ABSTRACT
Token payment systems were the first application of blockchain technology and are still the most widely used one. Early implementations of such systems, like Bitcoin or Ethereum, provide virtually no privacy beyond basic pseudonymity: all transactions are written in plain to the blockchain, which makes them linkable and traceable.

Several more recent blockchain systems, such as Monero or Zerocash, implement improved levels of privacy. Most of these systems target the permissionless setting, and as such are not suited for enterprise networks. These require token systems to be permissioned and to bind tokens to user identities instead of pseudonymous addresses. They also require auditing functionalities in order to satisfy regulations such as AML/KYC.

We present a privacy-preserving token management system that is designed for permissioned blockchains and supports fine-grained auditing. The scheme is secure under computational assumptions in bilinear groups, in the random-oracle model. We provide performance measurements for our prototype implementation built on top of Hyperledger Fabric.

All of these solutions are however designed for permissionless blockchains. Enterprise networks, on the other hand, favor permissioned platforms for their higher throughput and built-in governance [31, 32], with the latter being achieved by a combination of identity management, auditability and non-deniability. Although existing solutions can be tailored for permissioned networks, they are not designed with auditability and accountability in mind. This paper bridges that gap: it hides the content of transactions without preventing authorized parties from inspecting them.

Another goal of this paper is to move away from complex and non-falsifiable computational assumptions that underpin zkSNARK-based schemes and instead work with more conservative assumptions. This is driven by financial use-cases that have a preference for well-established primitives with standard security assumptions. By restricting ourselves to the permissioned setting we were able to leverage a combination of signatures and standard ZK-proofs to achieve this goal.

1 INTRODUCTION

1.1 Motivation
As the blockchain technology matures, public and private companies alike are exploring the technology to streamline their business [32]. An emerging paradigm to accommodate enterprise use-cases is tokenization [33]. Tokens provide a natural abstraction to describe the lifecycle of an asset in terms of simple operations such as issue and transfer. However, moving to blockchain-based token systems raises the challenge of preserving privacy.

Several approaches already exist to add different levels of privacy to blockchain-based token systems. Tumblers such as CoinJoin [37] combine several transfer operations from different users and obscure the relation between senders and receivers. In mix-in-based systems such as CryptoNote [48], token transactions reference multiple superfluous senders that do however not actually participate in the transaction and only serve as a cover-up for the actual sender. Confidential Assets [42] hide the values in a token transfer but leave the sender-receiver relation in the open. Finally, advanced systems such as Zerocash [3] both encrypt the values and fully hide the sender-receiver relation.

Satisfying these three requirements is crucial for implementing a token system that ensures governance, protects user privacy and at the same time complies with regulations such as AML/KYC.

The system we propose is based on the unspent transaction output (UTXO) model pioneered by Bitcoin [39] and supports multi-input-multi-output transactions. It inherits several ideas from prior work, such as the use of Pedersen commitments from Confidential Assets [42] and the use of serial numbers to prevent double-spending from Zerocash [3]. These are combined with a blind certification mechanism that guarantees the validity of tokens via
threshold signatures, and with an auditing mechanism that allows flexible and fine-grained assignment of users to auditors.

We use a selection of cryptographic schemes that are based in the discrete-logarithm or pairing settings and are structure-preserving, such as Dodis-Yampolskiy VRF [20], ElGamal encryption [21], Groth signatures [27], Pedersen commitments [41], and Pointcheval-Sanders signatures [43]. This allows us to use the relatively efficient Groth-Sahai proofs [29] and achieve security under standard assumptions, in the random-oracle model.

1.3 Related work

Miers et al. [38] introduced Zerocoin, which enables users to anonymize their bitcoins by converting them into zerocoins using Pedersen commitments and zero-knowledge proofs. Zerocoins can be changed back to bitcoins without leaking their origin. Zerocoin however does not offer any transacting or auditing capabilities.

Confidential Assets of Poelstra et al. [42] protect privacy (in a limited form) by hiding the types and the values of the traded assets. The idea, similarly to Zerocoin, is to use Pedersen commitments to encode the amount and types of traded assets, and zero-knowledge proofs to show the validity of a transaction. The proposed scheme however does not hide the transaction graph or the public keys of the transactors. While this allows for some form of public auditability, it hinders the privacy of the transacting parties. Pretty Good Confidentiality of Chen et al. [19] follows a similar approach but adds explicit auditing functionality.

Zerocash [3] is the first fully anonymous decentralized payment scheme. It offers unconditional anonymity, to the extent that users can repudiate their participation in a transaction. Thanks to a combination of hash-based commitments and zkSNARKs, Zerocash validates payments and prevents double-spending relatively efficiently. On the downside, Zerocash requires a trusted setup and an expensive transaction generation and its security relies on non-falsifiable assumptions.

Extensions to Zerocash have been proposed in [23] to support expressive validity rules to provide accountability: notably, the proposed solution ensures regulatory closure (i.e. allowing exchanges of assets of the same type only) and enforcing spending limits. In terms of accountability, the proposed scheme allows the tracing of certain tainted coins, while not really extensively and consistently allowing transactions to be audited. By building on Zerocash, the proposed scheme inherits the same limitations regarding computational assumptions and trusted setup.

QuisQuis [22] and Zether [4] propose solutions that provide partial anonymity. On a high level, instead of sending a transaction that refers only to the accounts of the sender and the recipients of a payment, the sender adds accounts of other users, who act as an anonymity set (similar to CryptoNote [48]). Both schemes couple ElGamal encryption with Schnorr zero-knowledge proofs to ensure that user accounts reflect the correct payment flows. Contrary to Zerocash, QuisQuis and Zether rely on falsifiable assumptions and do not require any trusted setup. Furthermore, both schemes can be extended to provide auditability in a permissioned setting using verifiable public-key encryption. However, their privacy guarantees are weaker than ours: namely, the anonymity set in our solution corresponds to all system participants.

Solidus [17] is a privacy-preserving protocol for asset transfer that is suitable for intermediated bilateral transactions, where banks act as mediators. Solidus conceals the transaction graph and values by using banks as proxies. The authors leverage ORAMs to allow banks to update the accounts of their clients without revealing exactly which accounts are being updated. The novelty of Solidus is PVORM, which is an ORAM that comes with zero-knowledge proofs that show that the ORAM updates are correct with respect to the transaction triggering them. In Solidus there is no dedicated auditing functionality; however banks could open the content of relevant transactions at the behest of authorized auditors.

The zkLedger protocol of Narula, Vasquez, and Virza [40] is a permissioned asset transfer scheme that hides transaction amounts as well as the sender-receiver relationship and supports auditing. One main difference with our approach is the end user: zkLedger aims at a setting where the transacting parties are banks, whereas our solution considers the end user to be the client of "a bank." This is why zkLedger enjoys relatively more efficient proofs and could afford a transaction size that grows linearly with the number of total transactors in the platform (i.e. banks), which is inherently small. In our scheme, transaction size does not grow with the number of overall parties; it only depends on the number of parties involved in the transaction. Concerning auditability, zkLedger offers richer and more flexible semantics but requires the participation of the banks for the audit to take place.

Centralized e-cash. Our solution uses threshold blind signatures to validate tokens and allow them to be transferred. While this shows similarities with centralized e-cash [10, 11, 18, 45], our solution, by leveraging the blockchain, differs in the following fundamental ways: (i) double spending detection is performed in real-time by all the nodes in the network; (ii) and a receiver of a token is assured of its validity without contacting the issuing bank.

Outline. The remainder of the paper is structured as follows. In Section 2, we provide further background on several important techniques. Section 3 then shows an overview of our protocol. Section 4 describes the types of cryptographic schemes used in the protocol, before Section 5 specifies the security model. Section 6 contains the protocol description and the security statement. In Section 7, we describe the implementation and the performance measurements. Section 8 concludes.

2 BACKGROUND

2.1 Decentralized token systems

A decentralized token transfer is performed by appending a transaction to the blockchain. Such a transaction comprises the transfer details (e.g. sender, receivers, type and value) and a proof that the author of the transaction possesses enough liquidity to perform the transfer. The transaction is then validated against the blockchain state (i.e. the ledger). More precisely, the blockchain checks that the origin of the transaction has the right to transfer the token and that the overall quantity of tokens is preserved during the transfer. Existing decentralized token systems can be account-based (e.g. [30]) or unspent transaction outputs (UTXO)-based (cf. [39]). A valid transfer in an account-based system results in updating the accounts of the sender and the receivers. In a UTXO-based token
system, a transfer transaction includes a set of inputs—tokens to be consumed—and outputs—tokens to be created. A valid transfer in such systems destroys the inputs and adds the outputs to the ledger to be later consumed by subsequent transactions.

2.2 Privacy-preserving token systems
Decentralization of token systems gives rise to serious privacy threats: if transactions contain the transfer information in the clear, then anyone with access to the ledger is able to learn each party’s transaction history. We call a decentralized token system privacy-preserving if it partially or fully hides the transfer details. Examples of decentralized and privacy-preserving token systems are Confidential Assets [42], Zether [4], QuisQuis [22] and Zerocash [3], with the latter offering the highest level of privacy protection.

Zerocash. The privacy in Zerocash relies on a combination of commitments, zkSNARKs and Merkle-tree membership proofs. Namely, a token in Zerocash is computed as a hiding commitment to a value, a type and an owner’s pseudonym. After its creation, a token is added to a public Merkle tree and during a transfer, the origin of the transaction proves in zero-knowledge that the token is valid (i.e. included in the Merkle tree), that it was not spent before and that she owns it. Thanks to zkSNARKs, transaction validation in Zerocash is quite fast. Yet, this comes at the cost of a complex trusted setup and a very expensive proof generation. To obviate these limitations, we exploit the properties of permissioned token systems to replace Merkle trees with signature-based membership proofs, and devise a solution that does not use zkSNARKs.

2.3 Permissioned token systems
In a permissioned token system such as Hyperledger Fabric [1] or Quorum [34], a user is given a long-term credential that reflects her attributes. Tokens are introduced by special users, called issuers, through issue transactions. These transactions are then validated against predefined policies that reflect existing norms and regulations. For example, issuing policies define which issuers are authorized to create which tokens and under which conditions. Similarly to issue transactions, transfer can also be validated against policies: the simplest of which is that a transfer can take place only between registered users. A fundamental property of permissioned systems is that transactions are signed using long-term credentials. As a by-product, transactions can be traced back to their origin, enforcing thus the requirements of auditability and accountability.

2.4 Signature-based membership proofs
We use signatures to implement zero-knowledge membership proofs [5]. Roughly speaking, consider a set $S$ that consists of elements that are signed using a secret key $sk$ associated with $S$. Proving knowledge of some element $e$ in $S$ in zero-knowledge amounts to (i) computing a hiding commitment of $e$; (ii) and then proving knowledge of a signature, computed with $sk$, on the committed value. In this paper, we use this mechanism for two purposes: (i) to prove that a user is in the set of registered users; (ii) and to show that a token is in the set of valid tokens recorded in the ledger.

