can accuse the two other shareholders of being paralyzed, by moving the \( V \) coins into the Pattern1 covenean.

Note that the coveneans PatternIJ and Pattern1 must be distinct for different values of \( I,J \), in order to avoid collusion attacks. For example, if PatternIJ allowed any 2-out-of-3 to spend the
A Paralysis Proof mechanism can also be implemented without funds after the timeout, then two malicious shareholders

\[ V \]

could pretend that \( P_2 \) is paralysed, so that \( P_1, P_2 \) would accuse \( P_3 \), and after the 150 blocks timeout, \( P_2, P_3 \) will spend the funds arbitrarily (without the consent of the honest \( P_1 \)).

There is certain similarity between the SGX protocol of Fig. 8 and the covenants implementation of Fig. 10. The main difference is that the \( pk_1, pk_2 \) multisig replaces \( pk_{SGX} \) in the condition \( pk_{SGX} \land CSV \geq \Lambda \). Hence, by taking the paralysis use-case as an example, it can be inferred that the complexity of the covenants approach is significantly higher than that of an SGX implementation (in terms of conceptual as well as on-chain complexity, see also Appendix E). As there have been recent proposals to support stateless covenants in Ethereum (for better scalability, cf. [75]), the comparative advantages of our SGX-based design may prove useful in other contexts too.

D PURELY SCRIPT-BASED PARALYSIS PROOFS FOR BITCOIN

A Paralysis Proof mechanism can also be implemented without SGX (on the current Bitcoin mainnet), albeit with subpar security and more than exponential overhead.

\[
\text{Figure 10: Basic paralysis covenants for three shareholders.}
\]

\[
\text{Figure 11: Bitcoin-based Paralysis Proofs with } N \text{ players (with public keys } \{pk_n\}_{n \in [N]}\text{). Each player } P_i \text{ will prepare unsigned transactions } \{t_{i,j,k} \}_{j \in [N] \setminus \{i\}, k \in [K]} \text{ that accuse } P_j (\text{these transactions are similar to } t_1), \text{and all players will sign transactions } t'_{i,j,k} \text{ that take } \text{UTXO}_b \text{ and the output of } t_{i,j,k} \text{ as inputs (these transactions are similar to } t_2). K \text{ is a security parameter specifying the number of accusation attempts that can be made. Fig. 11 illustrates the transactions in the aforementioned scheme.}
\]

Our construction utilizes the “life signal” method of Section 4. In the initial setup phase, each player \( P_i \) will prepare unsigned transactions \( \{\text{utx}_i,k \}_{j \in [N] \setminus \{i\}, k \in [K]} \) that accuse \( P_j \) (these transactions are similar to \( t_1 \)), and all players will sign transactions \( t'_{i,j,k} \) that take \( \text{UTXO}_b \) and the output of \( t_{i,j,k} \) as inputs (these transactions are similar to \( t_2 \)). \( K \) is a security parameter specifying the number of accusation attempts that can be made. Fig. 11 illustrates the transactions in the aforementioned scheme.

This scheme can be implemented post-SegWit [39], where transaction hash \( \text{txid} \) excludes the \( \text{ScriptSig} \) witness. In particular, SegWit allows one to prepare \( t'_{i,j,k} \) and condition its validity on that of unsigned \( t_{i,j,k} \).

After every player receives all the signed transactions, the players will move the high-value fund into \( \text{UTXO}_b \). This guarantees atomicity: either every player will have the ability to eliminate all the incapacitated player, or none of the player will have this ability. The output of \( t_{i,j,k} \) requires a signature from \( P_j \) before the CSV timeout and a signature from \( P_i \) after the CSV timeout, and \( P_i \) may embed this signature into \( t'_{i,j,k} \) after \( P_j \) failed to spend the output of \( t_{i,j,k} \) on the blockchain. Since \( \text{UTXO}_b \) requires the signatures of all parties, the only way to eliminate an incapacitated player is by using the signed transactions \( t'_{i,j,k} \) that were prepared in advance.

