Abstract. Secure sketch produces public information of its input $w$ without revealing it, yet, allows the exact recovery of $w$ given another value $w'$ that is close to $w$. Therefore, it can be used to reliably reproduce any error-prone secret sources (i.e., biometrics) stored in secret storage. However, some sources have lower entropy compared to the error itself, formally called “more error than entropy”, a standard secure sketch cannot show its security promise perfectly to these kind of sources. This paper focuses on secure sketch. We propose a concrete construction for secure sketch. We show security to all noisy sources, including the trivial source with zero min-entropy. In addition, our construction comes with efficient recovery algorithm operates in polynomial time in the sketch size, which can tolerate high number of error rate arbitrary close to $1/2$. Above result acts in conjunction to our derivation on the solution to an NP-complete coding problem, implying $P=NP$.

1 Introduction

Traditional cryptography systems rely on uniformly distributed and recoverable random strings for secret. For example, random passwords, tokens, and keys. These secrets must present exactly on every query for a user to be authenticated and get accessed into the system. Besides, it must also consist of high enough entropy, thus making it very long and complicated, further resulted in the difficulty in memorizing it. On the other hand, there existed plentiful non-uniform strings to be utilized for secrets in practice. For instance, biometrics (i.e., human iris, fingerprint) which can be used for human recognition/identification purpose. Similarly, long passphrase (S. N. Porter, 1982 [1]), answering several questions for secure access (Niklas Frykholm et al., 2001 [2]) or personal entropy system (Ellison et al., 2000 [3]), and list of favorite movies (Juels and Sudan, 2006 [4]), all are non-uniformly distributed random strings that can be utilized for secrets.

The availability of non-uniform information prompted the generation of uniform random string from non-uniform materials. Started by Bennette et al., (1988) [5], identified two major approaches to derive a uniform string from noisy non-uniform sources. The first approach is information-reconciliation, by tolerating the errors in the sources without leaking any information. The second
approach refers to the privacy amplification, which converts high entropy input into a uniformly random input. The information-reconciliation process can be classified into interactive (includes multi messages) and non-interactive (only includes single message) versions. For non-interactive line of work, it has been first defined by Dodis et al., (2004) [6] called the fuzzy extractor. Likewise, the fuzzy extractor used two approaches to accomplish the task, which is the secure sketch (for error tolerance), and randomness extractor (for uniform string generation). Secure sketch is demanding because it enables information-reconciliation, e.g., exact recovery of a noisy secret while offering security assurance to it. Moreover, a secure sketch can be easily extended to fuzzy extractor for uniform string generation by using a randomness extractor. The generated random string can be used in independent security system for access control, identification, digital signature, etc.

This work focuses on secure sketch. We reviewed the limitations of current secure sketch constructions in Section 1.1. To overcome such limitations, we introduced the usage of resilience vector (RV) in Section 5 to support better understanding of the structure of the noisy sources. We proposed a concrete construction with included RV for sketching and recovery (secure sketch) in Section 6 and 7 respectively. Our proposed recovery mechanism has shown to be efficient in polynomial in the sketch size and allows error tolerance of error rate arbitrary close to 1/2 (Section 9). In the end, in Section 10 we formalize the security of our construction and show security to all noisy sources with computationally unbounded attacker. We also compared our proposal with existing secure sketch construction, showing our construction enjoys the better upper bound of min-entropy requirement for a standard secure sketch (Section 11).

1.1 Issues in Existing Secure Sketch Construction

There existing various secure sketch constructions in the literature. Some notable constructions involved the code-offset construction proposed by Juels and Wattenberg (1999) [7] that operates perfectly over hamming matrix space. Besides, Juels and Sudan (2006) [4] have also proposed another construction for metric other than hamming called the fuzzy vault. An improved version of the fuzzy vault is proposed by Dodis et al., (2004) [6], and also the Pin-sketch that relies on syndrome encoding/decoding with t-error correcting BCH code C, which works well for non-fixed length input over a universe \( U \).

However, the above mentioned secure sketch construction only works for limited noisy sources. Briefly, given a point (some value) \( w \), the sketch would allow the acceptance of its nearby point \( w' \) within distance \( t \) for exact recovery of \( w \). Therefore, if an adversary can predict an accepting \( w' \) with noticeable probability, the sketch must reveal \( w \) to the adversary with noticeable probability as well. The tension between security and error tolerance capability is very strong. Precisely, the security is measured in term of the residual (min-) entropy, which is the starting entropy of \( w \) minus the entropy loss. Given some non-uniform sources with low min-entropy, especially, when the sources consist of more error than entropy itself, deducting the entropy loss from the sources’ min-entropy
always output a negative value, hence, show no security. Because of this, correcting $t$ errors regardless of the structure of the input distribution would have to assume sufficient high min-entropy to the input sources. To show meaningful security for standard secure sketch, the min-entropy must at least half of the input length itself [8], hence, limiting the availability of secure sketch construction for low entropy sources.

Through exploitation of the structure of the input distributions, Fuller et al., (2013) [9] have show that the crude entropy loss over ‘more error than entropy’ sources can be avoided by the measurement of fuzzy min-entropy, which defined as the min-entropy with maximized chances for a variable of $W$ within distance $t$ of $w'$:

$$H_{t,\infty}^{\text{fuzz}}(W) \overset{\text{def}}{=} -\log \left( \max_{w'} \Pr[W \in B_t(w')] \right),$$

where $B_t(w')$ denoted a hamming ball of radius $t$ around $w'$. Conceivably, the fuzzy min-entropy is equivalent to the residual entropy, which is at least the min-entropy $H_\infty(W)$ minus the loss signified by the hamming ball $B_t(w')$ of radius $t$, s.t.

$$H_{t,\infty}^{\text{fuzz}}(W) \geq H_\infty(W) - \log(B_t(w')).$$

$H_{t,\infty}^{\text{fuzz}}(W)$ is useful for security measurement instead of $H_\infty(W)$ especially when the residual entropy shows negative value (i.e. more error than entropy). However, due to the fact that $H_{t,\infty}^{\text{fuzz}}(W)$ depends on the error tolerance distance $t$, and it is not necessary referring to the worst-case distribution for $W$, therefore, traditional way of showing security with $H_{t,\infty}^{\text{fuzz}}(W)$ measurement have to deal with such distribution uncertainty by considering a family of distributions $W$ for different variables i.e., $\{W_1,W_2,\ldots\} \in W$ rather than single distribution. Viewed this way, $H_{t,\infty}^{\text{fuzz}}(W)$ measurement is only sufficient for computational secure sketch construction [9], [10], which means that the security property of such construction only hold for computationally bounded attacker (i.e., polynomial time bounded) accompanies with strong assumption on the user has a precise knowledge over $W$. However, it is unrealistic to assume every sources distribution can be modelled precisely, especially for high entropy sources like human biometric.

2 Overview Results

We highlighted our main five results as follow.

To construct a secure sketch for all noisy sources, it was believed that the exploitation of the input structure is necessary [11]. Follow in this way, our works adopted the principle of Locality Sensitive Hashing (LSH) to generate a resilient vectors pair (trivially, a pair of longer strings with resilience property) for sketching and recovery. Details discussion on the resilient vector (RV) is covered in Section 5. The RV pair possessing resilience property, i.e., distance preserving that is useful for the exploitation of the input noisy sources structure.
Our first result is the metric of correlation measure between the RV pair and their input pair (Eq. 1 and Eq. 2).

Since the RV is used for sketching, such correlation measurement implies the entropy loss from the input. Therefore, the minimum entropy loss from the sketch reduced to the maximum correlation measured in between the RV pair, conditioned on their inputs. We formalize such minimum entropy loss based on the worst-case distribution of the RV pair and their given inputs pair. Such worst-case distribution is identified by random error parsing, which considered the maximized weight of the codeword after an encoding process. This refers to our second result, where the maximum tolerance distance corresponds to the worst-case input distribution (Corollary 1), implies the minimum entropy loss from the sketch (Eq. 4).

Thirdly, we show that the minimum entropy loss could be at least three bits with BCH error correction codes. This pushed the upper bound of minimum entropy requirement for our secure sketch construction to accept any sources of entropy at least three bits, which is much lower compared to existing constructions.

Later, we deemed that the three bits upper bound can be further pushed down to zero by considering any attacker could have unlimited computation power in modelling the input distribution with other random distribution (viewed as site information), lead to a successful decoding and recovery of the input vector (Eq. 15). Nevertheless, the attacker requires to brute-force the input where its security is defined by the Shannon entropy of the introduced error’ distribution during the sketching phase. This refers to our fourth result, which is information-theoretic in claiming security for all noisy sources with any positive value of min-entropy, included the trivial source with min-entropy zero (Proposition 3).

The last result we would like to highlight is the efficiency of the recovery algorithm in our construction. Without the consideration on the computational power in running the recovery algorithm, the recovery of the input from the sketch can be done with high probability (close to one) given the sketch size is large enough (Proposition 1). On the other hand, considering the computational power in running the recovery algorithm, we noticed that higher computational power, i.e., exponential time in the input (Eq 8) is needed in order to tolerate more errors (Eq. 8). Nonetheless, such exponential computation time can be relaxed to polynomial time in the sketch size to ensure efficient recovery while allowing more errors to be tolerated (Proposition 2). This result shows deep connection in between a difficult decoding problem over smaller metric space (of size $k^*$) could be reduced down to an easier problem over larger metric space $n > k^*$, implying $P=NP$.