2.5 Encryption-based auditability
In an encryption-based auditable token system, transactions carry ciphertexts intended for the authorized auditors, see e.g. [10, 11, 23]. For such a mechanism to be viable, it is important to ensure that (i) the ciphertexts encrypt the correct information; (ii) and they are computed using the correct keys. This can be achieved through zero-knowledge proofs—computed by the creator of the transaction—that link the ciphertexts to the transfer details and attest that the two requirements listed above are not violated.

3 OVERVIEW

3.1 Design Approach
The first component of our solution is token encoding. Each token is represented by a hiding commitment (e.g. Pedersen’s) that contains the identifier of the token owner, the value of the token and its type. The life-cycle of a token is governed by two transactions: issue and transfer. An issue transaction creates a token of a given type and value and assigns it to the issuer (i.e. author of the transaction). For an issue transaction to be valid it should be submitted by the authorized issuer. For ease of exposition, we assume that a token issuer can issue only one type of token and we conflate the type of a token with its issuer. Once a token is created, it changes ownership through transfer transaction. Given that we operate within the UTXO framework, a transfer transaction consists of a set of input tokens to be consumed and a set of output tokens to be created and it is validated against the following rules:

- The author of the transaction is the rightful owner of the input tokens;
- the owners of the output tokens are registered;
- the type and the value of tokens are preserved;
- the input tokens can be traced back to valid transactions in the ledger;
- the input tokens were not consumed before (to prevent double spending).

Our solution moves away from zkSNARK and their trusted setup assumption and relies only on standard NIZK proofs (e.g. Groth-Sahai’s [29]). More precisely, it leverages the permissioned setting to use ZK signature-based membership proofs to ascertain that a user is registered and that a token belongs to the ledger in a privacy-preserving manner. Namely, we assume that there is a registration authority that provides authorized users with long-term credentials (i.e. signatures) with their attributes, and a certifier that a user contacts with a certification request to vouch for the validity of tokens she owns. A certification request contains a token (i.e. commitment) and upon receiving such a request the certifier checks whether the token is included in a valid transaction in the ledger. If so, the certifier blindly signs the token and the resulting signature can be used subsequently to prove that the token is legitimate.

To prevent double spending, we leverage serial numbers to identify tokens when they are consumed as in Zerocash. It is important that these serial numbers satisfy the following security properties: (i) collision resistance: two tokens result in two different serial numbers; (ii) determinism: the same token always yields the same serial number; (iii) unforgeability: only the owner of the token can produce a valid serial number. We use verifiable random functions
(e.g. Dodis-Yampolskiy [20]) to generate serial numbers that are a function of the token owner’s secret key and a randomness that is tied to the token at its creation time.

To enable auditability, we encrypt the information in transfer transactions (i.e. sender, receivers, types and values) under the public keys of the sender’s and the receivers’ auditors. To accommodate real-world use-cases, our solution does not assume a single auditor for all users. This means that the encryption scheme must not only be semantically-secure but also key-private, such as ElGamal.

3.2 Architectural Model

3.2.1 Participants. Our solution involves the following parties:

Users. They own tokens that represent some real-world assets and wish to exchange their tokens with other users in the network. This is achieved through transfer transactions.

Issuers. They are users who are authorized to introduce tokens in the system through issue transactions. For simplicity purposes, an issuer is assumed to introduce one type of tokens only and that the type of a token is defined as the identifier of its issuer.

Auditors. These are entities with the authority to inspect transactions. We assume that each user in the system is assigned an auditor at registration time and that this assignment is immutable.

Certifier. This is a privileged potentially-distributed party that provides users with certificates that vouch for the validity of their tokens. More specifically, a user who wishes to transfer a token contacts the certifier with the token; the certifier in turn inspects whether the token appears in a valid transaction in the ledger. If so, the certifier sends back a certificate (i.e. signature) to that effect.

Registration authority. This is a privileged party that generates long-term credentials for all the participants in the system, including users, issuers, auditors and certifiers. Namely, the credentials tie the real-world identity of the requestor to her attributes and her public keys. An example of an attribute is role (e.g., “user”, “auditor”, “certifier”) that determines the type of credentials to be generated. A user credential is a signature that binds the user’s public keys to her identifier and the identifier of her auditor; whereas an auditor credential is a signature that links the auditor’s encryption key to her identifier; finally the certifier’s credential is a signature of her public key.

Ledger. This is a decentralized data store that keeps records of all issue and transfer transactions that have been previously submitted. It is accessible to all parties to read from and submit transactions to. The ledger has a genesis block that contains (i) the system security parameters; (ii) the public information of the registration authority and the credentials of the certifier; and (iii) the identifiers of the issuers authorized to introduce new tokens.

3.2.2 Interactions. The interactions between system participants are shown in Figure 1. At first users, issuers, auditors and certifier engage with the registration authority in a registration protocol to get long-term credentials for their subsequent interactions.

A genesis block is created that announces the system parameters, the public information of the registration authority, the credentials of the certifiers and an initial list of authorized issuers. From now on, the system is able to accommodate token management requests. More precisely, issuers submit issue transactions to the ledger to introduce new tokens, and the ledger ensures that all incoming transactions are correctly stored. Anyone with access to the ledger, in particular the certifier and auditors, can verify whether a transaction is valid or not using the information in the genesis block. Subsequently, token transfer operations take place between users through transfer transactions. The ledger again stores the transaction to make it available to all participants. For simplicity, we assume that the ledger accepts all transactions without verification. However to transfer a token, a user contacts the certifier that checks if the transaction including the token is valid. Only then the certifier signs the token making it transferable. To inspect a user’s activity, an auditor reads transactions from the ledger, checks their validity and tries to decrypt them with her secret key only if they are valid.

3.3 Trust Model

Registration authority. We assume that the registration authority is trusted to assign correct credentials to all parties in the system. A participant presents a set of attributes and her public key to the registration authority and receives in return a credential that binds her attributes to her public key. It is incumbent upon the registration authority to verify the correctness of the attributes of a participant prior to sending the credential. For example, it should verify that the participant knows the secret key underlying the advertised public key. In the case of users, it should also verify that the announced auditors are legitimate. Furthermore, the registration authority is trusted to assign one unique credential per participant. However, it is not trusted regarding the privacy of users.

Figure 1: This figure shows the interactions between the participants in our system. Users, issuers, auditors and the certifier are granted credentials by interacting with the registration authority. To create new tokens, an issuer submits an issue transaction to the ledger and the ledger automatically adds the transaction. To transfer a token, a user contacts the certifier with a certification request that references the token to be signed and the transaction that created it. If it is an issue transaction, the certifier checks if the author of the transaction is authorized. If it is a transfer transaction, the certifier verifies if the ZK proof is valid. Once the owner of a token receives the corresponding certificate, she can transfer it to registered users. Finally, auditors assigned to a user can audit that user’s transactions by obtaining access to the ledger.
Notice that the trust assumption in the registration authority can be relaxed via a distributed registration protocol.

**Users.** Users may collude to compromise the security of the system. They may attempt to steal tokens of others, double-spend their own tokens, forge new tokens, transfer tokens to non-registered users, encrypt incorrect information in the auditors’ ciphertexts, etc. They may also attempt to undermine the privacy of honest users by de-anonymizing transactors, linking tokens, learning the content of transactions, etc.

**Issuers.** Issuers are users that are trusted to introduce tokens of a certain type. However, issuers may collude to surreptitiously create tokens on behalf of other honest issuers, compromise the privacy of users and obviate auditing among other things.

**Certifier.** To transfer a token, a user contacts the certifier to receive a signature that proves the token validity (i.e., inclusion in a valid transaction in the ledger). The certifier is hence trusted to generate signatures only for tokens created by valid transactions. We relax this trust assumption using a threshold signature scheme that distributes the certification process and guarantees its integrity as long as the majority of the signers (i.e., certifiers) is honest.

While certifiers may be able to link transfer transactions referencing certified tokens to certification requests, they should not be able to derive any further information about the transactions in the ledger or the tokens they certify.

**Auditors.** Auditors are authorized to only learn the information pertaining to their assigned users. That is, colluding users and auditors should not be able to derive any information about the token history of users who are not assigned to the malicious auditors.

**Ledger.** For simplicity purposes, we use the ledger only as a time-stamping service. It does not validate transactions, rather it stores the full transaction including the proofs of correctness. Anyone later can check the transaction, verify the proofs and decide if the transaction is valid or not. We assume however that the ledger is live and immutable: a transaction submitted to the ledger will eventually be included and cannot be deleted afterwards.

4 CRYPTOGRAPHIC SCHEMES

The section presents the cryptographic schemes that will be used to build the protocol. We only present them briefly, and provide more information on concrete instantiations later in the paper. All cryptographic algorithms are parametrized by a so-called security parameter $\lambda \in \mathbb{N}$ given (sometimes implicitly) to the algorithms.

4.1 Commitment schemes

A commitment scheme $\text{COM}$ consists of three algorithms $\text{ccrsgen}$, $\text{commit}$, and $\text{open}$. The common reference string (CRS) generator $\text{ccrsgen}$ is probabilistic and, on input the security parameter $\lambda$, samples a CRS $\text{crs} \leftarrow \text{ccrsgen}(\lambda)$. The commitment algorithm is a probabilistic algorithm that, on input of a vector $(m_1, \ldots, m_t)$ of messages, outputs a pair $(cm, r_{cm}) \leftarrow \text{commit}(\text{crs}, (m_1, \ldots, m_t))$ of commitment $cm$ and opening $r_{cm}$. We also use the notation $cm \leftarrow \text{commit}(\text{crs}, (m_1, \ldots, m_t); r_{cm})$ to emphasize that a specific randomness $r_{cm}$ is used. Finally, $\text{open}(\text{crs}, cm, (m_1, \ldots, m_t), r_{cm})$ is a deterministic algorithm that outputs either true or false.

Commissions must be hiding in the sense that, without knowledge of $r_{cm}$, they do not reveal information on the committed messages, and they must be binding in the sense that it must be infeasible to find a different set of messages $m'_1, \ldots, m'_t$ and randomness $r'_{cm}$ that open the same commitment.

4.2 Digital signature schemes

A digital signature scheme $\text{SIG}$ consists of algorithms $\text{kkeygen}$, $\text{sign}$, and $\text{verify}$. The key generation algorithm $(sk, pk) \leftarrow \text{kkeygen}(\lambda)$ takes as input the security parameter $\lambda$ and outputs a pair of private (or secret) key $sk$ and public key $pk$. Signing algorithm $s \leftarrow \text{sign}(sk, m)$ takes as input private key $sk$ and message $m$, and produces a signature $s$. Deterministic verification algorithm $b \leftarrow \text{verify}(pk, m, s)$ takes as input public key $pk$, message $m$, and signature $s$, and outputs a Boolean $b$ that signifies whether $s$ is a valid signature on $m$ relative to public key $pk$. The standard definition of signature scheme security, existential unforgeability under chosen-message attack, has been introduced by Goldwasser, Micali, and Rivest [26]. It states that given an oracle that generates valid signatures, it is infeasible for an efficient adversary to output a valid signature on a message that has not been queried to the oracle. The security of a signature scheme can also be described by an ideal functionality $F_{\text{SIG}}$, which can be found in Appendix A.4.