The parameter \( K \) specifies the number of accusation attempts that can be made; hence a malicious player that pretends to be incapacitated more than \( K \) times will break this scheme. The SGX scheme does not exhibit this deficiency, because any player can send a fresh small amount of bitcoins to the enclave and thereby create an accusation transaction.

Furthermore, in order to support sequences of \( \ell > 1 \) incapacitated players, the \( N \) players will need to prepare in advance additional transactions that spend the outputs of \( t'_{i,j,k} \) in order to eliminate another player, and so on. The scheme offers the most safety when \( \ell = N - 1 \), as this implies that any lone active player (i.e., all other players became incapacitated) will be able to gain control over the fund. The number of signed transactions that need
to be prepared in advance is
\[ f(\ell, N, K) \triangleq KN(N - 1) \cdot K(N - 1)(N - 2) \cdots K(N - \ell + 1)(N - \ell) \geq \Omega(K^{\ell} N^\ell). \]

Thus, \( \ell = N - 1 \) implies that \( f(\ell, N, K) \) grows faster than \( g(N) = 2^N \).

## E THE COMPLEXITY OF ACCESS STRUCTURE REALIZATIONS

The ideal functionality of Section 4 is threshold predicates that require consent from \( \mu N \) of the \( N \) live shareholders in order to spend the funds. (\( \mu = 1 \) would mean unanimous consent.) However, it is also possible to consider an extended functionality that requires signatures according to a more complex access structure. E.g., any subset of 35 out of \( \{P_1, P_2, \ldots, P_{40}\} \) can spend the funds, otherwise the funds can be spent with the consent of all shareholders in the privileged set \( \{P_1, P_2, P_3, P_4\} \), or otherwise the privileged \( P_1, P_{35}, P_{68}, P_{37}, P_{38}, P_{39}, P_{40} \) can spend the funds.

Such an access structure can be accomplished using cryptographic constructions, in particular mesh signatures [17] and attribute-based signatures [46]. However, these schemes involve bilinear pairings and are rather complex, which entails that the on-chain verification of such schemes will be impractical or costly.

Recently, the use of SGX has been suggested for functional encryption that is far more efficient in comparison to a standard cryptographic variant [32]. In a similar fashion, the use of SGX for an access structure based signature scheme implies substantial efficiency gains too. Thus, the improved efficiency applies both to the off-chain protocol that produces signatures, and to the on-chain cost of verifying the signature (i.e., the on-chain complexity is reduced to just one ordinary signature verification against \( pk_{SGX} \)).

The ideal functionality of Section 4 can therefore be replaced with an extended functionality that supports an access structure, and the Bitcoin protocol of Fig. 8 will essentially remain the same. This is because the off-chain complexity of creating the signature will be handled by the SGX enclave code, and the on-chain complexity will be absorbed into a verification against \( pk_{SGX} \).

It is worth considering whether it is inherently the case that the high efficiency requires SGX, or whether it is possible to design a cryptocurrency with built-in support to access structure based signatures. In fact, certain support is offered via the use of Merklized Abstract Syntax Trees [41, 64] and Schnorr aggregate signatures [79]. As in the “Large multi-signature constructs” of [41], we can for example have a Merkle tree with \( 2 + (40^2) - (36^2) - (35^2) + (25^2) < 2^{18} \) leaves, such that all but two of the leaf nodes require a multisig by a specific subset of \( \{P_1, P_2, \ldots, P_{40}\} \) of size 35 (excluding subsets that already include the privileged sets \( \{P_1, P_2, P_3, P_4\} \) and \( \{P_1, P_{35}, P_{68}, P_{37}, P_{38}, P_{39}, P_{40}\} \), without double counting), put only the root hash on the blockchain, and expect a valid Merkle authentication path to spend the coins. Further, the script of the leaf can use a single aggregated public key that is created from the public keys of the 35 signers (using delinearization [13, 74]), so that the on-chain complexity is on par with that of verifying one ordinary signature. Regarding the total on-chain complexity, we have that transaction that spends the funds consists of one aggregated signature for the leaf node and a Merkle authentication path of 18 sibling hashes.