### 3 Preliminaries

There are some preliminaries to introduce the background of a standard secure sketch, entropy, and error correction code.
Secure sketch: [6] An \((\mathcal{M}, m, \tilde{m}, t)\)-secure sketch is a pair of randomized procedures “sketch” (\(SS\)) and “Recover” (\(Rec\)), with the following properties:

- **SS:** takes input \(w \in \mathcal{M}\) returns a secure sketch (e.g., helper string) \(ss \in \{0, 1\}^*\).
- **Rec:** takes an element \(w' \in \mathcal{M}\) and \(ss\). If \(\text{dis}(w, w') \leq t\) for some tolerance threshold \(t\), then \(Rec(w', ss) = w\) with probability \(1 - \beta\), where \(\beta\) is some negligible quantity. If \(\text{dis}(w, w') > t\), then no guarantee is provided about the output of \(Rec\).

The security property of secure sketch guarantees that for any distribution \(W\) over \(\mathcal{M}\) with min-entropy \(m\), the values of \(W\) can be recovered by the adversary who observes \(ss\) with probability no greater than \(2^{-\tilde{m}}\). That is the residual entropy \(\tilde{H}_\infty(W|W') \geq \tilde{m}\).

**Min-Entropy:** For security, one is always interested in the probability for an adversary to predict a random value, i.e., guessing a secret. For a random variable \(W\), \(\max_w \Pr[W = w]\) is the adversary’s best strategy to guess the most likely value, also known as the predictability of \(W\). The min-entropy thus defined as

\[
H_\infty(W) = - \log (\max_w \Pr[W = w])
\]

min-entropy also viewed as worst-case entropy.

**Conditioned min-entropy:** Given pair of random variable \(W, W'\) (possible correlated), given an adversary find out the value \(w'\) of \(W'\), the predictability of \(W\) is now become \(\max_w \Pr[W = w | W' = w']\). The conditioned min-entropy of \(W\) given \(W'\) is defined as

\[
\tilde{H}_\infty(W|W') = - \log \left( \mathbb{E}_{w' \sim W'} \left[ \max_w \Pr[W = w | W' = w'] \right] \right)
\]

**Error correction code:** [12] Let \(q \geq 2\) be an integer, let \([q] = \{1, \ldots, q\}\), we called an \([n, k, d]_q\)-ary code \(C\) consist of following properties:

- \(C\) is a subset of \([q]^n\), where \(n\) is an integer referring to the blocklength of \(C\).
- The dimension of code \(C\) can be represented as \(|C| = [q]^k = V\)
- The rate of code \(C\) to be the normalized quantity \(k/n\)
- The min-distance between different codewords defined as \(\min_{c,c' \in C} \text{dis}(c, c')\)

It is convenient to view code \(C\) as a function \(C : [q]^k \rightarrow [q]^n\). Under this view, the elements of \(V\) can be considered as a message \(v \in V\) and the process to generate its associated codeword \(C(v) = c\) is called encoding. Viewed this way, encoding a message \(v\) of size \(k\), always adding redundancy to produce codeword \(c \in [q]^n\) of longer size \(n\). Nevertheless, for any codeword \(c\) with at most \(t = \lfloor \frac{k-1}{2} \rfloor\) symbols are being modified to form \(c'\), it is possible to uniquely recover \(c\) from \(c'\) by using certain function \(f\) s.t. \(f(c') = c\). The procedure to
find the unique \( c \in C \) that satisfied \( \text{dis}(c, c') \leq t \) by using \( f \) is called as \textit{decoding}. A code \( C \) is said to be efficient if there exists a polynomial time algorithm for encoding and decoding. Sometime, we refer \([n, k, d]\) code \( C \) as \([n, k, t]\) code \( C \) if the error tolerance distance \( t \) is of interested rather than its minimum distance \( d \).

### 4 Main Idea

We here highlight some common notation to be used in this work, and a brief overview of our construction, focus on binary metric space.

**Notations:** Let \( \mathcal{M}_1 = \{0, 1\}^{k^*} \), and \( \mathcal{M}_2 = \{0, 1\}^n \) denote two different sizes of metric spaces where \( n > k^* \). The distance between different binary string \( w \) and \( w' \) denoted as \( \text{dis}(w, w') \) is the binary hamming distance (e.g., the number of disagree elements), i.e., \( \text{dis}(w, w') = \|w \oplus w'\| \) where \( \| \| \) is the hamming weight that count the number of non-zero elements, and \( \oplus \) is the addition modulo two operation (XOR). Besides, the error rate in between the input \( w, w' \in \mathcal{M}_1 \) is denoted as \( \|w \oplus w'\| (k^*)^{-1} \) which is simply their normalized hamming distance.

For error correction code notation, despite there existing a lot of error correction codes available in practice, due to the efficiency consideration, we used the commonly studied binary error correction code named as BCH code [13] with minimum distance \( d \geq 2t + 1 \) and efficient decoding algorithm \( f \) via algebraic method, i.e., syndrome decoding [13]. Our construction used two BCH codes. We called one of these as ‘inner’ code \( C_{\text{in}} \), and another one called the ‘outer’ code \( C_{\text{out}} \). Both of them are chosen to be BCH codes with parameter \([n^*, k^*, t^*]_2\) for \( C_{\text{in}} \) and \([n, k, t]_2 \) for \( C_{\text{out}} \), where \( k^* < n^* < k < n \) holds. We denote the tolerance rate of code \( C_{\text{in}} \) and \( C_{\text{out}} \) as \( \xi^* = t^*/n^* \) and \( \xi = t/n \) respectively.

**Overview Construction:** Suppose Alice wishes to conceal a noisy non-uniform string \( w \in \{0, 1\}^{k^*} \) while allows exact recovery of \( w \) by using another noisy string \( w' \in \{0, 1\}^{k^*} \) that is close to \( w \).

Firstly, Alice encodes \( w \) using the ‘inner’ code \( C_{\text{in}} \) to output a codeword \( c^* \). Then, \( c^* \) is used to generate a noisy string \( v^* \in \{0, 1\}^k \) with \( w \). Eventually, \( v^* \) is being encoded by the ‘outer’ code \( C_{\text{out}} \) to output the final codeword \( c \in C_{\text{out}} \). Alice then conceals \( c \) by generating a sketch \( ss = c \oplus \delta \) which is then made public and leaving the offset \( \delta \) in the clear. The offset \( \delta \) is characterized by a pair of resilient vectors \( \phi, \phi' \in \{0, 1\}^n \), which is generated from a pair of random noisy strings \( w'_e, w_e \in \{0, 1\}^{k^*} \), i.e., \( w_e = w \oplus e \) (with additional error vector \( e \)) through \( \Omega \) with public shared random string \( N \). The resilient vectors offer resilience for the recovery of \( w \) from \( w' \) if \( \|\delta\| \leq t \) and \( \|w \oplus w'\| \leq t^* \).

### 5 Resilient Vector: Properties and Generation

Since RV is a core element of our construction, we here provide details discussion on its properties and how it can be generated. The concept of RV is derived from Locality Sensitive Hashing (LSH) defined as below.
Locality Sensitive Hashing [14] Given that \( P_2 > P_1 \), while \( w, w' \in \mathcal{M} \), and \( \mathcal{H} = h_i : \mathcal{M} \rightarrow \mathcal{U} \), where \( \mathcal{U} \) refers to the output metric space (after hashing), which comes along with a similarity function \( S \), where \( i \) is the number of hash functions \( h_i \). A locality sensitive hashing can be viewed as a probability distribution over a family \( \mathcal{H} \) of hash functions follows

\[
P_{h \in \mathcal{H}}[h(w) = h(w')] = S(w, w').
\]

In particular, the similarity function \( S \) described the hashed collision probability in between \( w \) and \( w' \).

\[
P_{h \in \mathcal{H}}(h_i(w) = h_i(w')) \leq P_1 \quad \text{if} \quad S(w, w') < R_1
\]

\[
P_{h \in \mathcal{H}}(h_i(w) = h_i(w')) \geq P_2 \quad \text{if} \quad S(w, w') > R_2
\]

LSH transforms input \( w \) and \( w' \) to its output metric space \( U \) with property that ensuring similarity inputs render higher probability of collision over \( U \), and vice versa.

For RV generation, we only focus on a particular LSH family called hamming-hash [15]. The hamming hash is considered as one of the easiest ways to construct an LSH family by bit sampling technique.

Hamming hash strategy: Let \( [k^*] = \{1, \ldots, k^*\} \). For Alice with \( w \in \{0, 1\}^{k^*} \) and Bob with \( w' \in \{0, 1\}^{k^*} \). Alice and Bob agreed on this strategy as follow:

1. They are told to each other a common random integer \( N \in [k^*] \).
2. They separately output ‘0’ or ‘1’ depend upon their private string \( w \) and \( w' \), i.e., Alice output ‘1’ if the \( N \)-th bit of \( w \) is ‘1’, else output ‘0’.
3. They win if they got the same output, i.e., \( w(N) = w'(N) \).