4.3 Threshold signature schemes

A non-interactive threshold signature scheme $\text{TSIG}$ consists of four algorithms $\text{kkeygen}$, $\text{sign}$, combine, and verify. Threshold key generation $(sk_1, \ldots, sk_n, pk_1, \ldots, pk_n, pk) \leftarrow \text{tkeygen}(\lambda, n, t)$ gets as input security parameter $\lambda$, total number of parties $n$, and threshold $t$. Each party can sign with their own secret key $sk_i$ as above to generate a partial signature $s_i$. Any $t$ valid signatures can be combined using combine into a full signature $s$, which is verified as in the non-threshold case. A signature produced honestly by any $t$ parties verifies correctly, but any signature produced by less than $t$ parties will not verify.

4.4 Public-key encryption.

A public-key encryption scheme $\text{PKE}$ consists of algorithms $\text{ekeygen}$, $\text{enc}$, and $\text{dec}$. Key-generation algorithm $(sk, pk) \leftarrow \text{ekeygen}(\lambda)$ takes as input security parameter $\lambda$ and outputs a pair of private key $sk$ and public key $pk$. Probabilistic encryption algorithm $c \leftarrow \text{enc}(pk, m)$ takes as input message $m$ and public key $pk$ and produces ciphertext $c$. We also write $c \leftarrow \text{enc}(pk, m, r)$ to emphasize that the encryption uses randomness $r$. Deterministic decryption $m \leftarrow \text{dec}(sk, c)$ takes as input ciphertext $c$ and private key $sk$ and recovers message $m$. Correctness requires that $\text{dec}(sk, \text{enc}(pk, m)) = m$ for all $(sk, pk)$ generated by ekeygen. For our work, we require semantic security as first defined by Goldwasser and Micali [25]. The scheme must additionally satisfy key privacy as defined by Bellare et al. [2], which ensures that, given a ciphertext $c$, it is hard to determine the public key under which the ciphertext is computed.

4.5 Verifiable random functions

A verifiable random function $\text{VRF}$ consists of three algorithms $\text{vkeygen}$, $\text{eval}$, and $\text{check}$. Key generation $(vsk, vk) \leftarrow \text{vkeygen}(\lambda)$ takes as input the security parameter and outputs a pair of private
key vsk and public key vpk. Deterministic evaluation \((y, \pi) \leftarrow \text{eval}(vsk, x)\) takes as input secret key vsk and input value \(x\), and produces as output the value \(y\) with proof \(\pi\). Deterministic verification \(b \leftarrow \text{check}(vpk, x, y, \pi)\) takes as input public key vpk, input \(x\), output \(y\), and proof \(\pi\), and outputs a Boolean that signifies whether the proof should be accepted.

The scheme satisfies correctness if honest proofs are always accepted. Soundness means that it is infeasible to produce a valid proof for an output value that was not correctly computed. Each party has an identity that consists of a party identifier pid and a session identifier sid. The environment and adversary have specific, constant identifiers, and ideal functionalities have party identifier \(\perp\). The understanding here is that all ITIs that share the same code and the same sid are considered a session of a protocol. It is natural to use the same pid for all ITIs that are considered the same party.

ITIs can invoke other ITIs by sending them messages, new instances are created adaptively during the protocol execution when they are first invoked by another ITI. To use composition, some additional restrictions on protocols are necessary. In a protocol \(\mu^{\phi \rightarrow \pi}\), which means that all calls within \(\mu\) to protocol \(\phi\) are replaced by calls to protocol \(\pi\), both protocols \(\phi\) and \(\pi\) must be subroutine respecting. This means, in a nutshell, that while those protocols may have further subroutines, all inputs to and outputs from subroutines of \(\phi\) or \(\pi\) must only be given and obtained through \(\phi\) or \(\pi\), never by directly interacting with their subroutines. (This requirement is natural, since a higher-level protocol should never directly access the internal structure of \(\phi\) or \(\pi\); this would obviously hurt composition.) Also, protocol \(\mu\) must be compliant. This roughly means that \(\mu\) should not be invoking instances of \(\pi\) with the same sid as instances of \(\phi\), as otherwise these instances of \(\pi\) would interact with the ones obtained by the operation \(\mu^{\phi \rightarrow \pi}\).

In summary, a protocol execution involves the following types of ITIs: the environment \(\mathcal{Z}\), the adversary \(\mathcal{A}\), instances of the protocol machines \(\pi\), and (possibly) further ITIs invoked by \(\mathcal{A}\) or any instance of \(\pi\) (or their subroutines). The contents of the environment’s output tape after the execution is denoted by the random variable \(\text{exec}_{\pi, \mathcal{A}, \mathcal{Z}}(\lambda, z)\), where \(\lambda \in \mathbb{N}\) is the security parameter and \(z \in \{0, 1\}^*\) is the input to the environment \(\mathcal{Z}\). The formal details of the execution are specified in [14]. We say that a protocol \(\pi\) UC-realizes a functionality \(\mathcal{F}\) if

\[
\forall \mathcal{A} \exists S \forall \mathcal{Z} : \text{exec}_{\pi, \mathcal{A}, \mathcal{Z}} = \text{exec}_{\phi, S, \mathcal{Z}},
\]

where “≈” denotes indistinguishability of the respective distribution ensembles, \(S\) refers to the simulator and \(\phi\) is the dummy protocol that simply relays all inputs to and outputs from functionality \(\mathcal{F}\).

Multi-protocol UC. The standard UC framework does not allow to modularly prove protocols in which, e.g., a zero-knowledge proof system is used to prove that a party has performed a certain evaluation of a cryptographic scheme correctly. Camenisch et al. [6] recently showed how this can be overcome. In a nutshell, they start from the standard UC realization \(\mathcal{F}_{\text{nizk}}\)-functionality which is parameterized by a relation \(\mathcal{R}\) and show that if \(\mathcal{R}\) is described in terms of evaluating a protocol, then the protocol can equivalently be evaluated outside of the functionality, and even used to realize another functionality \(\mathcal{F}'\). This results in a setting where \(\mathcal{F}_{\text{nizk}}\) validates a pair \((y, w)\) of statement \(y\) and witness \(w\) by “calling out” to the other functionality \(\mathcal{F}'\). We use this proof technique extensively in this work.

5.2 The privacy-preserving token functionality

The functionality \(\mathcal{F}_{\text{token}}\) realized by our privacy-preserving token system is formalized in Figure 2. To keep the presentation simple, the functionality formalizes the guarantees for the case of a single token issuer \(I\). The functionality initially requires registration authority \(\mathcal{A}\), certifier \(C\), and issuer \(I\) to initialize. (This corresponds to the fact that all protocol steps depend on those parties’ keys.) Likewise, regular parties \(P\) have to generate and register their keys before they can perform operations. Each party can then read the...
tokens they own and generate transfer transactions that reference those tokens and transfer them to one or more receivers. The issuer can additionally issue new tokens. In the inputs and outputs of the functionality, \( v \) always represents the value of a token, and \( cm \) serves as a handle identifying the token (it stems from the commitment that represents the token on the ledger). Finally, the functionality specifies which information is potentially leaked to the adversary, and which operations the adversary can perform in the name of corrupted parties.

5.3 Set-up functionalities

Our protocol calls for a number of set-up functionalities; most of which are widely used in the literature. This is why we only briefly describe them here and defer the details to Appendix A.

Common reference string. Functionality \( F_{	ext{CRS}} \) provides a string that is sampled at random from a given distribution and accessible to all participants. All parties can simply query \( F_{	ext{CRS}} \) for the reference string. The functionality is generally used to generate common public parameters used in a cryptographic scheme.

Transaction ledger. We describe a simplified transaction ledger functionality as \( F_{	ext{ledger}} \) in Figure 3. In a nutshell, every party can append bit strings to a globally available ledger, and every party can retrieve the current ledger.

\( F_{	ext{ledger}} \) intentionally idealizes the guarantees achieved by a real-world ledger; transactions are immediately appended, final, and available to all parties. We also use \( F_{	ext{ledger}} \) as a local functionality. These simplifications are intended to keep the paper more digestible.

Secure and private message transfer. Functionality \( F_{	ext{SMT}} \) provides a message transfer mechanism between parties. The functionality builds on the ones described by Canetti and Krawczyk [16], but additionally hides the sender and receiver of a message, if both are honest. This is required since our protocol passes information between transacting parties, and leaking the communication pattern would revoke the anonymity otherwise provided by our protocol.

Public-key registration. The registration functionality \( F_{	ext{REG}} \) models a public-key infrastructure. It allows each party \( P \) to input one value \( x \in \{0, 1\}^* \) and makes the pair \((P, x)\) available to all other parties. This is generally used to publish public keys, binding them to the identity of a party.

Anonymous authentication. As our protocol is in the permissioned setting but supposed to provide privacy, we need anonymous credentials to authorize transactions. Our schemes integrate well with the Identity Mixer family of protocols [9]. As these topics are not the core interest of this paper, we abstract the necessary mechanisms in the functionality \( F_{	ext{AUTH}} \) as depicted in Figure 4.

\( F_{	ext{AUTH}} \) allows parties to first register and then "authorize" commitments; the functionality returns "proofs" \( \psi \) assuring that the party’s identity is contained in a certain position of that commitment. \( F_{	ext{AUTH}} \) also allows to bind the proof to a bit string \( m \), which intuitively can be understood as "party \( P \) (as referenced in the commitment) signs message \( m \)." The exact reason for this mechanism will become clear in the protocol description in Section 6.5.

Privacy-preserving token functionality \( F_{	ext{TOKEN}} \)

Functionality \( F_{	ext{TOKEN}} \) stores a list of registered users and an initially empty map \( \text{Records} \). The session identifier is of the form \( \text{sid} = (A, C, I, \text{sid}') \).