However, per the discussion of \( OP_{EVAL} \) in [41], the use of a Merklized Abstract Syntax Trees becomes significantly more challenging for a predicate that involves a more complex relation than a logical OR among the leaves. For instance, if the access structure specified that \( P_1, P_2, P_3 \) must consent, and either \( P_4, P_5 \) or \( P_6, P_7 \) must also consent, then this cannot be handled by the implementation of [41]. By contrast, SGX can handle this instance just as easily as the previous example.

As the above discussion illustrates, harnessing SGX to spend funds according to an access structure can be highly useful even for a cryptocurrency with a Turing-complete scripting language (such as Ethereum). Let us point out that as long as [79] is not yet operational, it can be quite beneficial to employ SGX even for threshold signatures, since an ECDSA threshold scheme (without a trusted dealer) is rather complex, cf. [33].

The use of access structures in a cryptocurrency can also incorporate a notion of time, which in turn can help to avoid system paralysis that is caused by disagreement together with the disappearance of some players. For instance, the functionality can require 75% of the active players to agree on how to spend the funds, but require only 50% of the active players after one year, and only 20% after three years. In the UTXO model of Bitcoin, this can be accomplished via trusted hardware: whenever the players agree to spend the funds they will specify absolute timeouts for the 50% and 20% cutoffs (using CLTV [71]), and whenever the SGX enclave is asked to remove an incapacitated player it will create a transaction whose output hardcoded the same absolute timeouts as the input that is being spent. If the access structures for the different points in time are complex, the trusted hardware based implementation will be particularly beneficial (otherwise covenants could be used).

## F DAILY WITHDRAWAL LIMIT USING SGX

Let us consider a functionality \( F_{daily} \) that allows \( N \) shareholders to spend the funds if at least \( \mu N \) of them reach an agreement (for \( \mu \leq 1 \)), and allows each individual shareholder to spend a small portion of the funds (e.g., 0.1%) each day. Moreover, the functionality allows \( \rho N \) shareholders to disable the daily spending of funds by individual shareholders (for \( \rho \leq \mu \), which is useful in the case that some shareholders appear to spend too much). By using \( \rho < \mu \), it is easier to block the daily withdrawals than to reach consensus on a large expenditure.

It may be quite useful to combine \( F_{daily} \) with a functionality for paralysis proofs, but for simplicity we focus in this section on a bare implementation of just \( F_{daily} \) itself. Given an expressive enough covenants support for Bitcoin (such as [43]), it is possible — though quite complex — to implement \( F_{daily} \) using similar methods to the ones that we describe in Appendix C. However, let us present here the more efficient implementation that relies on trusted hardware, and can be deployed on the current Bitcoin mainnet.

The SGX-based protocol \( \Pi_{daily} \) that implements \( F_{daily} \) is given in Fig. 12.

Since Bitcoin outputs must be fully consumed, \( \Pi_{daily} \) does not realize \( F_{daily} \) exactly, but instead lets each one of the shareholders
Protocol $\Pi_{\text{daily}}$