Based on above strategy, we are interested in the probability for Alice and Bob outputting the same value. This probability can be described by a similarity function \( S(w, w') = P \) where \( P \in [0, 1] \).

**Theorem 1.** Hamming hash strategy is a LSH with similarity function \( S(w, w') = 1 - \|w \oplus w'\|(k^*)^{-1} \)

The hamming hash strategy can also be operated in between Alice and Bob in an non-interactive way. To do so, Alice and Bob simply repeat Step 1 and Step 2 for \( n \) number of times with a set of pre-shared random integers \( N = [N(1), N(2), \ldots, N(n)] \in [k^*]^n \). In the end, they can output a \( n \) bits string \( \phi \), and \( \phi' \) respectively over \( \{0, 1\}^n \), which we have earlier named as resilient vectors. We denote such non-interactive hamming-hash algorithm as \( \Omega : \mathcal{M}_1 \times [k^*]^n \rightarrow \mathcal{M}_2 \), which serves to sample the input binary string of size \( k^* \) into a longer binary string a.k.a resilient vector of size \( n > k^* \).

Given input \( w \in \{0, 1\}^{k^*} \), and \( N \in [k^*]^n \), the algorithm for \( \Omega : \mathcal{M}_1 \times [k^*]^n \rightarrow \mathcal{M}_2 \) can be described as follow:
Theorem 2. Suppose two resilient vectors $\phi, \phi' \in \{0,1\}^n$ are generated from $w, w' \in \{0,1\}^k$ respectively using hamming hash algorithm $\Omega$ with a random integer string $N \in [k^*]^n$. Then $E[\|\phi \oplus \phi'\|] = n\|w \oplus w'\|(k^*)^{-1}$.

Correlation Measure in RVs: Let $\Phi$ and $\Phi'$ be two random variables over $\{0,1\}^n$, and $W$ and $W'$ be two random variables over $\{0,1\}^k$. Given a resilience vector $\phi \in \Phi$ generated from $w \in W$ with random string $N$, it follows $\Phi$ must correlate with $W$ where the probability to look for any random variable $\Phi \in B_t(\phi')$ (also means similar resilience vector s.t. $\|\phi \oplus \phi'\| \leq t$) varies conditioned on either $W \not\in B_t'(w')$ or $W \in B_t'(w')$. Note that $W \in B_t'(w')$ implies the inputs $w \in W$ and $w' \in W'$ must similar within distance $t'$ (e.g. $\|w \oplus w'\| \leq t'$), while $W \in B_t'(w')$ means $\|w \oplus w'\| > t'$. Such correlation can be measured by using the conditional probability described as $Pr[\Phi \in B_t(\phi') | W \not\in B_t'(w')]$ or $Pr[\Phi \not\in B_t(\phi') | W \in B_t'(w')]$ respectively. In particular, we are more interested on the maximum correlation, which can be conveniently expressed by the conditioned maximum probability in looking for $\Phi \in B_t(\phi')$ given $W \not\in B_t'(w')$ defined as:

$$E_{w'^{-}\cdot \cdot W'}[\max_{\phi'} Pr[\Phi \in B_t(\phi') | W \not\in B_t'(w')]]$$

(1)

On the other hand, the conditioned minimum probability in looking for $\Phi \not\in B_t(\phi')$ given $W \in B_t'(w')$ is defined as:

$$E_{w'^{-}\cdot \cdot W'}[\min_{\phi'} Pr[\Phi \not\in B_t(\phi') | W \in B_t'(w')]]$$

(2)

6 Sketching

We denote the sketching algorithm that employs the hamming-hash algorithm, $\Omega$, an $[n^*, k^*, t^*]_2$ ‘inner’ code $C_{in}$ and an $[n, k, t]_2$ ‘outer’ code $C_{out}$ as $SS_{\Omega, C_{in}, C_{out}}$. The sketching algorithm $SS_{\Omega, C_{in}, C_{out}}$ with inputs $w, N$, and $\epsilon_{ss}$ is described as follow:

\begin{verbatim}
$\Omega(w, N)$
1:  $\phi \leftarrow \emptyset$
2:  for $i = 1, \ldots, n$ do
3:      $x = w(N(i))$ if $x$ is the $N(i)$-th bits of $w$
4:      $\phi = \phi \parallel x$
5:  endfor
6:  return $\phi$
\end{verbatim}
Secure Sketch for All Noisy Sources

Our sketching procedure consists of mainly two encoding steps. Given an input $w \in \{0, 1\}^{k^*}$, the first encoding stage used $C_{in}$ to encode $w$ to generate a codeword $c^* \in \{0, 1\}^{n^*}$. In principle, $c^*$ can be any random codeword over $C_{in}$, including the trivial codeword of all zeros i.e. $c^* = 0^{n^*}$. Then, we generate a noisy string $w_e$ and pad it with zeros in front to generate a longer bit string, which can be viewed as the syndrome vector denoted as $v_{syn} = c^* \oplus (0^{n^*-k^*} \| w_e)$. Clearly, $v_{syn}$ conceals $c^*$ by using $w_e$. The syndrome vector itself is also a codeword $v_{syn} \in C_{in}$. Then, the second encoding stage used $C_{out}$ to encode $v^* = 0^{k-n^*} \| v_{syn}$ to generate the final codeword $c$. The $0^{k-n^*}$ zeros in front is used to notify the recovery algorithm if the decoding is success. The final sketch is formed by hiding $c$ with RV generated from $w_e$.

For the realisation of the noisy string $w_e$, we parse additional error to the original input $w$ using a random error vector $e \in E_{ss}$ sampled from some random distribution $E_{ss}$. Such error distribution is parametrized by an error parameter $\epsilon_{ss} > 0$. To be specific, all error vector $e \in E_{ss}$ is of weight $\|e\| = [k^* \epsilon_{ss}]$, and the generation of the noisy string follows $w_e = w \oplus e$. The error vector $e$ is leaving in clear after it has being parsed into the input $w$ to form $w_e$.

All steps on $SS_\Omega,C_{in},C_{out}(w,N,\epsilon_{ss})$ can be done in $O(n^2)$, and the size of $ss$ is now depend upon the blocklength $n$ of the chosen ‘outer’ code $C_{out}$.

7 Recovery

We denote the recover algorithm that employed the hamming-hash algorithm, $\Omega$, an $[n^*, k^*, t^*]_2$ ‘inner’ code $C_{in}$ and an $[n, k, t]_2$ ‘outer’ code $C_{out}$ as $R_{ec}\Omega,C_{in},C_{out},f$. The recover algorithm $Rec_\Omega,C_{in},C_{out},f$ with inputs $ss$, $w'$, $N$, $\epsilon_{rec}$ to recover $w$ is described as follow:
Rec\(\Omega C_{in},C_{out},f(ss,w',N,\epsilon_{rec})\)

1: \(E_{rec} \leftarrow \{0,1\}^{k^*}\) // initiate \(E_{rec}\) with error parameter \(\epsilon_{rec}\)
2: for \(i = 1, \ldots, |\text{supp}(E_{rec})|\)
3: \(e'_i \leftarrow E_{rec}\) // sample \(e'_i\) differently at random, where \(\|e'_i\| = \lfloor k^* \epsilon_{rec} \rfloor\)
4: \(w'_e = w' \oplus e'_i\)
5: \(\phi'_i \leftarrow \Omega(w'_e, N)\)
6: \(c'_i = ss \oplus \phi'_i\) // also \(ss \oplus \phi'_i = c \oplus (\phi \oplus \phi'_i)\)
7: \(c \leftarrow f(c'_i)\) // first decoding
8: return \(v^* = C_{out}^{-1}(c)\)
9: if \(v^*[1], \ldots, v^*[k - n^*] = 0^{k - n^*}\) // first \(k - n^*\) bits of \(v^*\) are zeros
10: set \(v_{syn}\) as the last \(n^*\) elements of \(v^*\)
11: \(c^* = v_{syn} \oplus (0^{n^* - k^*} \| w'_e)\)
12: \(c^* \leftarrow f(c^*)\) // second decoding
13: return \(w = C_{in}^{-1}(c^*)\)
14: break
15: endif
16: endfor

Our proposal for the recovery algorithm consists of mainly two decoding processes, for decoding, we refer \(f\) be the syndrome decoding algorithm which operate in \(O\left((n^*)^t\right)\) and \(O(n^t)\) for \(C_{in}\) and \(C_{out}\) respectively. The first decoding process is designed to be iterative decoding uses \(C_{out}\) and \(f\) to output the codeword \(c\) from the sketch. It can be conveniently viewed as a brute-force decoding procedure of \(|\text{supp}(E_{rec})|\) trials with some distribution \(E_{rec}\), parametrized by another error parameter \(\epsilon_{rec} > 0\). Considering the general case where the person in recovering \(w\) may or may not know \(E_{ss}\), the error distribution introduced in the recovery phase is different compared to the error distribution used in sketching phase \((E_{ss})\). Therefore, the brute-force complexity for the first decoding is highly depends on the given error distribution \(E_{rec}\), where all error vector \(e' \in E_{rec}\) is of weight \(\|e'\| = \lfloor k^* \epsilon_{rec} \rfloor\). The main goal of the first decoding is to output the syndrome vector \(v_{syn}\). This can be done by examining the recovered vector \(v^* = 0^{k - n^*} \| v_{syn}\). If the first \(k - n^*\) bits of \(v^*\) are all zeros, the decoding is viewed as success and thus the recovery algorithm could proceed to the second decoding stage to recover \(c^*\) and so \(w\) from \(v_{syn}\) using \(C_{in}\).