- Upon input \( \text{init} \) from \( P \in \{A, C, I\} \), output to \( \mathcal{A} \) (initialized, \( P \)). (This must happen for all three before anything else.)
- Upon input \( \text{register} \) from a party \( P \), if \( P \) is unregistered, then mark \( P \) as registered and output (registered, \( P \)) to \( \mathcal{A} \). (Otherwise ignore.)
- Upon input \( \text{read} \) from a registered party \( P \), issue \( (\text{read}?, P) \) to \( \mathcal{A} \). Upon receiving response \( (\text{read}!, P) \) from \( \mathcal{A} \), return to \( P \) a list of all records of the type \((cm, v)\) that belong to \( P \).
- Upon input \((\text{issue}, v)\) from \( I \), output \((\text{issue}, v)\), then \( I \). Receiving from \( \mathcal{A} \) a response \((\text{issue}, cm)\), if \( cm \neq \perp \) then abort, else set \( \text{Records}[cm] = (v, I, \text{alive}) \). Return \((\text{issue}, cm)\) to \( I \).
- Upon receiving an input \((\text{issue}, v, cm)\) from \( \mathcal{A} \), where \( I \) is corrupted, check and record the commitment in the previous step. Return to \( \mathcal{A} \).
- Upon input \((\text{transfer}, (cm_j)_{j=1}^m, (v_{\text{out}}^i, R_j)_{j=1}^n)\) from an honest party \( P \), where \( P \) and all \( R_j \) for \( j = 1, \ldots, n \) are registered, proceed as follows.
  1. If, for any \( i \in \{1, \ldots, m\} \), \( \text{Records}[cm_j] = \perp \) then abort, else set \((v_{\text{out}}^i, P_j, st_i) = \text{Records}[cm_j] \).
  2. If, for any \( i \in \{1, \ldots, m\} \), \( st_i \neq \text{alive} \) or \( P_j \neq P \), then abort.
  3. If \( \sum_{i=1}^m v_{\text{out}}^i \neq \sum_{j=1}^n v_{\text{out}}^j \) then abort.
- Let \( L \) be an empty list. For all \( j = 1, \ldots, n \), if \( R_j \) is corrupt then append to \( L \) the information \((j, P, R_j, v_{\text{out}}^j)\). Output \((\text{transfer}, m, n, L)\) to \( \mathcal{A} \).
- Receiving from \( \mathcal{A} \) a response \((\text{transfer}, (cm_j)_{j=1}^m)\), if \( \text{Records}[cm_j] = \perp \) for any \( j \in \{1, \ldots, n\} \) then abort, else set \( \text{Records}[cm_j] = (v_{\text{out}}^j, R_j, \text{delayed}) \) for all \( j \in \{1, \ldots, n\} \) and set \( \text{Records}[cm_j] = (v_{\text{out}}^j, P', \text{consumed}) \) for all \( i \in \{1, \ldots, m\} \).
- Return \((\text{transfer}, (cm_j)_{j=1}^m)\) to \( P \).
- On \((\text{transfer}, P, (cm_j)_{j=1}^m, (v_{\text{out}}^i, cm_j)_{j=1}^n)\) from \( \mathcal{A} \) where \( P \) is corrupted, proceed analogously to above.
- Upon receiving an input \((\text{deliver}, cm)\) from \( \mathcal{A} \) with \( \text{Records}[cm] = (v, P, \text{delayed}) \) for some \( v \) and \( P \), set \( \text{Records}[cm] = (v, P, \text{alive}) \). If \( C \) is corrupted, then output \( P \) to \( \mathcal{A} \).

Figure 2: Privacy-preserving token functionality

Our description of \( F_{	ext{AUTH}} \) is simplistic and tailored to an easy treatment in our proofs. For a complete composable model of anonymous authentication schemes, see for e.g. the work of Camenisch, Dubovitskaya, Haralambiev, and Kohlweiss [7].
6 PRIVACY-PRESERVING AUDITABLE UTXO

This section describes the complete protocol. We begin by introducing the core ideas and mechanisms in Sections 6.1 – 6.3. Section 6.4 introduces multi-input multi-output transactions, followed by Section 6.5 that assembles all pieces and describes the full protocol. Section 6.6 presents the extension that makes the protocol auditable and Section 6.7 states the main security result of the paper.

6.1 Core protocol ideas

The protocol uses commitments \((cm, r_{cm}) \leftarrow commit((crs, (v, P)))\) to represent tokens, where \(v\) is the value and \(P\) is the current owner. Issuers create new tokens in their own name. Transferring tokens \((v, P)\) to a party \(R\) means replacing the commitment to \((v, P)\) with a commitment to \((v, R)\). We now describe the protocol steps in more detail, but still at an informal level.

To issue a token of value \(v\), the issuer generates a new commitment \((cm, r_{cm}) \leftarrow \text{commit}(crs, (v, I))\), which means a token with value \(v\) is created with owner \(I\). The protocol generates a proof

\[
\psi_0 \leftarrow \text{PK} \{(r_{cm}) : \text{open}(crs, cm, r_{cm}, (v, I)) = \text{true}\}
\]

which shows that the commitment contains the expected information. Issuer \(I\) also creates a signature \(s\) on message \((v, cm, \psi_0, s)\). The information written to \(F_{\text{LEDGER}}\) is \(tx = (\text{issue}, v, cm, \psi_0, s)\).

A party \(P\) transfers a token (i.e. a commitment \(cm\)) to a receiver \(R\) by computing a new commitment \((cm', r'_{cm}) \leftarrow \text{commit}(crs, (v, R))\). She generates a first NIZK \(\psi_1\), showing that \(cm'\) contains the correct information and that the receiver is registered, and a second proof \(\psi_2\) of eligibility (i.e. the initiator of the transfer owns \(cm\)) using \(F_{\text{AUTH}}\). The information written to \(F_{\text{LEDGER}}\) is \(tx = (\text{transfer}, cm', \psi_1, \psi_2)\). At this point, we cannot yet describe how \(P\) proves that (a) \(cm\) is a valid commitment on the ledger—we cannot include \(cm\) in the transaction as that would hurt privacy—and (b) that \(P\) is not double-spending \(cm\). These aspects will be covered subsequently. Party \(P\) also sends the message \((\text{token}, cm', r'_{cm}, v)\) to \(R\) privately.

So far, we have shown how to transfer a single token from a party \(P\) to a receiver \(R\). Following sections show how to (i) make sure that only valid and unspent tokens are transferred; and (ii) support multi-input multi-output transfers.

6.2 Certification via blind signatures

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{image.png}
\caption{Extended anonymous registration functionality}
\end{figure}

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{image.png}
\caption{Blind signature functionality, threshold version.}
\end{figure}

(Threshold) blind signature functionality \(F^{\text{TSIG,commit}}_{\text{BLINDSIG}}\) requires that \(\text{sid} = ((C_1, \ldots, C_n), t, t, \text{sid}^\prime)\), where \(C_1, \ldots, C_n\) are the party identifiers and \(t\) is the size of the vectors of messages to be signed. It is parametrized by the (deterministic) commit algorithm of the commitment as well as a threshold signature scheme \(\text{TSIG} = (\text{tkeygen, sign, verify})\). The functionality keeps an initially empty set \(S\) of signed messages.

- Upon init from some \(C_i\), run \((sk_1, \ldots, sk_n, pk_1, \ldots, pk_n, pk) \leftarrow \text{tkeygen}(\lambda, n, t, \ell)\), where \(\lambda\) is obtained from the security parameter tape, and store \((sk_1, \ldots, sk_n, pk)\). Output \((\text{init}, C_i)\) to \(A\).
- Upon input pubkey from party \(P\), return \((\text{pubkey}, pk)\).
- On input \((\text{request}, crs, r_{cm}, (m_1, \ldots, m_t))\) from party \(P\):
  1. Compute \(cm \leftarrow \text{commit}(crs, (m_1, \ldots, m_t); r_{cm})\) and store it internally along with the messages and randomness.
  2. Send delayed output \((\text{request}, P, cm, crs)\) to each \(C_i, i \in \{1, \ldots, n\}\).
- Upon input \((\text{sign}, cm)\) from \(C_i\):
  1. If no record with commitment \(cm\) exists, then abort.
  2. If there is a record \(((m_1, \ldots, m_t), S) \in \Sigma\) with \(S \subseteq \{C_1, \ldots, C_n\}\), update the record with \(S \leftarrow S \cup \{C_i\}\).
     Else set \(S \leftarrow S \cup \{((m_1, \ldots, m_t), \{C_i\})\}\).
  3. If \(|S| \geq t\), then compute \(s \leftarrow \text{sign}(sk_i, (m_1, \ldots, m_t))\) and output \(s\) to requestor \(P\).
- Upon input \((\text{verify}, pk', (m_1, \ldots, m_t))\) from \(P\), compute \(b \leftarrow \text{verify}(pk', (m_1, \ldots, m_t), s)\). If \(pk = pk'\) and \(b \wedge ((m_1, \ldots, m_t), S) \notin \Sigma \lor |S| < t\) then output \((\text{result, false})\) to \(P\). Else output \((\text{result, b})\) to \(P\).
- Upon input \((\text{seekkey, i})\) from \(A\), if \(C_i\) is corrupted, then return \(sk_i\).
as a commitment \( cm \) on \( T_{\text{ledger}} \) by issuing a signature \( s \) on \((v, P)\). In the proof \( \psi_1 \), \( P \) refers to signature \( s \) instead of commitment \( cm \).

A naive implementation of the above scheme would require party \( P \) to reveal the content \((v, P)\) of \( cm \) to certifier \( C \), so that the latter issues the corresponding signature \( s \) prior to signing. \( C \) checks that \( cm \) opens to \((v, P)\) and that \( cm \) is stored on \( T_{\text{ledger}} \). Disclosing the pair \((v, P)\) to \( C \) is both undesired and unnecessary. Instead we rely on a blind signature protocol, in which \( C \) learns only the value of commitment \( cm \) and blindly signs its content.

While \( C \) learns \( cm \) during the protocol, it will not be able to leverage the data on \( T_{\text{ledger}} \) to trace when \( P \) makes use of the corresponding signature \( s \). More precisely, within \( \psi_1 \), party \( P \) only proves knowledge of a signature \( s \) and does not reveal it.

Note that a malicious certifier can essentially generate tokens by providing its signature without checking for existence of the commitment on \( T_{\text{ledger}} \). Appendix D describes how to distribute the certification task, so that no single party is trusted for verification.

Figure 5 shows a threshold blind signature ideal functionality, which we will use in the description of our solution in Section 6.5.

### 6.3 Serial numbers prevent double-spending

Double-spending prevention is achieved via a scheme that is inspired by Zerocash [3] in that it uses a VRF to compute serial numbers for tokens when they are spent. The VRF key is here, however, bound to a user via a signature from the registration authority.

On a very high level, the above protocol is extended as follows.

1. Each user \( P \) creates a VRF key pair \((vsk, vpk)\). They obtain a signature \( s_A \) from registration authority \( A \) that binds \( vpk \) to their identity \( P \).

2. Each commitment contains an additional value \( \rho \).

3. During transfer, the value \( \rho \) is used to derive the serial number \((sn, \pi) \equiv \text{eval}(vsk, \rho)\). The transaction stored in \( T_{\text{ledger}} \) also contains \( sn \).

4. We cannot store the VRF proof \( \pi \) on \( T_{\text{ledger}} \), as it is bound to \( vpk \) and would deanonymize \( P \). Instead, \( P \) proves knowledge of signature \( s_A \), which binds \( vpk \) to her identity, and proves in zero-knowledge that check \((vpk, \rho, sn, \pi) \equiv \text{true} \).