1. Hardcode $\{\text{pk}_k\}_{k=1}^N$, $\mu$, $\rho$, $\ell$, $\Lambda$, $\Delta'$
2. Init:
   - Setup: securely generate and share $(sk_{\text{SGX}}, pk_{\text{SGX}}, (sk_{\text{SGX}}', pk_{\text{SGX}}'))$ and
   - $\{sk_{\text{SGX}_k}, pk_{\text{SGX}_k}\}_{k=1}^N$ among the enclaves.
3. Let $\phi_j \overset{\$}{\leftarrow} [\mu N \text{- out-of-} N \text{ multsig among pk}_k, \text{pk}_k, \ldots, \text{pk}_N]$.
4. For $j \in [N]$, let $\psi_j \overset{\$}{\leftarrow} \{\text{sk}_i \forall \text{pk}_i \vee (sk_{\text{SGX}_j} \land (CSV \geq \Lambda)) \lor (pk_{\text{SGX}_j} \land (CSV \geq \Delta'))\}$.
5. $(P_i)$ encodes UTxO_{fund} by publishing $(\text{UTxO}_{fund} \rightarrow (V, \psi_i))$.
6. Send:
   - $(P_i)$ sends $\mu N$ signatures, the escrowed $(V, \psi_{\text{curr}})$, and $T_{\text{new}}$ to the enclave.
7. The enclave returns a signed transaction $t = ((V, \psi_{\text{curr}}) \rightarrow T_{\text{new}})$.
8. Daily withdrawal:
   - $P_k$ sends a signed request with the escrowed $(V, \psi_{\text{curr}})$ and $(V', T')$ to the enclave.
9. The enclave verifies that $V' \leq V_{\text{max}}$.
10. The enclave fetches curr by parsing $\psi_{\text{curr}}$.
11. If $k = \text{curr}$ then $sk = sk_{\text{SGX}_j}$ else $sk = sk_{\text{SGX}_0}$.
12. If $k < N$ then $t = k + 1$ else $\ell = 1$.
13. The enclave uses $sk$ to create the signed transaction.
14. $t = ((V, \psi_{\text{curr}}) \rightarrow (V - V', \psi'), (V', T'))$, and returns $t$.
15. Disallow daily withdrawals:
   - $(P_i)$ sends $\rho N$ signatures and the escrowed $(V, \psi_{\text{curr}})$ to the enclave.
16. The enclave returns a signed transaction $t = ((V, \psi_{\text{curr}}) \rightarrow (V, [\psi_{\text{curr}} \lor pk_{\text{SGX}}]))$.

Figure 12: An SGX-based realization of $\mathcal{F}_{\text{daily}}$.

perform a daily withdrawal, in sequential order. Thus, the first shareholder has the privilege to withdraw a small amount on the first day, the second shareholder can withdraw a small amount on the second day, the third shareholder on the third day, and so on. If for example the third shareholder did not withdraw, then on the forth day any single shareholder can withdraw a small amount (on a first come first served basis), but on the fifth day the sequential order resumes and the forth shareholder will have the privilege to withdraw.

It should be noted that in a cryptocurrency that uses the accounts model rather than the UTXO model (e.g., Ethereum), a more expressive realization of $\mathcal{F}_{\text{daily}}$ is possible. E.g., multiple shareholders can withdraw small amounts as long as the daily limit has not yet been reached.

The gist of $\Pi_{\text{daily}}$ is an embedding of a public key $pk_{\text{SGX}}$ into the spending transaction, corresponding to the shareholder $P_j$ who currently has the daily withdrawal privilege. Since the secret key $sk_{\text{SGX}_j}$ is known only to the SGX enclave, $P_j$ cannot spend the funds arbitrarily, but instead has to submit to enclave a request to spend a small amount $V'$ of the $V$ coins to an arbitrary destination $T'$. The enclave will thus also produce a new output for the rest of the $V - V'$ funds, with $pk_{\text{SGX}_{j+1}}$ embedded into it.

Since $P_j$ may not necessarily wish to withdraw, the output that the enclaves produces also allows spending of a small amount with a special master public key $pk_{\text{SGX}_0}$, but only after a relative timeout of $\Delta$ blocks (since Bitcoin blocks are created once every 10 minutes on average, $\Delta \approx 144$ blocks implies $\approx 1$ day). Hence, any shareholder who submitted a request to withdraw from the current funds will be able to spend the signed transaction that the enclave produced for her, but only after $\Delta$ blocks so that $P_j$ has the opportunity to spend first.

In case $\mu N$ shareholders wish to spend an arbitrary amount, or in case $\rho N$ shareholders wish to disable the daily withdrawal feature, they can submit their $\mu N$ (or $\rho N$) signatures to the enclave and receive a signed transaction that takes precedence over any daily withdrawal transaction. This is accomplished by using a small relative timeout $\Delta'$ in the condition that allows the current privileged shareholder to perform a daily withdrawal, so that the transaction that was agreed upon by $\mu N$ (or $\rho N$) shareholders can be incorporated into the blockchain earlier (e.g., $\Delta' = 3$ is reasonable).

Other parts of the $\Pi_{\text{daily}}$ protocol (in particular the setup procedure) are identical to $\Pi_{\text{SGX}}$, see Section 4 for details.