The second decoding process is basically a generic BCH code decoding with \(f\). It decodes the corrupted syndrome vector \(v_{syn}\) (viewed as the corrupted codeword \(c^*\)) to output \(c^*\). The decoding itself must success if \(\|w_e \oplus w'_e\| \leq t^*\), thus \(w\) can be recovered from \(c^*\).
8 Distribution Hiding with Random Error Parsing

Recall that the recover algorithm $\text{Rec}_{C_{ss},C_{out},t}$ can be viewed as a brute-force decoding procedure of $|\text{supp}(E_{rec})|$ trials. We stress that such brute-force trial is necessary to show optimal security while allowing more errors to be tolerated. This is mainly because the input $w \in W_0$ could be under some random distribution $W_0$ over $\mathcal{M}_1$, yielding a random RV $\phi \in \Phi_0$ of random distribution $\Phi_0$ over $\mathcal{M}_2$. However, tolerating $t$ errors using an $[n,k,t]$ error correction code eventually reveal $W_0$. This is because the encoding process must ensure all random variable $W_0 \in B_i(w')$ can be tolerated by decoding function $f$, therefore, the encoding process must know $W_0$. Adding redundancy to $W_0$ inevitably introduce $t$ information loss, hence cannot show security to more error than entropy sources. Moreover, it is understood that potential attacker may have better computational power in modelling $W_0$, leading to better knowledge over $W_0$ and so higher entropy loss from $W_0$ is possible.

To resolve the above issue, a straightforward way is to hide $W_0$ before adding redundancy to it. This can be done by parsing an error randomly and uniformly chosen from a list $\{e_0,e_1,\ldots,e_{|\text{supp}(E_{ss})|}\} \in E_{ss}$ into the input string $w \in W_0$ during the sketching phase. Doing so will produce a list of possible noisy strings over different distributions $\{W_0,W_1,\ldots,W_{|\text{supp}(E_{ss})|}\} \in \mathcal{W}$ respectively. This list of noisy strings corresponds to a list of possible RVs in different distributions $\{\Phi_0,\Phi_1,\ldots,\Phi_{|\text{supp}(E_{ss})|}\} \in \Psi$. Remark here we have $W_0 \in \mathcal{W}$, and $\phi_0 \in \Psi$ referring to the trivial case when the error vector $e_0 \in E_{ss}$ is all zeros. This also means that the original distribution $W_0$ is now hidden over $\mathcal{W}$. Therefore, it is more appropriate to consider the family of distributions in $\mathcal{W}$ and $\Psi$ rather than single distribution $W_0$ and $\Phi_0$ over $\mathcal{M}_1$ and $\mathcal{M}_2$ respectively in deriving the security of the sketch. Based on above argument, compared to the generic BCH encoding procedure, our proposed sketching algorithm can be viewed as a more general encoding procedure by considering a more general case where the error parameter $\epsilon_{ss} \geq 0$ (or $\|e\| \geq 0$).

Because the sketch is generated by concealing the final codeword $c$ with an RV $\phi$. It follows that the best (worst-case) security of the sketch is manifested by the worst-case distribution over $\Psi$, where all points (or RVs) in this distribution are very close to each other. Suppose the worst-case distribution is $\Phi \in \Psi$, one shall use the min-entropy $H_{\infty}(\Phi)$ measurement to measure the entropy of such worst-case distribution. Arguing that the points in the worst-case distribution are most close to each other, it must offer highest probability of success in getting a similar RV within distance $t$. Compared to blindly modelling $\Psi$ to determine $\Phi$, it is relatively easier to measure its maximum probability of success in getting a similar RV within a maximum achievable distance $t \leq t_{\max}$ among all possible distributions $\{\Phi_0,\Phi_1,\ldots,\Phi_{|\text{supp}(E_{ss})|}\} \in \Psi$.

To do so, since $\Phi$ is conditioned on some random distribution $W \in \mathcal{W}$, it is necessary to first define a maximum tolerance distance $t_{(+)}$ over $W \in \mathcal{W}$ for sketching. The main intuition of doing this is to stimulate the worst-case scenario for $\phi$ with respect to the worst-case error measurement over $W$. Such worst-case error corresponds to the maximum tolerance distance which is defined as
Given similar RV $\phi \parallel \Psi$ family of distributions $W$ achieving tolerance distance of conditioned maximum probability in getting similar RV within a maximum characterized the worst-case security of RVs. Such security is measured in term of conditioned maximum probability to look for similar RV over $\Psi$ can be reduced to measuring the maximum correlation among all variables $\{\Phi_0, \Phi_1, \ldots, \Phi_{\text{supp}(\xi_0)}\} \in \Psi$ given $W \in W$ (see Eq. 1). The Corollary below characterized the worst-case security of RVs. Such security is measured in term of conditioned maximum probability in getting similar RV within a maximum achievable tolerance distance $t \leq t_{\text{max}}$ over $\Psi$ given any input distribution $W \in W$ and a noisy string $w' \in W'$ over some random distribution $W'_0 \in \{0, 1\}^{k*}$.

**Corollary 1.** Given $W \in W$, and a noisy string $w' \in W'_0$. For all RV over a family of distributions $\Psi$, the conditioned maximum probability to look for any similar RV $\phi$ in the worst-case distribution $\Phi \in B_t(\phi')$ over $\Psi$ (i.e. $\|\phi \odot \phi'\| = \|\delta\| \leq t$ for all $\phi \in \Phi$) when $W \notin B_{t(\phi')}(w')$ is measured to be

\[
\begin{align*}
&= \mathbb{E}_{w' \sim W'_0} \left[ \max_{\phi'} \Pr[\Phi \in B_t(\phi') \mid W \notin B_{t(\phi')}(w')] \right] \\
&= \max_{t = t_{\text{max}}} \Pr[\|\delta\| \leq t \mid \|w_c \odot w'\| \geq t_{(\phi')}] \leq \exp(-2n\epsilon_{ss}^2) \quad (3)
\end{align*}
\]

**Proof.** For $W \notin B_{t(\phi')}(w')$, it means the would have a noisy strings $w_c \in W$, where $\|w_c \odot w'\| \geq t_{(\phi')}$ or $\|w_c \odot w'\|(k*)^{-1} \geq \xi + \epsilon_{ss}$ must hold. Let denote $t(n) = n\xi$ be a function of $n$, it follows that $t(n) \leq (\|w_c \odot w'\|(k*)^{-1} - \epsilon_{ss})n$ can be yielded by multiplying both sides of the inequality with $n$. Clearly, the maximum value of $t(n)$ can be viewed as $t_{\text{max}} = (\|w_c \odot w'\|(k*)^{-1} - \epsilon_{ss})n$. Then the probability for $\|\delta\| \leq t_{\text{max}}$ given $\|w_c \odot w'\|(k*)^{-1} \geq \xi + \epsilon_{ss}$ can be computed by Hoeffding’s inequality follows the last line of Eq. 3.

By Corollary 1, the conditioned min-entropy of RV over $\Psi$ measured to be

\[
\tilde{H}_\infty(\Psi|W) = -\log \left( \mathbb{E}_{W \sim W} [\Pr[\Psi = \Phi \mid W = W]] \right) \\
= -\log \left( \mathbb{E}_{w' \sim W'} \left[ \max_{\phi'} \Pr[\Phi \in B_t(\phi') \mid W \notin B_{t(\phi')}(w')] \right] \right) \\
\geq \log(1/\exp(-2n\epsilon_{ss}^2)) \quad (4)
\]

9 Correctness with Regardless Computational Power

We are here to discuss the correctness of $\text{Rec}_{\Omega, \mathcal{C}_i, \mathcal{C}_{\text{out}}, t}$ in recovering $w$ from a sketch. specifically, such correctness characterizes the success rate of the recovery of $v_{\text{syn}}$ and so $w$ from a sketch generated by $\text{SS}_{\Omega, \mathcal{C}_i, \mathcal{C}_{\text{out}}}$. Noting that the
number of iterations (or computational power) requirement for \( \text{Rec}_\Omega, \mathcal{C}_{in}, \mathcal{C}_{out}, f \) is proportional to the value of \( |\supp(\mathcal{E}_{rec})| \), which is parametrized by \( \epsilon_{rec} \). In such a case, higher value of \( \epsilon_{rec} \) would result to higher number of \( |\supp(\mathcal{E}_{rec})| \), implying higher computational power requirement for \( \text{Rec}_\Omega, \mathcal{C}_{in}, \mathcal{C}_{out}, f \). Besides, the efficiency of the decoding algorithm \( f \) used for the given error correction code, i.e. \( \mathcal{C}_{in} \) and \( \mathcal{C}_{out} \) also plays an important rules in computing the final computational power requirement for \( \text{Rec}_\Omega, \mathcal{C}_{in}, \mathcal{C}_{out}, f \). Nonetheless, we here consider the correctness with negligible error without the consideration of the computational power requirement in running \( \text{Rec}_\Omega, \mathcal{C}_{in}, \mathcal{C}_{out}, f \). Formally, it can be expressed in Eq. 5 below with some negligible probability \( \beta > 0 \) for all \( \epsilon_{rec} > 0 \), regardless the efficiency of the decoding algorithm \( f \) itself.

\[
\Pr[\text{Rec}_\Omega, \mathcal{C}_{in}, \mathcal{C}_{out}, f(\mathcal{S} \mathcal{S}_0, \mathcal{C}_{in}, \mathcal{C}_{out}(w, N, \epsilon_{ss}), w', N, \epsilon_{rec}) = w] = 1 - \beta. \tag{5}
\]

To attain such correctness claim (without considering the computational power), it is desired to show that the probability of success in recovering \( w \) is at least \( 1 - \beta \). In viewed of this, the maximum value of \( \beta \) have to be computed, which is indeed referring to the maximum error in recovering \( w \) from a sketch with \( \text{Rec}_\Omega, \mathcal{C}_{in}, \mathcal{C}_{out}, f \).