We stress that authority \( A \) must be trusted to prevent double-spending, otherwise it could register multiple VRF keys for the same user. It is thus recommended to implement \( A \) in a distributed fashion.

The proof \( \psi_1 \) made by \( P \) during a transfer of token \((v, P, \rho)\) is:

\[
\psi_1 \leftarrow \text{PK}\{\{r'_{cm}, s_A, s_C, P, \rho, \rho_{out}, \pi, v\} : \\
\text{verify}(pk_C, (v, P, \rho), s_C) \land \text{open}(crs, cm', (v, P, \rho_{out}), r'_{cm}) \\
\land \text{verify}(pk_A, (P, vpk), s_A) \land \text{check}(vpk, \rho, sn, \pi)\}
\]

which can be parsed as follows: prior to the transfer, \( P \) obtains signature \( s_C \) on \((v, P, \rho)\) under \( pk_C \) from certifier \( C \). The first condition in the proof statement checks that \( P \) knows signature \( s_C \) on the triplet \((v, P, \rho)\). The second condition checks that the new commitment \( cm' \) contains the same value \( v \). These two conditions, together with trust in the correctness of \( C \), ensure that the token corresponding to \( cm' \) is properly derived from a token existing on \( T_{\text{ledger}} \). The third condition checks that the VRF public key \( vpk \) indeed belongs to \( P \), and the fourth condition checks that the computation of the serial number \( sn \) is correct. These two conditions, together with trust in the correctness of \( A \), prevent token \((v, P, \rho)\) from being double-spent.

### 6.4 Multi-input multi-output transactions

Multi-input multi-output transactions allow a sender to transfer tokens contained in multiple commitments at once, and to split the accumulated value into multiple outputs for potentially different receivers. We therefore modify the transaction format to contain multiple inputs and multiple outputs. We also have to extend the NIZK: besides the fact that we have to prove consistency of multiple inputs and multiple outputs, we now have to show that the sum of the inputs equals the sum of the outputs.

Due to arithmetics in finite algebraic structures, we also have to prove that no wrap-arounds occur. This is achieved, as in previous work, by the use of range proofs. For a given value \( max \in \{1, \ldots, p\} \), the condition is that \( 0 \leq v \leq max \) for any value \( v \) that appears in an output commitment.

The proof, in more detail, now becomes:

\[
\psi_1 \leftarrow \text{PK}\{\{(s_j, v_j^{in}, \rho_j^{in}, \pi_j)_{j=1}^m, P, s_A, \\
(R_j, r_j^{out}, v_j^{out}, \rho_j^{out}, vpk_j, s_A)_{j=1}^m : \\
\forall i \in \{1, \ldots, m\} : \text{verify}(pk_C, (v_j^{in}, P, \rho_j^{in}), s_j) \\
\land \forall j \in \{1, \ldots, n\} : \text{open}(crs, cm_j, (v_j^{out}, R_j, \rho_j^{out}), r_j^{cm}) \\
\land \text{verify}(pk_A, (P, vpk_j), s_j) \\
\land \forall j \in \{1, \ldots, n\} : \text{check}(vpk, \rho_j^{in}, sn_j, \pi_j) \\
\land \forall i \in \{1, \ldots, m\} : v_i^{out} = \sum_{j=1}^n v_j^{out} \\
\land \forall j \in \{1, \ldots, n\} : 0 \leq v_j^{out} \leq max\}. \quad (1)
\]

The processing of the transaction is analogously modified to check this more complex NIZK. We now argue that the statement proved in the NIZK indeed guarantees the consistency of the system.

The first sub-statement (together with the honesty of \( C \)) guarantees that all commitments used as inputs indeed exist in the ledger, and the fact that the commitment is binding further implies that the values \((v_i^{in}, P, \rho_i^{in})\) indeed correspond to the expected state of the system. The next sub-statement shows that the output commitments indeed contain the expected values \((v_j^{out}, R_j, \rho_j^{out})\). The two subsequent statements ensure that all parties are registered users, and the statement check \((vpk, \rho_j^{in}, sn_j, \pi_j)\) prevents double-spending by showing that the serial numbers are computed correctly.

The final two equations guarantee the global consistency of the system: the summation equation shows that no tokens have been created or destroyed in this transaction; whereas the range proof shows that all outputs contain a value in the valid range, which avoids wrap-arounds.
6.5 The protocol $\pi_{\text{TOKEN}}$

This section describes the protocol sketched previously more formally. The protocol has a bit registered $\leftarrow$ false and keeps an initially empty list of commitments. We begin by describing the protocol for a user $P$ of the system.

- Upon input $\text{register}$, if registered is set, then return. Else, retrieve the public keys of $A$, $C$ and $I$ from $\mathcal{F}_\text{REG}$. Query $\text{crs}$ from $\mathcal{F}_\text{REG}$. Generate a VRF key pair $(\text{vsk}, \text{vpk})$ and send a message $(\text{register}, \text{vpk})$ to $A$ via $\mathcal{F}_\text{SMT}$ to obtain a signature $s_A$ on $(P, \text{vpk})$. If all steps succeeded, then set registered $\leftarrow$ true send register to $\mathcal{F}_\text{AUTH}$.

- Process pending messages and retrieve new data from $\mathcal{F}_\text{LEDGER}$. This is a subroutine called from functions below.

  - For transactions $tx = (\text{issue}, v, cm, \psi, s)$ from $\mathcal{F}_\text{LEDGER}$, validate $\psi$ by inputting $(\text{verify}, (\text{crs}, cm, cm, v, I), \psi)$ to $\mathcal{F}_\text{NIZK}$ and verify $s$ via verify $(pk_I, (v, cm, \psi), s)$. If both checks succeed, record $cm$ as a valid commitment.

  - For $tx = (\text{transfer}, (sn_i, j, m), cm_i, \psi_i)$, check the serial numbers $sn_{i1}, ..., sn_{im}$ in uniqueness, validate $\psi_i$ via $\mathcal{F}_\text{NIZK}$ and verify $\psi_{21}, ..., \psi_{2n}$ by calling $\mathcal{F}_\text{AUTH}$ with $(\text{verify}, (\text{crs}, \psi_{2i}, m)$ for $m = ((sn_i), m), (cm_i), \psi_i)$. If all checks succeed, then store $cm_{i1}, ..., cm_{im}$ as valid.

  - For each incoming message (sent, $S, P, m$) buffered from $\mathcal{F}_\text{SMT}$, parse as $(\text{token}, cm, cm, \psi, v)$ and test whether the commitment is correct, i.e. whether it holds that open $(\text{crs}, cm, cm, v, P, \rho) = \text{true}$. Check whether there is a valid transfer transaction $tx$ that appears in $\mathcal{F}_\text{LEDGER}$ and contains $cm$. If all checks are successful, input $(\text{request}, cm, cm, \psi, v, P, \rho))$ to $\mathcal{F}_\text{BLINDDISG}$ and wait for a response $s_c$. Store the complete information in the internal list.

- Upon input read, if $\text{~registered~}$ then abort, else first process pending messages. Then return a list of all unspent assets $(cm, v)$ owned by the party.

- Upon input $(\text{transfer}, (cm_i, m), \psi_i, \theta_i)$, assuming that registered, query $\text{lookup}, R_i$ to $\mathcal{F}_\text{REG}$ for all $j = 1, ..., n$ in order to make sure that $R_j$ is registered. Then process pending messages and proceed as follows.

  1. If, for any $i \in \{1, ..., m\}$, there is no internal record of commitment $(cm_i, r_i, \psi_i, \theta_i, \rho_i)$, then abort.

  2. If $\sum_{i=1}^{m} v_i \neq \sum_{j=1}^{n} v_j$ then abort.

  3. Choose uniformly a random $\rho_j$ for $j = 1, ..., m$ and compute $(cm_i, r_i) \leftarrow \text{commit}(\text{crs}, (v_j, \theta_j, r_j))$.

  4. Compute the serial numbers $(sn_i, \pi)$ as $\text{eval}(\text{vsk}, \rho_i)$, for $i = 1, ..., m$.

  5. Generate proof $\psi_i$ as in Equation (1).

  6. Set $m \leftarrow (sn_i, \pi, (cm_i), \theta_j, \psi_i)$. For $i = 1, ..., m$ send $(\text{prove}, cm_i, r_i, v_j, \theta_j, \pi, m)$ to $\mathcal{F}_\text{AUTH}$ to obtain $\psi_{2i}$.

  7. Send $(\text{token}, cm_i, r_i, v_j, \theta_j)$ to $R_i$ via $\mathcal{F}_\text{SMT}$ for $j = 1, ..., n$ and call $\mathcal{F}_\text{LEDGER}$ with input (append, $tx$) for $tx = (\text{transfer}, (sn_i, \psi_{2i}, \pi, (cm_i), \theta_j, \psi_i))$.

(8) Delete the internal records of $cm_i$ for $i = 1, ..., m$ and return $(\text{transfer}, cm_i, \theta_j)$.

- Upon receiving $(\text{send}, S, P, m)$ from $\mathcal{F}_\text{SMT}$, buffer it for later processing. Respond ok to sender $S$.

The protocol machines for parties $I, C$ and $A$ are easier to describe. Issuer $I$ behaves the same as a user $P$ except when introducing new tokens. More specifically:

1. Upon init, generate a key pair $(sk_I, pk_I) \leftarrow \text{skeygen}(\lambda)$ for the signature scheme and input $(\text{register}, pk_I)$ to $\mathcal{F}_\text{REG}$.

2. Upon (issue, $v$), choose randomly $\rho$ and compute commitment $(cm, cm) \leftarrow \text{commit}(\text{crs}, (v, I, \rho))$ and proof $\psi_0 \leftarrow$ PK $(\text{crs}, \rho) : \text{open}(cm, cm, \text{crs}, (v, I, \rho)) = \text{true}$, where $I$ and $v$ are publicly known. This is achieved by sending $(\text{prove}, x, w)$ to $\mathcal{F}_\text{NIZK}$, where $x = (crs, cm, v, I)$ and $w = (\text{crs}, \rho)$. Next compute a signature $s \leftarrow \text{sign}(sk_I, (v, cm, \psi_0))$ and send (append, $tx$), with $tx = (\text{issue}, v, cm, \psi, s)$, to $\mathcal{F}_\text{LEDGER}$. Finally, store $(cm, cm, v, \rho)$ internally and return $(\text{issue}, cm)$.

Certifier $C$ signs a commitment if it finds it in a valid transaction in the ledger. In more detail:

1. Upon init get $crs$ from $\mathcal{F}_\text{REG}$ and input init to $\mathcal{F}_\text{BLINDDISG}$.

2. Upon receiving $(\text{request}, P, crs')$ from $\mathcal{F}_\text{BLINDDISG}$ check that $crs = crs'$. Query $\mathcal{F}_\text{LEDGER}$ for the entire ledger. For each yet unprocessed transaction $tx$ on $\mathcal{F}_\text{LEDGER}$, validate the proofs as described previously. Check whether $cm$ is marked as a valid commitment.

3. If the above check is successful, send $(\text{sign}, cm)$ to $\mathcal{F}_\text{BLINDDISG}$.

Registration authority $A$ signs VRF public keys of the parties.

1. Upon init, generate a key pair $(sk_A, pk_A) \leftarrow \text{skeygen}(\lambda)$ for the signature scheme and input $(\text{register}, pk_A)$ to $\mathcal{F}_\text{REG}$.

2. When activated, input retrieve to $\mathcal{F}_\text{SMT}$ to obtain the next message. Let it be $m$ from $P$. If no message has been signed for $P$ yet, then sign $s_A \leftarrow \text{sign}(sk_A, (P, m))$ and send $s_A$ via $\mathcal{F}_\text{SMT}$ back to $P$.

6.6 Auditing

Each user $U$ in the system is assigned an auditor $AU$, which can decrypt all transaction information related to $U$. Notably, the transaction outputs owned by $U$ and the full content of transactions produced by $U$. We denote the set of auditors by $AU$.

We formalize next our security guarantees using functionality $\mathcal{F}_\text{TOKEN}$. $\mathcal{F}_\text{TOKEN}$ stores a list of registered users and an initially empty map Records and has as a session identifier $sid = (A, C, I, AU, sid')$.

- Upon input init from $P \in \{A, C, I\} \cup AU$, output to $\mathcal{A}$ (initialized, $P$). (This must happen for all before anything else.)

- For inputs register, read, issue and deliver see $\mathcal{F}_\text{TOKEN}$.

- For inputs issue, register, read, issue and deliver see $\mathcal{F}_\text{TOKEN}$.

- Upon input (bind, $U, AU')$ from $A$, where $U$ is a registered user and $AU \in AU$ is an initialized auditor, and there is not yet a pair $(U, AU')$ with $AU \neq AU'$ in AU, record $(U, AU)$ and output (bound, $U, AU$) to $\mathcal{A}$. 
• Upon input \(\{\text{transfer}, (cm)_{j=1}^{n}, (v_{j}^\text{out}, R_{j})_{j=1}^{n}\}\) from an honest party \(P\), where \(P\) and \(P'\) are registered, proceed as follows.

1. If, for any \(i \in \{1, \ldots, m\}\), \(\text{Records}[cm]_i = \perp\) then abort, else set \((v_{j}^\text{in}, P', st_i) \leftarrow \text{Records}[cm]_i\).
2. If, for any \(i \in \{1, \ldots, m\}\), \(st_i \neq \text{alive or } P'_i \neq P\), then abort.
3. If \(\sum_{i=1}^{m} v_{j}^\text{in} = \sum_{j=1}^{n} v_{j}^\text{out}\) then abort.
4. Let \(L\) be an empty list. For all \(i, j, n, r, P\) or its auditor \(A_{U}\) are corrupt, then append to \(L\) the information \((P, R, v_{j}^\text{in})\). If the auditor \(A_{U}\) of \(P\) is corrupt, include the information for all inputs and all outputs. Output \((\text{transfer}, L)\) to \(A\).
5. Receiving from \(A\) a response \((\text{transfer}, (cm)_{j=1}^{n})\), if \(\text{Records}[cm]_{j} = \perp\) for any \(j \in \{1, \ldots, n\}\) then abort, else set \(\text{Records}[cm]_{j} \leftarrow (v_{j}^\text{in}, R_{j}, \text{delayed})\) for all \(j \in \{1, \ldots, n\}\) and for all \(i \in \{1, \ldots, m\}\) set \(\text{Records}[cm]_{i} \leftarrow (v_{i}^\text{in}, P, \text{consumed})\).
6. Return \((\text{transfer}, cm)_{j=1}^{n})\) to \(P\).

• Upon input \((\text{audit}, cm)\) from auditor \(A_{U}\), if \(\text{Records}[cm] = \perp\) then return \(\perp\). Otherwise, set \((v, P, st) \leftarrow \text{Records}[cm]\).

The protocol is adapted as follows. First, each commitment also contains the identity of the previous owner. This is not technically necessary but helps prove that the auditable information is correct while keeping the description here compact. The binding between the auditor and the user is achieved through a (structure-preserving) NIZK proof: 

\[
\text{PK}\{v^\text{in}, P, P', \rho^\text{in}, \sigma, pk_{AU}, s_A, r_1, r_2, r_3\}:
\]

\[
\text{verify}(pk_{C}, (v^\text{in}, P, P', \rho^\text{in}, \sigma),) \\
\wedge \text{verify}(pk_{A}, (P, pk_{AU}), s_A) \wedge c_1 = \text{enc}(pk_{AU}, P, r_1) \\
\wedge c_2 = \text{enc}(pk_{AU}, R, r_2) \wedge c_3 = \text{enc}(pk_{AU}, v^\text{out}, r_3)
\]

Then \(P\) also gets the resulting ciphertexts in the transfer transaction, and proves that the encryption is consistent with the information in the commitments.

For concreteness, consider an input described by commitment \(cm = \text{commit}(crs, (v^\text{in}, P, P', \rho^\text{in}), r_{cm})\). We encrypt current owner \(c_1 = \text{enc}(pk_{AU}, P, r_1)\) and value \(c_2 = \text{enc}(pk_{AU}, v^\text{out}, r_2)\). Then we generate a NIZK proof:

\[
\text{PK}\{v^\text{out}, R, P, r^\text{out}, r_{cm}, pk_{AU}, s_A, r_1, r_2, r_3\}:
\]

\[
\text{open}(crs, cm, (v^\text{out}, R, P, r^\text{out}), r_{cm}) \\
\wedge \text{verify}(pk_{A}, (P, pk_{AU}), s_A) \wedge c_1 = \text{enc}(pk_{AU}, P, r_1) \\
\wedge c_2 = \text{enc}(pk_{AU}, R, r_2) \wedge c_3 = \text{enc}(pk_{AU}, v^\text{out}, r_3)
\]

with public parameters \(crs\) and \(pk_{A}\), as well as \(cm\), \(c_1\), \(c_2\), and \(c_3\) taken from the transaction.

Appendix C provides details on how to instantiate the above protocol using well-established primitives that do not require any complex setup assumptions.

### 6.7 Security analysis

This section shows that the protocol in Section 6.5 instantiates functionality \(F^\text{Token}\).

#### Theorem 6.1

Assume that \(COM = (\text{ccrs gen, commit, open})\) is a perfectly hiding and computationally binding commitment scheme. Assume that \(VRF = (v\text{keygen, eval, check})\) is a verifiable random function. Then \(F^\text{Token}\) realizes \(F^\text{Token}\) with static corruption. Corruption is malicious for all users, and honest-but-curious for \(C\). \(A\) is required to be honest, but is inactive during the main protocol phase.

The restriction that \(C\) is only honest-but-curious is necessary; otherwise \(C\) can sign arbitrary commitments, even ones that are not stored in \(F^\text{Ledger}\). The proof is deferred to Appendix B.

### 7 IMPLEMENTATION AND PERFORMANCE

To evaluate our protocol, we implemented a prototype using the primitives described in Appendix C. By design, our prototype is compatible with Hyperledger Fabric and requires minimal changes to be integrated. This section elaborates on the integration effort and measures the overhead incurred by our scheme.

#### 7.1 Hyperledger Fabric

Hyperledger Fabric is a permissioned blockchain system in which entities exchange messages, called transactions. A transaction is used to introduce either a new smart contract (chaincode in Hyperledger Fabric terms) into the system or changes to the state of an already existing chaincode. The first process is called chaincode instantiation, whereas the latter is referred to as chaincode invocation. A special type of transactions, reconfiguration transactions, is used to introduce changes to the system configuration.

In Hyperledger Fabric, we identify three types of participants: (i) clients who submit transactions to the network in order to instantiate or invoke chaincodes, or to reconfigure the system; (ii) peers which execute chaincodes, validate transactions and maintain a (consistent) copy of the ledger; and (iii) orderers which jointly decide the order in which transactions would appear in the ledger.

For the proper operation of the system, each instance of Hyperledger Fabric considers one or more membership service providers (in short, MSPs) that issue long-term identities to parties falling under their authority. These identities allow system entities to securely interact with each other; essentially, MSPs provide the required abstractions to compute and verify signatures. The configuration
of valid MSPs is included in the genesis block of each Hyperledger Fabric instance and is updated via reconfiguration transactions.

Hyperledger Fabric follows an execute-order-validate model. Here, chaincodes are speculatively executed on one or more peers upon a client request, called chaincode proposal, prior to submitting the resulting transaction for ordering. Execution results are signed by the peers that generated them in chaincode endorsements and are returned to the client who requested them. Endorsements (i.e. peer signatures) are included in the transaction that the client constructs and sends to the ordering service. The latter orders the transactions it receives and outputs a first version of the ledger called raw ledger. Raw ledger is provided to the peers of the network upon demand. Upon receiving the raw ledger, peers validate the ordered transactions against the endorsement policy of their origin chaincodes. An endorsement policy specifies the endorsements that a transaction should carry to be deemed valid. If validation completes successfully, the transaction is committed to the ledger.

Notice that although there is a separation in Hyperledger Fabric between clients and peers, there still is a communication channel between the two, leveraged by the clients to acquire endorsements on the chaincodes they wish to invoke, and perform queries on the ledger state. In the following section, we show how to make use of this channel to extend Hyperledger Fabric with our protocol.

7.2 Integration architecture

We first require that each issuer, user and auditor operates a Hyperledger Fabric client. These clients are used to generate an issue or transfer transactions, submit token certification requests and read from the ledger. Along these lines, we outsource the cryptographic operations required to generate token transactions to a prover chaincode in the aim of alleviating the load at the client. This setting assumes that each client possesses a peer that she trusts with the computation of the zero-knowledge proofs and serial numbers. We contend that this is a reasonable assumption especially for Hyperledger Fabric that focuses on enterprise applications.

We also make use of the already-existing communication protocol between the clients and the peers to implement what we call, for convenience, certifier chaincode. This is a chaincode that runs only on a selective set of peers chosen at setup time and trusted to jointly certify valid tokens, following the protocol in Appendix D. Each such a peer is endowed with a share of the certification signing key, and whenever invoked, provides its share to the certifier chaincode.

Finally, we leverage the membership service infrastructure of Hyperledger Fabric to grant long-term identities to issuers and users. In particular, we integrate the identity mixer MSP of Hyperledger Fabric with our solution to allow privacy preserving user authentication. To assign auditors to users, we use an off-hand channel to bind identity mixer user identities with auditor encryption public keys. In a real implementation, this could be accommodated by an external identity management service, preferably distributed.