Suppose a sketch \( \mathcal{S} \mathcal{S} \) generated through \( \mathcal{S} \mathcal{S}_0, \mathcal{C}_{in}, \mathcal{C}_{out}(w, N, \epsilon_{ss}) = \mathcal{S} \mathcal{S} \), where \( \mathcal{S} \mathcal{S} \in \mathcal{S} \mathcal{S} \) under some random distribution \( \mathcal{S} \mathcal{S} \) over \( \mathcal{M}_2 \). Since the total number of possible RVs generated from the input \( w \) (with random string \( N \)) implies the total number of possible sketches, therefore, all RVs over the family of distributions \( \{\Phi_0, \Phi_1, \ldots, \Phi_{|\supp(\mathcal{E}_{ss})|}\} \in \Psi \) will yield different sketches in different distributions \( \{\mathcal{S} \mathcal{S}_0, \mathcal{S} \mathcal{S}_1, \ldots, \mathcal{S} \mathcal{S}_{|\supp(\mathcal{E}_{ss})|}\} \in \mathcal{S} \) as well. In such a case, the error (in term of probability) to recover \( w \) from a sketch \( \mathcal{S} \mathcal{S} \in \mathcal{S} \) reduced to the error to look for a random variable \( \mathcal{S} \mathcal{S} \) over family of distributions \( \mathcal{S} \), where the RV pair \( (\phi, \phi') \) used for sketching and recovery is in distinct, (i.e., \( \|\phi \oplus \phi'\| = \|\delta\| \geq t \)). Therefore, to maximize such error for maximum value of \( \beta \), the optimal distribution in \( \Psi \), where all points (or RVs) in such distribution are farthest away to each other needs to be identified. Suppose the optimal distribution is \( \Phi \in \Psi \), since the points in \( \Phi \) is farthest to each other, it should correspond to the highest probability in looking for a distinct RV. Because \( \{\Phi_0, \Phi_1, \ldots, \Phi_{|\supp(\mathcal{E}_{ss})|}\} \in \Psi \) are conditioned on some random distribution \( W \in \mathcal{W} \), likewise the way in determining the worst-case distribution from \( \Psi \) (refer to last section), one shall first define another minimum tolerance distance \( t_{(-)} = \lceil(\xi - \epsilon_{ss})k^* \rceil \) over \( W \in \mathcal{W} \) for sketching. As an important remark, for \( t_{(-)} \) to be minimum given \( \mathcal{C}_{in} \) and \( \mathcal{C}_{out} \), one needs \( t_{(-)} \leq t^* < t \) to hold as well. The following Corollary revealing \( \beta \leq \exp(-2n\epsilon_{ss}^2) \).

**Corollary 2.** Given \( W \in \mathcal{W} \), and a noisy string \( w' \in W_0 \). For all RV over a family of distributions \( \Psi \), the conditioned maximum probability to look for any distinct RV \( \phi \) in optimal distribution \( \Phi \not\in B_t(\phi') \) over \( \Psi \) (i.e., \( \|\phi \oplus \phi'\| = \|\delta\| \geq t \)
for all $\phi \in \Phi$ when $W \in B_{t_{(-)}}(w')$ is measured to be

$$
E_{w' \sim W_0} \left[ \max_{\phi' \neq \phi} \Pr[\Phi \notin B_t(\phi') \mid W \in B_{t_{(-)}}(w')] \right]
= \max_{t \leq t_{\min}} \Pr[\|\delta\| \geq t \mid \|w_e + w'\| \leq t_{(-)}] \leq \exp(-2n\epsilon_{ss}^2).
$$

Proof. For $W \in B_{t_{(-)}}(w')$, it means that there would have one noisy string $w_e \in \mathcal{W}$, where $\|w_e + w'\| \leq t_{(-)}$, or $\|w_e + w'\|(k^*)^{-1} \leq \xi - \epsilon_{ss}$ must hold. Let denote $t(n) = n\xi$ be a function of $n$, it follows that $n\|w_e + w'\|(k^*)^{-1} \leq n\xi - n\epsilon_{ss}$ can be yielded by multiplying both sides of the inequality with $n$. Clearly, the minimum value of $t(n)$ can be viewed as $t_{\min} = (\|w_e + w'\|(k^*)^{-1} + \epsilon_{ss})n$. The probability for $\|\delta\| \geq t_{\min}$ given $\|w_e + w'\|(k^*)^{-1} \leq \xi - \epsilon_{ss}$ can be computed by Hoeffding’s inequality follows the last line of Eq. 6.

The following Proposition can be obtained by comparing Eq. 5 and Eq. 6.

**Proposition 1.** For all $\epsilon_{rec} > 0$, $\epsilon_{ss} > 0$, and $\|w_e + w'\| \leq t_{(-)} \leq t^*$,

$$
\Pr[\text{Rec}^\Omega,\mathcal{C}_{in},\mathcal{C}_{out}.f(\mathcal{S}^\Omega,\mathcal{C}_{in}.c_{out}(w, N, \epsilon_{ss}), w', N, \epsilon_{rec}) = w]
\geq 1 - \exp(-2n\epsilon_{ss}^2).
$$

Proposition 1 concluded given an error parameter $\epsilon_{ss} > 0$. For all $\epsilon_{rec} > 0$, the success rate for $\text{Rec}^\Omega,\mathcal{C}_{in},\mathcal{C}_{out}.f$ in recovering $w$ is at least $1 - \exp(-2n\epsilon_{ss}^2)$ if $\|w_e + w'\| \leq t_{(-)} \leq t^*$. This resultant probability is overwhelming when $n$ is sufficiently large without considering the computational power in running $\text{Rec}^\Omega,\mathcal{C}_{in},\mathcal{C}_{out}.f$.

### 10 Correctness with Regard to Computational Power: The NP-Complete Problem

In general, without considering the computational power in running $\text{Rec}^\Omega,\mathcal{C}_{in},\mathcal{C}_{out}.f$, the claim of correctness in Proposition 1 demonstrating at most $t_{(-)} \leq t^*$ of errors (or error rate of $\xi - \epsilon_{ss}$) can be tolerated over $W \in \mathcal{W}$, which applied to any input distribution $W_0 \in \{0,1\}^k$. In this section, we will show that given one has set the value of $\epsilon_{rec}$ of sufficiently large, i.e., $\epsilon_{rec} \geq 2\epsilon_{ss}$, and $\text{Rec}^\Omega,\mathcal{C}_{in},\mathcal{C}_{out}.f$ is allowed to run in $|\text{supp}(\mathcal{C}_{rec})|$ number of iterations, one can actually tolerate higher error rate, arbitrary close to one.

Our main intuition is to tolerate $t_{(+)} > t_{(-)}$ number of errors. To do so, for any error described as the distance $\|w_e + w'\| \leq t_{(+)}$, or the error rate is $\|w_e + w'\|(k^*)^{-1} \leq \xi + \epsilon_{ss}$. By introducing an error parameter $\epsilon_{rec}$ of higher value compared to $\epsilon_{ss}$, e.g., $\epsilon_{rec} \geq 2\epsilon_{ss}$, the final worst-case error rate can be described as $\|w_e + w'\|(k^*)^{-1} \leq \xi + \epsilon_{ss} + \epsilon_{rec}$. Viewed this way, any error rate of $\|w_e + w'\|(k^*)^{-1} \leq \xi + \epsilon_{ss}$ is possible to be reduced down to $\|w_e + w'\|(k^*)^{-1} \leq \xi - \epsilon_{ss}$ given high enough $\epsilon_{rec}$ during recovery. Eventually, the remaining errors $\|w_e + w'\| \leq t_{(-)}$ can be tolerated with overwhelming probability by Proposition 1.
To make the idea more explicit, suppose one knows the value of $\epsilon_{ss}$, he/she can simply choose a minimum $\epsilon_{rec} = 2\epsilon_{ss}$ during recovery, this would allow him/her to produce another list of possible error vectors $\{e'_0, \ldots, e'_{|\text{supp}(E_{rec})|}\} \in E_{rec}$, which would yield a list of possible noisy string $w'_e \in W'_0$ over another family of distributions $W'$, s.t. $\{W'_0, \ldots, W'_{|\text{supp}(E_{rec})|}\} \in W'$. Here the trivial case $\epsilon_{rec} = \epsilon_{ss} = 0$ (or $|e'_0| = 0$) applied to the original input distribution $W'_0 \in W'$. To look for the non-trivial solutions for $e' \in E_{rec}$, one shall have $\text{Rec}_{C_{in}, \epsilon_{out}, f}$ running in $|\text{supp}(E_{rec})|$ iterations to try all possible $\{e'_1, \ldots, e'_{|\text{supp}(E_{rec})|}\} \in E_{rec}$ until he/she found such noisy string $w'_e$, s.t. $\|w_e \oplus w'_e\| \leq t_{(-)}$ holds. Let $d' = \lceil \xi k^* \rceil$. Suppose the original distance $\|w \oplus w'\| \leq d'$ (when $\epsilon_{ss} = 0$). Parsing an error $e \in E_{ss}$ of weight $\lceil k^* \epsilon_{ss} \rceil$ to the input $w \in W_0$ yields $w_e$. It follows there should be a resultant case where

$$\|w_e \oplus w'\| = \|w \oplus w'\| \pm \lceil k^* \epsilon_{ss} \rceil \leq d' \pm \lceil k^* \epsilon_{ss} \rceil$$

Note that when $\|w_e \oplus w'\| \leq t_{(-)} = d' - \lceil k^* \epsilon_{ss} \rceil$ (refers to ‘-’ sign), such errors is trivial which can be tolerated by means of $C_{in}$ since $t_{(-)} \leq t^*$. For nontrivial case when $t_{(+)} = d' + \lceil k^* \epsilon_{ss} \rceil$ (refers to the ‘+’ sign), one has to trial all $e' \in E_{rec}$ of weight $\lceil 2k^* \epsilon_{ss} \rceil$. It follows that there must have at least one solution for $e'$ s.t.

$$\|w_e \oplus w'_e\| = \|(w \oplus e) \oplus (w' \oplus e')\| = \|(w \oplus w') \oplus (e \oplus e')\| \leq d' + \lceil k^* \epsilon_{ss} \rceil \pm \lceil 2k^* \epsilon_{ss} \rceil \leq d' - \lceil k^* \epsilon_{ss} \rceil = t_{(-)} \quad (7)$$

Doing so means one needs to find the nontrivial error vector $e' \in E_{rec}$ using error parameter $\epsilon_{rec}$ s.t. the distance $\|w_e \oplus w'_e\| \leq t_{(-)} \leq t^*$ holds by minimum. Once such error vector is found, the remaining errors $t_{(-)}$ can be tolerated via generic BCH code decoding using $C_{in}$ comes across with error tolerance distance $t^* \geq t_{(-)}$. To look for such nontrivial error vector using a typical deterministic computer machine (i.e., Turing machine), the value of $\epsilon_{ss}$ used in the sketching phase have to be known by the recovery algorithm. Even so, only with the knowledge of $\epsilon_{ss}$, there is no short-cut or direct way rather than brute-forcing for such $e'$. Therefore, we shall see that to tolerate more error (more than $t_{(-)}$), it is inevitable that ones have to deal with the issue of computational power in running $\text{Rec}_{C_{in}, \epsilon_{out}, f}$, where the knowledge on the chosen error parameter $\epsilon_{ss}$ during sketching phase is necessary.

Given $\epsilon_{ss} \in [(2k^*)^{-1}, 1/4]$, with minimum $\epsilon_{rec} = 2\epsilon_{ss}$, one can use Stirling approximation to compute minimum value for $|\text{supp}(E_{rec})|$: 

$$|\text{supp}(E_{rec})| = \left[ \frac{k^*}{2k^* \epsilon_{ss}} \right] \leq 2^\lceil k^* h_2(2\epsilon_{ss}) \rceil$$

where $h_2(x) = -x \log(x) - (1-x) \log(1-x)$ is the binary entropy function with input error rate of $x$.

Taking into consideration that one could also run the recovery algorithm in parallel with different value of $\epsilon$ using several computation machines (i.e., non-deterministic Turing machine), the brute-force complexity should be bounded by
the order of $O(2^{k^* h_2(2\varepsilon_{ss})})$. This result implies after $2^{k^* h_2(2\varepsilon_{ss})}$ number of iterations, we shall have $\text{Rec}_\Omega, \mathcal{C}_{in}, \mathcal{C}_{out, t}$ to recover $w$ successfully with overwhelming probability for both deterministic and non-deterministic Turing machine.

Follows Eq. 7 (second line), viewing that meaningful correctness can only be shown for any errors in term of distance $||w_c \oplus w_{c'}|| \leq t(-)$ which is positive. To make sure $t(-) \geq 0$ always hold for nontrivial error, one shall consider $d' \geq [k^*\varepsilon_{ss}]$, hence $||w_c \oplus w_{c'}|| = d' + [k^*\varepsilon_{ss}] - [2k^*\varepsilon_{ss}] = t(-) \geq 0$ must follow by minimum. Therefore, the permissible minimum distance in our construction should be described as

$$||w \oplus w'|| \geq d' = [k^*\varepsilon_{ss}].$$

(9)

Based on above reasoning, recall that $\varepsilon_{ss} \leq \max\{\xi^*, \xi\}$ is bounded by the maximum tolerance rate among $\mathcal{C}_{in}$ and $\mathcal{C}_{out}$ in practice. Choosing a BCH code $\mathcal{C}_{out}$ with tolerance rate $\xi < 1/4$ arbitrary close to $1/4$ (maximum achievable rate by Plotkin bound) allows one to tolerate at most

$$t(+) = d' + [k^*\varepsilon_{ss}] = [2k\varepsilon_{ss}] \leq k^*/2,$$

(10) number of errors, and achieving error tolerance rate of arbitrary close to $2\varepsilon_{ss} \leq 2\xi < 1/2$ by using algorithm pair $(\mathcal{S}\mathcal{S}_{\Omega, \mathcal{C}_{in}, \mathcal{C}_{out}}, \text{Rec}_\Omega, \mathcal{C}_{in}, \mathcal{C}_{out, t})$.

### 10.1 Relaxation to Polynomial Time Recovery

Nonetheless, Eq. 8 suggesting exponential computation time in the input size $k^*$ with $\varepsilon_{rec} = 2\varepsilon_{ss}$, which is highly inefficient for large $k^*$. This result is not suprised because looking for such nontrivial vector, which viewed as the minimum-weight solution to Eq. 7 is in fact an NP-complete problem [16], also commonly refer to the maximum likelihood decoding problem for a linear code [17]. More precisely, its corresponding decision problem can be formalised as follow:

**Problem:** Maximum likelihood decoding

**Instance:** A $\alpha \times n$ binary matrix $H$, a vector $y \in \mathbb{F}_2^n$, and integer $z > 0$

**Question:** Is there a vector $x \in \mathbb{F}_2^n$ of weight $\leq z$, such that $Hx = y$

Clearly, the answer for above question would be ‘yes’ if one able to find $x$, which can be viewed as the solution for $c' \in \mathcal{E}_{rec}$ where Eq. 7 holds. More explicitly, let $H$ be the parity check matrix of $\mathcal{C}_{out}$, so $\alpha = n - k$. Note that $Hc \Leftrightarrow \text{syn}(c) = 0^\alpha$, where $\text{syn}(c)$ is the syndrome of the encoded codeword $c \in \mathcal{C}_{out}$. Given the corrupted codeword $c'$, the RV $\phi'$ and $H$, the syndrome decoding algorithm $f$ computes

$$f(c') = H \cdot (c \oplus (\phi' \oplus \phi)) = Hc \oplus H\delta = 0^\alpha \oplus \text{syn}(\delta) = \text{syn}(\delta)$$

yields the syndrome of $\delta$. Given the distance $||\phi \oplus \phi'|| = ||\delta||$ is small, i.e., $||\delta|| \leq t$, knowing $\text{syn}(\delta)$ is enough to determine the offset $\delta$, which can be done via $f$ in $\text{poly}(n)$ running time. Treating $x = \delta$, follows the constrains of $||\delta|| \leq t$. $\delta$,
the hardness of looking for $\delta$ (of size $n$) is as hard as the above mentioned
decision problem related to the maximum likelihood decoding. Nevertheless, the
results in Section 9 showed that if one able to find an error vector (during
recovery) $e' \in E_{rec}$ s.t. $\|w_e \oplus w_e'\| \leq t_{(\cdot)} \leq t^*$ holds, then $\|\delta\| \leq t$ can be
achieved with probability at least $1 - \exp(-2n\epsilon_{ss})$ follows Proposition 1, hence
the answer for the above question is immediate. This show a reduction on the
above NP-complete problem to look for $e'$ (of size $k^*$) over $E_{rec}$. In viewed of this,
efficient searching process for $e'$ immediately implies efficient maximum
likelihood decoding algorithm, hence resolve the NP-complete problem discussed
above in an efficient manner.

Based on above argument, since $k^* < n$, it is convenient to use $n$ as upper
bound and define $\text{Rec}_{\alpha,C_{in},C_{out},f}$ to be efficient if it can run in polynomial time
poly$(n)$ in the input sketch size $n$ to show correctness.