Notice that our protocol uses the ledger only as a time-stamping service, without any validation functionalities; those are offloaded indirectly to certifiers and auditors. This could be supported in Hyperledger Fabric directly by setting the endorsement policy of the prover chaincode to any. We note that we plan to extend our prototype to allow the ledger to also validate token transactions. More concretely, we intend to exploit the fact that Hyperledger Fabric supports pluggable transaction validation [35] that allows chaincodes to specify their own custom validation rules, in our case, the custom validation would consist of verifying the ZK proofs.

7.3 Performance numbers

We installed Hyperledger Fabric client and peer infrastructure on a MacBook Pro (15-inch, 2016), with 2.7 GHz Intel Core i7, and 16 GB of RAM. We implemented our prototype in golang, as this is the core language of Hyperledger Fabric, and used EC groups in BN256 curves. We instantiated both prover and certifier chaincodes on all the peers in the network, while disseminating the secret shares needed for token certification only to the peers reserved for that purpose. For efficiency reasons, we used Schnorr proofs [46] to implement some of the zero-knowledge proofs.

We measured the time required to produce and validate a transfer transaction as these operations are the most costly. We produced our results using the measurements of 100 runs of each operation.

Our results are shown in Table 1 for transfers with two inputs and two outputs. Although our scheme supports an arbitrary number of inputs and outputs, we opt for this combination as it is the most common configuration in existing schemes. We assume that there is one certifier and that the maximum value of a token that can be issued or transferred at anytime is capped at 216.

In the performance evaluation of transaction generation and validation, we present separately the overhead resulting from (i) checking that the input and outputs preserve value and type; (ii) hiding the transaction graph, cf. entries token validity and serial numbers; (iii) and auditability. Our measurements show that the overall transaction construction time is little less than 2s, whereas transaction validation takes a little less than 3s. Auditability is the most expensive operation as it requires the generation and the verification of multiple proofs of correct encryption under obfuscated public keys; around 2/3 of the overall computation time. Second comes the operations that hide the transaction graph with proof generation time of almost 0.5s and verification time of roughly 0.7s. This shows that in applications where auditability and full privacy are not a priority, our solution performs relatively-well, less than 158ms for transaction generation and 287ms for its verification. Our performance figures exclude proofs of ownership as the performance of those is outweighed by the Identity Mixer overhead.

While these numbers are not yet favorable to a wide adoption, we would like to stress that the AMCL library underlying our implementation is not optimized. An optimization in the crypto libraries is expected to bring in a speedup of at least one order of magnitude [36]. We also note that the current implementation did not investigate possibilities of parallelization.

We also measured the time it takes to get a token certificate. Table 1 shows that the computation at the user takes around 199ms, whereas the overhead at the certifier is 123ms.

---

1The auditor assignment requires structure preserving signatures, which as of now lack single-round distributed instantiations.

2To preserve universal composability one would need to use an online extractable variant of Schnorr proofs.
through the use of structure-preserving primitives, we achieve practical transaction size and near-practical computation times that are expected to become practical once an optimized implementation of the underlying schemes is available.

## 8 CONCLUSION

We described a privacy-preserving and auditatable token management scheme for permissioned blockchains, which is instantiated without complex setup and relies only on falsifiable assumptions. Through the use of structure-preserving primitives, we achieve practical transaction size and near-practical computation times that are expected to become practical once an optimized implementation of the underlying schemes is available.

### Table 1: Performance numbers of token certification and transfer in milliseconds (ms). Transaction size is a little over 63KB; this figure however can be further optimized.

## REFERENCES

[34] https://www.goquorum.com/.

A FUNCTIONALITIES

We describe here in more detail some ideal functionalities that are commonly used and that we therefore omitted from the preliminaries of the paper.

Functionality \( F_{\text{crs}} \)

\( F_{\text{crs}} \) is parametrized by a probabilistic algorithm crs gen. Initially, it sets \( \text{crs} \leftarrow \text{crs gen}(\lambda) \).

1. On input read from a party \( P \), return \( \text{crs} \) to \( P \).

Figure 6: Common reference string

A.1 Common reference string

Functionality \( F_{\text{crs}} \) is parametrized by a CRS generator crs gen, which on input of security parameter \( \lambda \) samples a fresh random string \( \text{crs} \leftarrow \text{crs gen}(\lambda) \).

Functionality \( F_{\text{NIZK}}^{R} \)

\( F_{\text{NIZK}} \) is parametrized by a relation \( R \) for which we can efficiently check membership. It keeps an initially empty list \( L \) of proven statements and a list \( L_0 \) of proofs that do not verify.

1. On input \( (\text{prove}, y, w) \) from a party \( P \), such that \( (y, w) \in R^a \), send \( (\text{prove}, y) \) to \( A \).
2. Upon receiving a message \( (\text{done}, \psi) \) from \( A \), with \( \psi \in \{0, 1\}^* \), record \( (y, \psi) \) in \( L \) and send \( (\text{done}, \psi) \) to \( P \).
3. Upon receiving \( (\text{verify}, y, \psi) \) from some party \( P \), check whether \( (y, \psi) \in L \), then return \( 1 \) to \( P \), or whether \( (y, \psi) \in L_0 \), then return \( 0 \) to \( P \). If neither, then output \( (\text{verify}, y, \psi) \) to \( A \) and wait for receiving answer \( (\text{witness}, w) \). Check \( (y, w) \in R \) and if so, store \( (y, \psi) \) in \( L \), else store it in \( L_0 \). If \( (y, \psi) \) is valid, then output \( 1 \) to \( P \), else output \( 0 \).

\(^a\)Inputs that do not satisfy the respective relation are ignored.

Figure 7: Non-interactive zero-knowledge functionality based on the one described by Groth et al. [28].

A.2 Non-interactive zero-knowledge

Our functionality \( F_{\text{NIZK}} \) is adapted from the work of Groth et al. [28], with a few modifications, most of which are mainly stylistic. The most relevant difference is that we store a set \( L_0 \) of false statements that have been verified. We need this to ensure that a statement that was evaluated as false by one honest party will also be evaluated as false by all other honest parties. Otherwise \( F_{\text{NIZK}} \) has the two expected types of inputs \text{prove} and \text{verify}, and the adversary is allowed to delay proof generation unless \( F_{\text{NIZK}} \) is used in the context of responsive environments [8].

A.3 Secure message transmission

Functionality \( F_{\text{smt}} \) models a secure channel between a sender \( S \) and a receiver \( R \). In comparison to the functionality introduced by Canetti and Krawczyk [16], our functionality additionally provides privacy and hides the parties that are involved in the transmission.

A.4 Digital signatures

We use the variant of the signature functionality \( F_{\text{sig}} \) that was introduced by Camenisch et al. [6]. This version of the functionality is compatible with the modular NIZK proof technique introduced in the same paper.

A.5 Distributed key generation

Functionality \( F_{\text{kg}} \) idealizes a distributed key-generation protocol such as, for discrete-log based schemes, the one of Gennaro et al. [24]. The simplified functionality given in Figure 10 is not directly realizable since it does not model for example that the communication may be delayed or prevented by the adversary. We decided to still use this version to simplify the overall treatment.
This section proves Theorem 6.1. We use the composition result $S$ below.

For all valid transactions $tx$ where in the meantime the corresponding private message (request, $P$, crs, $cm_j$) is delivered to $F_{BLINDSIG}$, input (deliver, $cm_j$) to $F_{TOKEN}$.

- When $A$ instructs $S$ to deliver a message (token, $cm_j$, $r_F^{out}$, $r_F^{out}$) anonymously to its receiver, simulate the corresponding private delayed message (request, $P$, crs, $cm_j$) from $F_{BLINDSIG}$.

- Upon receiving (read?, $P$) from $F_{TOKEN}$, process pending messages and return (read!, $P$) to $F_{TOKEN}$.

- On receiving (issue, $v$) from $F_{TOKEN}$, first process pending messages. Then, generate a new all-zero commitment ($cm_j$, $r_F^{out}$) and compute (token, $cm_j$) to commit($crs$, $(0, 0, 0))$. Next, emulate an output (prove, $y$) from $F_{NIEK}$ for the statement $y = (crs, cm_j, v, l)$ and proceed upon input an answer done, $\psi_0^F$ for the same instance of $F_{NIEK}$. Emulate the signature $s'$ as in $F_{SIG}$, storing the respective instance as a record. Append (issue, $v$, cm, $\psi_0^F$, $s'$) to the internal ledger. Input (issue, cmj) to $F_{TOKEN}$.

- Upon receiving (transfer, $m$, $n$, $L$) from $F_{TOKEN}$, first process pending messages. For each $i = 1, \ldots, m$ generate a random serial number $m_i$. Then proceed as follows for $j = 1, \ldots, n$. If there is no entry for $j$ in $L$, then generate a commitment ($cm_j$, $r_F^{out}$) to commit($crs$, $(0, 0, 0))$. If there is an entry $(j, P, \psi^j_F)$, then randomly sample $\psi^j_F$ and compute (token, $cm_j$, $r_F^{out}$) to commit($crs$, $(\psi^j_F, R_j, r_F^{out})$). Next, emulate the output (prove, $y$) from $F_{NIEK}$ for instance $y = (pk_C, crs, (cm_j, r_F^{out})_{j=1}^n, p_s, (m_i, \psi^{m_i}_F)_{i=1}^L)$ and record the proof $\psi^j_F$ returned by $A$. Emulate the proofs $\psi^j_F, \ldots, \psi^n_F$ as in $F_{NIEK}$. Append (token, $cm_j, r_F^{out}, \psi^j_F$) to the internal ledger and emulate transmission of the messages of the same length as (token, $cm_j, r_F^{out}, v, l, \psi^j_F$) for the corresponding $j$ to $F_{TOKEN}$. When $A$ delivers a message on $F_{NIEK}$, input (deliver, $cm_j$) for the corresponding $j$ to $F_{TOKEN}$.

- Upon input (append, $x, P'$) from $A$ for a corrupt $P'$, append $x$ to the ledger and mark for delayed processing. Return to $A$.

If $S$ obtains from $A$ a query to $F_{AUTH}$ in the name of a corrupt party $P$ that is marked as registered, then $S$ internally handles the inputs prove and verify just like $F_{AUTH}$. If $A$ provides an input message $x$ to $F_{AUTH}$ on behalf of a corrupted party $P$, then the message is ignored unless it is of the format $x = (token, cm, crs, \psi, v, l)$. If it has the right format, then $S$ checks whether the corresponding transaction $tx$ exists on $F_{EDGERS}$; if it does, then input the respective deliver message to $F_{TOKEN}$. If such a transaction does not exist, then store the message $x$ for later.

Our goal is now to prove that if the commitment and the VRF are secure, then the ideal and real experiments are indistinguishable. We prove this by describing a sequence of experiments, where EXECD is the real experiment and we transform it step-by-step into the ideal experiment, showing for each adjacent pair of steps that they are indistinguishable. The overall statement then follows via the triangle inequality.