As both decoding stages use syndrome decoding algorithm which operates
in $O\left((n^*)^2\right)$ and $O(n^t)$ for $C_{in} \in \{0,1\}^n$ and $C_{out} \in \{0,1\}^n$ respectively. It
is clearly shown that every decoding step performed in $\text{Rec}_{\alpha,C_{in},C_{out},f}$ is efficient
in polynomial time poly$(n)$. Nonetheless, such efficient claim for $f$ only holds if
$\|\delta\| \leq t$. Therefore it is reasonable to say that the efficiency of $f$ depends on the
correctness (regardless computational power) of $\text{Rec}_{\alpha,C_{in},C_{out},f}$ which referring
to the derived value $\beta \leq \exp(-2n\epsilon_{ss}^2)$. It is not difficult to see that the value
of $\beta$ is in fact closely tied to the numbers of zeros padding to the syndrome
vector $v_{syn}$ to form $v^* = 0^{k^* - n^*}\|v_{syn}$ (see Step 5 of $SS_{\alpha,C_{in},C_{out}}$). This is because
$\text{Rec}_{\alpha,C_{in},C_{out},f}$ will only proceed to the second decoding if the first decoding return
$v^*$ with the first $k^* - n^*$ bits are all zeros. Eventually, the second decoding must
success in recovering $w$ with probability at least $1 - \beta$ given $\|w_e \oplus w_e'\| \leq t_{(\cdot)}$.
Due to the selection of $e' \in E_{rec}$ is random, every iteration of the first decoding
should return a random codeword $c \in C_{out}$, hence its first $k^* - n^*$ bits are random
over $\{0,1\}^{k^* - n^*}$. In viewed of this, we could have $\beta = 2^{-(k^* - n^*)}$ of probability for
the first $k^* - n^*$ bits are all zeros, which implies the second decoding shall success
with probability $1 - 2^{-(k^* - n^*)}$ revealed by the number of zeros padding to the
syndrome vector. However, for such argument to hold, one needs to ensure

$$\beta \leq \exp(-2n\epsilon_{ss}^2) \leq 2^{-(k^* - n^*)},$$

(11)

which shall give us the tighter upper bound of error rate measured as $2^{-(k^* - n^*)}$
compared to Eq. 6. As we shall see, Eq. 11 can be achieved easily with sufficient
large value of $n$ for a given $\epsilon_{ss}$, $n^*$ and $k$.

In such a case, the dependency of our correctness derived previously in Section
9 reduced to the number of zeros padding in the sketching phase, measured
as $k - n^*$. Noting that such reduction is computational. It depends upon the
construction itself, where the selection of the error correction codes $C_{in}$ and
$C_{out}$ (given $\epsilon_{ss}$) with parameters $[n^*,k^*,t^*]$ and $[n,k,t]$ respectively is viewed
as an important factor for efficiency claim. In particular, under the designation
of an BCH code [13] used in our construction for $C_{in}$ and $C_{out}$, its correctness
is defined using some positive integer $m' \geq 3$. Given the value of tolerance
distance $t < 2^{m'-1}$, we can construct an $[n,k,t]$ BCH code $C_{out}$ with parameters
\[ n = 2^{m'} - 1, \ n - k \leq m't \ \text{and minimum distance} \ d \geq 2t - 1 \ \text{(something applied to} \ C_{in}) \]. With such reasoning, follows Eq. 11, for sufficiently large \( n \), we shall have the derived value for \( m' \):

\[
m' = \left\lfloor \log(1/ \exp(-2n^2_{ss})) \right\rfloor \geq 3 = k - n^*
\]

Above statement also prove the existence of BCH codes for \( C_{out} \) and \( C_{in} \) in our construction with efficient syndrome decoding algorithm \( f \) only if Eq. 11 holds, i.e., at least three zeros padding to \( v_{syn} \).

With the efficient decoding claim by Eq. 12, the efficiency of \( \text{Rec}_{\Omega, C_{in}, C_{out}, f} \) thus reduced to the brute-force complexity itself, which is proportional to the value of \( |\text{supp}(\mathcal{E}_{rec})| \). Follows Eq. 8 and Eq. 12, if one properly choose \( C_{in} \) and \( C_{out} \) s.t. \( [k^*h_2(2\epsilon_{ss})] \leq k - n^* \), such complexity can be bounded in term of the sketch size \( n \) described as:

\[
|\text{supp}(\mathcal{E}_{rec})| \leq 2^{[k^*h_2(2\epsilon_{ss})]} \leq 2^{(k-n^*)} = 2^m = n + 1
\]

Expressing so would allow us to relax the number of iteration for \( \text{Rec}_{\Omega, C_{in}, C_{out}, f} \) from exponential time in \( k^* \) to linear time in \( n \). In particular, since the syndrome decoding for both decoding stages operate in \( \mathcal{O}(n^t) \), the remaining steps on \( \text{Rec}_{\Omega, C_{in}, C_{out}, f} \) are operate in \( \mathcal{O}(n^{k^*}) \). Therefore the overall recovery complexity is in \( \text{poly}(n) \).

Remark that above complexity is derived given one has the knowledge of \( \epsilon_{ss} \) and running \( \text{Rec}_{\Omega, C_{in}, C_{out}, f} \) with a deterministic Turing machine. In such a case, \( \epsilon_{ss} \) can be viewed as an special information required for \( \text{Rec}_{\Omega, C_{in}, C_{out}, f} \) to run in \( \text{poly}(n) \) deterministically. By Eq. 9, 10, 12, and 13, we can formalise the following Proposition to characterize the correctness of \( \text{Rec}_{\Omega, C_{in}, C_{out}, f} \) for higher error rate \( \xi + \epsilon_{ss} \) in efficient manner.

**Proposition 2.** For both \( C_{in} \in \{0,1\}^{k^*} \) and \( C_{out} \in \{0,1\}^n \) are BCH codes with syndrome decoding algorithm \( f \), Given \( \epsilon_{ss} \in [(2k^*)^{-1}, \xi] \), and \( \epsilon_{rec} = 2\epsilon_{ss} \), where the following hold (for \( t(+) = \lceil (\xi + \epsilon_{ss})k^* \rceil \), \( \xi = t/n \)):

1. \( \|w \oplus w'\| \geq \lceil k^* \epsilon_{ss} \rceil \)
2. \( \left\lfloor \log(1/ \exp(-2n^2_{ss})) \right\rfloor \geq 3 \)
3. \( [k^*h_2(2\epsilon_{ss})] \leq k - n^* \)

Then, \( \Pr[\text{Rec}_{\Omega, C_{in}, C_{out}, f}(SS_{\Omega, C_{in}, C_{out}}(w, N, \epsilon_{ss}), w', N, \epsilon_{rec}) = w] \geq 0.875 \) can be achieved efficiently operating in time \( \text{poly}(n) \) and the maximum achievable error tolerance rate is \( 2\xi < 1/2 \).

The results in Proposition 2 have also suggested the NP-complete problem mentioned in [16] can be solved in polynomial time by using algorithm pair \( \langle SS_{\Omega, C_{in}, C_{out}}, \text{Rec}_{\Omega, C_{in}, C_{out}, f} \rangle \) running with a deterministic Turing machine. Follows the work in [18] stated, if any NP-complete problem possesses a polynomial time algorithm to solve, then so does every NP-problem, and hence we shall have \( \text{P=NP} \).
11 Security

Based on the previous discussion, we learned that for some input variable \( W_0 \in \mathcal{M}_1 \), rather than deal with the entire metric space \( \mathcal{M}_1 \) of size \( 2^k \), sketching with \( \text{SS}_{\Omega, \mathcal{C}_{in}, \mathcal{C}_{out}} \) is able to reduce our focus to a family of distribution \( \mathcal{W} \) (by random errors parsing), where \( W_0 \in \mathcal{W} \) is concealed under such family of distributions over \( \mathcal{M}_1 \). To show security for \( \text{SS}_{\Omega, \mathcal{C}_{in}, \mathcal{C}_{out}} \). Recall that given the knowledge of \( \epsilon_{ss} \), one could set \( \epsilon_{rec} = 2\epsilon_{ss} \), and tolerate at most \( \|w_e \oplus w'\| \leq t_{(+)} \) number of error efficiently by running \( \text{Rec}_{\Omega, \mathcal{C}_{in}, \mathcal{C}_{out}, t} \) with a deterministic Turing machine (see Proposition 2). Therefore, for any adversary knowing \( \epsilon_{ss} \), he/she should be able to look for any variable \( W \in B_{t_{(+)}(w')} \) efficiently by modelling \( \mathcal{W}' \) with error parameter \( \epsilon_{rec} > 0 \) by the correctness of the recovery algorithm itself. In such a case, rather than define its security of \( \text{SS}_{\Omega, \mathcal{C}_{in}, \mathcal{C}_{out}} \) in term of the hardness in looking for the encoded string \( w \in W_0 \), it is more appropriate to define it as the hardness in looking for a variable \( W \in \mathcal{W} \) satisfies \( W \in B_{t_{(+)}(w')} \).

Based on the Eq. 12, the minimum information to show correctness using \( \text{Rec}_{\Omega, \mathcal{C}_{in}, \mathcal{C}_{out}, t} \) (efficiently) could be expressed as the number of zeros padding to \( v_{\text{syn}} \), which is \( k - n^* \). Therefore, above statement explained any adversary should be able to gain certain minimum information due to the zeros padding. This minimum information leakage is independent of how liberal or conservative is the selection of the input string \( w \). Rather, it is a limit (lower bound), which required to be set in before constructing any error tolerance system, to satisfy certain minimum requirement of correctness with proper selection of \( \mathcal{C}_{in}, \mathcal{C}_{out} \) and \( \epsilon_{ss} \). Formally, follows Eq. 4 and Eq. 12, such minimum information leakage can be used to express the conditioned min-entropy of RV:

\[
\tilde{H}_\infty(\Psi|\mathcal{W}) \geq \left\lfloor \log(1/\exp(-2n\epsilon_{ss}^2)) \right\rfloor = k - n^* = m' \geq 3.
\]

However, merely consider the minimum information leakage is not sufficient to attain strong security claim. This is because one have to consider also the correlation in between different distributions or among different family of distributions. In such a case, the input \( w \) could also be found in some random distribution \( I \in \mathcal{I} \) over other family of distributions \( \mathcal{I} \), apart from \( \mathcal{W}' \). This also can be argued with the adversary may have better computational power in modelling \( \mathcal{W}' \) using another family of distributions \( \mathcal{I} \), leading to higher entropy loss from \( \mathcal{W} \) compared to the minimum entropy loss derived in Eq. 14. In light of this, it is good to go into the deeper analysis on how well is \( \mathcal{W} \) being concealed over \( \mathcal{M}_1 \), given the additional information derived from \( \mathcal{I} \). This question can also be interpreted as how well is the syndrome vector \( v_{\text{syn}} \in W \) is hidden over \( \mathcal{W} \) given some random distribution \( I \in \mathcal{I} \) while sketching with \( \text{SS}_{\Omega, \mathcal{C}_{in}, \mathcal{C}_{out}} \).

Since \( \text{SS}_{\Omega, \mathcal{C}_{in}, \mathcal{C}_{out}} \) accepts any random codeword \( c^* \), included the trivial case when \( c^* = 0^n \) is all zeros. The answer for the above question should cover the minimum entropy of \( W \) s.t. \( H_\infty(W) \geq m \) for some integer \( m \geq 0 \). Because the error parsing process is random, hiding \( W \) over \( \mathcal{W} \) of size \( |\mathcal{W}| = |\text{supp}(\mathcal{E}_{ss})| \) would add entropy to it. The resultant entropy can be expressed as the min-entropy of
\[ W: \]
\[ H_\infty(W) = H_\infty(W; \mathcal{E}_{ss}) \geq H_\infty(W) + |\log(\text{supp}(\mathcal{E}_{ss}))| = m + [k^* h_2(\epsilon_{ss})] \tag{15} \]

Considering the entropy loss due to the zero bits padding to the syndrome vector \( v_{\text{syn}} \) to form \( v^* = 0^{k-n^*}\parallel v_{\text{syn}} \). It must leak information with any string in some distribution \( I \in \mathcal{I} \) over \( \{0,1\}^{k-n^*} \) by simply XOR operation with the first \( k-n^* \) bits of \( v^* \). This can be done with the help of the integer vector \( N \) used for hamming hash, lead to higher entropy loss from the input source. Recall such zeros padding stage is necessary for \( \text{Rec}_{f, \mathcal{I}_n, \mathcal{C}_{out}, f} \) to be notified when the first decoding is success, which means \( v_{\text{syn}} \in W \) is revealed from \( W \). Since \( v^* \in W \) simply follows the distribution of the syndrome vector, therefore it can also be interpreted in such a way that certain understanding over \( W \) is necessary for our derived correctness (in Proposition 1) to hold. We refer such scenario as the distribution precision. Padding more zeros means higher distribution precision over \( W \), thus \( \text{Rec}_{f, \mathcal{I}_n, \mathcal{C}_{out}, f} \) can be well-notified that the first decoding stage is succeed. Our construction has perfectly captured such distribution precision notion, measured in term of the entropy loss proportional to the number of zeros padding to the syndrome vector \( v_{\text{syn}} \). To be specific, it can be expressed as \( m' = k - n^* \geq 3 \) (see Eq. 11). In such a case, the conditioned min-entropy of \( W \) given \( \mathcal{I} \) can be described by using Eq. 15 as:

\[ \bar{H}_\infty(W|\mathcal{I}) = H_\infty(W, \mathcal{E}_{ss}|\mathcal{I}) \geq m + [k^* h_2(\epsilon_{ss})] - (k - n^*) \tag{16} \]

Since the min-entropy of \( W \) is at least \( m \), straightforwardly, the worst-case entropy loss due to the zeros bit padding is at most \( m \). This means if \( k - n^* \geq m \), the source is considered has loss all the entropy. This also implies when worst comes to the worst, there could have such a powerful attacker with unlimited computational power that can reveal \( W \) precisely by using some random string in the worst-case distribution \( I \in \mathcal{I} \) over \( \{0,1\}^{k-n^*} \). Based on this, the security of \( \text{SS}_{f, \mathcal{I}_n, \mathcal{C}_{out}} \) can be measured in term of the conditioned min-entropy with the worst-case distribution \( I \in \mathcal{I} \) described as below (say \( H(X) \) is the Shannon entropy of distribution \( X \)):

\[ \bar{H}_\infty(W|\mathcal{I}) \geq \bar{H}_\infty(W, \mathcal{E}_{ss}|\mathcal{I} = I) \geq [k^* h_2(\epsilon_{ss})] \geq H(\mathcal{E}_{ss}) \tag{17} \]

Refer to Eq. 15 and 17, under the worst-case when all input entropy is loss, the conditioned min-entropy of \( W \) is at least the Shannon entropy over binary channel of rate \( \epsilon_{ss} \), i.e., \( H(\mathcal{E}_{ss}) = k^* h_2(\epsilon_{ss}) \). Such minimum entropy characterized the worst-case security of \( \text{SS}_{f, \mathcal{I}_n, \mathcal{C}_{out}} \) even for computationally unbounded attacker in modelling the family of distribution \( W \) with \( I \in \mathcal{I} \) over \( \{0,1\}^{k-n^*} \).

Based on the correctness discussed in Proposition 2, and the security reasoning follows Eq. 15, 16 and 17, the Proposition below is formalised to characterize our construction as a standard secure sketch.

**Proposition 3.** Given some integer \( m_c > 0 \). For any error distribution \( \mathcal{E}_{ss} \) with entropy \( H(\mathcal{E}_{ss}) \geq m_c \), then algorithm pair \( \langle \text{SS}_{f, \mathcal{I}_n, \mathcal{C}_{out}}, \text{Rec}_{f, \mathcal{I}_n, \mathcal{C}_{out}, f} \rangle \) is an efficient \( (\mathcal{M}_2, m, m_c, t(\epsilon)) \)-secure sketch.
Table 1 below depicted the security bound (upper bound min-entropy requirement) for existing secure sketch construction.

Table 1: Summary of security bound of existing secure sketch in term of fuzzy-min entropy and min-entropy.

Obviously, compared to the computational secure sketch construction where its security property only holds for computationally bounded attacker, [9], [10], our construction offers stronger security claim over computationally unbounded attacker.

On the other hand compared to traditional single error correction code construction, i.e., [4], [6], [7], our construction is capable of claiming security for all noisy sources with min-entropy $m \geq 0$.

These results are clearly showed by Eq. 15 and 16, where $\tilde{H}_\infty(W, \mathcal{E}_s | \mathcal{I} = I) \geq H(\mathcal{E}_s)$ must hold regardless the value of $m$. Such property is crucial as merely claiming security according to the minimum residual entropy requirement, derived from the error correction construction itself cannot assure strong security. This is because any attacker could have higher computational power in modelling the input distribution $W$, results to significant low brute-force complexity in revealing $w$ from $W$. This scenario is even worst for computationally bounded attacker assumption over computational secure sketch construction. The attacker can be running in exponential time still eventually reveal $W$. Therefore, hiding $W$ over $W$ is our main contribution to claim meaningful security for computationally unbounded attacker (information-theoretically secure).

Formally, our result from Eq. 16 suggested that Shannon entropy is necessary and sufficient condition to show meaningful security for a standard secure.
13 Conclusion

Existing secure constructions have shown limitation in providing security for noisy sources with low entropy, i.e., lower than half of its input size. To overcome such limitation, recent approaches [9], [10] suggested constructing secure sketch where its security property only holds for computationally bounded attacker. Such computational construction accompanies with stringent requirement, s.t. the user must have precise knowledge over the sources distribution. However, under practical scenario, a lot of noisy sources, for instance biometric (human face, iris, fingerprint, etc) are difficult to model, hence assuming precise knowledge over such noisy sources is unrealistic.

In this work, we proposed a concrete construction for secure sketch. We introduce the usage of RV for sketching to facilitate the understanding of the input distribution. Besides, we suggested parsing random error to the input, which we showed later it acts as special information to support efficient recovery, deterministic polynomial time in the sketch size. For security, under the worst-case where any attacker (computationally unbounded) could model and mount brute-force guesses over the input. The source entropy shall vanish, therefore, in principle, have no security to show. However, we showed that with the random error parsing to the input during sketching, we can still show meaningful security (information-theoretically) in term of the brute-force complexity to look for such nontrivial error vector. These results are significant, where it implies our construction could accept any sources, included the trivial sources with zero entropy, which have no prior construction have considered.