Experiment EXECD is almost the same as EXECD but commitments generated during (issue, v) at an honest party $P$ as well as commitments generated during (transfer, $\ldots$) at an honest party $P$,
where receiver $R$ is also honest, are replaced by commitments generated via $(cm, r_{cm}) \leftarrow \text{commit}(crs, (0, 0, 0))$. Functionality $F_{\text{NIZK}}$ is changed so that it does not actually check the input of honest parties.

Experiments $\text{EXEC}_0$ and $\text{EXEC}_1$ are equivalent since the commitment is perfectly hiding and therefore the distribution of the output to the adversary is unchanged. As all inputs of the honest parties’ protocols to $F_{\text{NIZK}}$ are correct, omitting the checks has no effect.

Experiment $\text{EXEC}_2$ is almost the same as $\text{EXEC}_1$ but serial numbers output by honest parties are replaced by uniformly random values from the same set. Experiments $\text{EXEC}_2$ and $\text{EXEC}_1$ are indistinguishable because of the pseudorandomness of VRF, which is easily proved by reduction. Note that the environment never sees honestly generated proofs.

In the following, we describe the response to environment queries in both $\text{EXEC}_2$ and the ideal experiment and point out the differences. We assume that the state in terms of valid commitments is the same prior to the environment’s query, and show that the output to the query is the same and the state in terms of valid commitments remains consistent. The consistency of the input-output behavior is relatively straightforward to check for most inputs. We focus here on the ones used in $\text{transfer}$.

- On input $(\text{transfer}, \ldots)$ from an honest user $P$, if not both of $P$ and all $R_1, \ldots, R_n$ are registered, then the request is ignored in both cases. Also if not all transferable commitments $cm_1, \ldots, cm_m$ exist and are associated to user $P$, both invocations abort. The protocol $\pi_{\text{TOKEN}}$ then generates new commitments $cm'_1, \ldots, cm'_n$ and send them for the proof to $F_{\text{NIZK}}$, which requests a proof $\psi_i$ from $A$. Upon return, $\pi_{\text{TOKEN}}$ generates an additional proof $\psi_j$ via $F_{\text{TOKEN}}$ and sends the transaction $(\text{transfer}, \ldots)$ to $F_{\text{LEDGER}}$ and the token messages to $F_{\text{SAT}}$. If any $R_j$ is corrupt, this latter invocation means that $A$ learns $(r_{cm}^j, \psi_j^{\text{out}}, \psi_j^{\text{out}})$ as well as the sender $P$ via $F_{\text{SAT}}$ in addition.

The functionality $F_{\text{TOKEN}}$ provides either just $m, n$—if all $R_1, \ldots, R_j$ are honest—or the values $(j, P, R_j, \psi_j^{\text{out}})$ for each corrupt $R_j$. In the first case, $S$ generates a commitment to all-zero messages and requests the proof $\psi_j$ from $A$ via $F_{\text{NIZK}}$-interaction, in the second case $S$ has all the data available to perform the same computations as the protocol.

The output distribution is the same since in both cases the commitment is an all-zero commitment and the serial number is uniformly random.

- Processing of pending transactions. For all new (possibly adversarial) transactions on $F_{\text{LEDGER}}$, the honest parties first attempt to verify the proofs via $F_{\text{NIZK}}$. For adversarially-generated proofs, the first attempt for each such proof may lead to a message from $F_{\text{NIZK}}$ requesting the witness from $A$. The same messages are generated by $S$, which then records the messages and issues the proper requests to $F_{\text{TOKEN}}$. (Note that this processing in $F_{\text{TOKEN}}$ takes place at this point in time, but the timing is indistinguishable from that in the protocol as each honest user input leads to that user processing the pending transactions in the protocol.)

For (passively) corrupt $A$, if a commitment $cm$ is delivered to the receiver, the simulator learns the receiver’s identity and emulates the behavior in the real protocol where $C$ also learns both the commitment and the identity of the receiver.

For adversarial transfers sent to the party via $F_{\text{SAT}}$, it may mean that the message sent on $F_{\text{SAT}}$ is not proper (so it is ignored by both $\pi_{\text{TOKEN}}$ and $S$), or that it parses correctly but it does not have a corresponding transaction in $F_{\text{LEDGER}}$ (in the sense that the commitment $cm'$ in the message does not exist there—then it is also ignored), or that both message and transaction can be found, in which case the view of the party changes when the tokens are found.

The only difference between the two above executions is when the adversary fabricates a transaction in the name of a corrupt party that makes a state transition that is different from the one that is done in $F_{\text{TOKEN}}$. Let us first consider $\pi_{\text{Issue}}$ transactions, where the statement is $y = (crs, cm', v, I)$. When an honest party verifies the proof with $F_{\text{NIZK}}$, then $A$ has to provide a proper witness $(r_{cm}, \rho^*)$ such that open$(crs, cm', (v, I, \rho^*), r_{cm}) = \text{true}$.

Consider transaction $tx = (\text{transfer}, (sn^1_j, \psi^1_j)_{i=1}^m, (cm^1_j)_{j=1}^n, \psi^1_i)$ input by the adversary. When $\psi^1_i$ is verified by the honest party, then $A$ is given the statement $y = (pk_C, (crs, cm^i_j, \psi^1_i)_{i=1}^m, \pi)$ and sends a witness $w = ((s_i, v^i_j, \rho^i_j, \pi^i)_{i=1}^m, P, s_h, (R_j, r_{cm}^j, \psi^{\text{out}}_j, \psi^{\text{out}}_{j=1})^n)$ as a response, that satisfies the following PK-statement

$$\begin{align*}
\text{PK} & \{((s_i, v^i_j, \rho^i_j, \pi^i)_{i=1}^m, P, s_h, (R_j, r_{cm}^j, \psi^{\text{out}}_j, \psi^{\text{out}}_{j=1})_{j=1}^n) : \\
& \quad \forall i \in \{1, \ldots, m\} : \text{verify}(pk_C, (v^i_j, P, \rho^i_j, s_i)) \\
& \quad \land \forall j \in \{1, \ldots, n\} : \text{open}(crs, cm^j_i, (\psi^{\text{out}}_j, R_j, \rho^j_{out}), r_{cm}^j) \\
& \quad \land \text{verify}(pk_{\pi^1}, (P, v^i_j), s_h) \\
& \quad \land \forall i \in \{1, \ldots, m\} : \text{check}(v^i_j, \rho^i_j, s_h, \pi) \\
& \quad \land \sum_{i=1}^m v^i_j = \sum_{j=1}^n \psi^{\text{out}}_j \\
& \quad \land \forall j \in \{1, \ldots, n\} : 0 \leq \psi^{\text{out}}_j \leq \text{max}\}
\end{align*}$$

As verify$(pk_C, (v^i_j, P, \rho^i_j), s_i)$ are evaluated via $F_{\text{BLS}}$ and $C$ checks the correctness of $crs$, we also know that $s_1, \ldots, s_m$ were generated for inputs (request, $crs, cm^i_j, (v^i_j, P, \rho^i_j)$), and the commitment $cm_i = \text{commit}(crs, (v^i_j, P, \rho^i_j); r_{cm}^j)$ indeed exists on the ledger. Then either $cm_i$ was created during a previous transaction with the same input $(v^i_j, P, \rho^i_j)$ or we can turn $\mathcal{Z}$ into an adversary that breaks the binding property of COM.

As verify$(pk_{\pi^1}, (P, v^i_j), s_h)$ is evaluated via a call to $F_{\text{SIG}}$, and the correctness of both $F_{\text{SIG}}$ and the honesty of $A$ implies that $v^i_j$ is the unique VRF public key associated to $P$. So at this point we know that $\pi^1_j$ and $\rho^i_j$ are correct. As check$(v^i_j, P, v^i_j, s_h, \pi) = \text{true}$, either $(s^1_i, \ldots) \leftarrow \text{eval}(v^i_j, \rho^i_j)$ or we can turn $\mathcal{Z}$ into an adversary against the soundness of VRF. This means that $s^1_i$ is also correct, no double-spending occurred. The last two lines mean that the sum of all output values and the sum of all input values are the same, so the overall value is preserved (and the input provided by the simulator is accepted by $F_{\text{TOKEN}}$).

The construction has negligible correctness error due to collision of serial numbers.
C INSTANTIATION

C.1 Pedersen commitments

The commitment scheme is instantiated with Pedersen commitments [41] on multiple values. Consider a group \( G \) and generators \( g_0, g_1, \ldots, g_r \in G \) such that the relative discrete logarithms between the \( g_i \) are not known. A commitment to a vector \((x_1, \ldots, x_l) \in \{1, \ldots, |G|\}^l \) of inputs is computed by choosing a uniformly random \( r \in \{1, \ldots, |G|\} \) and computing \((cm, cm) \leftarrow (g_0^{x_1} \cdot g_r^r, r)\). Pedersen commitments are perfectly hiding and computationally binding under the discrete-logarithm assumption in group \( G \).

C.2 Pointcheval-Sanders (PS) signatures

We use the signature scheme of Pointcheval and Sanders [43] to implement the blind signature used for token certification. The functionality \( \Pi \) implements the blind signature used for token certification. PS signatures are CMA-secure under an interactive computation.

C.3 Certification through blind signatures

The functionality \( F_{\text{BLINDSIG}} \) is instantiated with the following protocol \( \pi_{\text{BLINDSIG}} \), which operates in the \( \{ F_{\text{NIZK}}, F_{\text{REG}}, F_{\text{SMT}} \} \)-hybrid model. \( \pi_{\text{BLINDSIG}} \) is based on the Coconut system proposed by Sonnino et al. [47], with the only difference that we sign a vector of messages instead of a single message. Let \( H_G : G_1 \rightarrow G \) denote a cryptographic hash function modeled as a random oracle.

- Upon input \((\text{prove}, y, w)\) at \( F_{\text{NIZK}} \) with \( y = (cm, h, u, a_1, \ldots, a_t, b_1, \ldots, b_t) \) and \( w = ((m_1, r_1)^{f_1}_{\ell=1}, \ldots, (m_t, r_t)^{f_t}_{\ell=1})\),
  - Call \( F_{\text{SMT}} \) with \((\text{send}, C, (\zeta, crs, cm, u, (a_i, b_i)^{f_i}_{\ell=1}))\).
  - Upon receiving \((\text{sent}, P, (\zeta, crs, cm, u, (a_i, b_i)^{f_i}_{\ell=1})\) from \( F_{\text{SMT}} \), signer \( C \) proceeds as follows:
    - Verify \( \xi \) via \( F_{\text{NIZK}} \) and compute \( h \leftarrow H_G(cm) \). If verification fails, inputs \((\text{send}, P, \perp)\) to \( F_{\text{SMT}} \) and stop.
    - Store \((\zeta, crs, cm, u, (a_i, b_i)^{f_i}_{\ell=1}, h)\) internally and output message \((\text{request}, P, \text{crs}, cm)\).
  - Upon input \((\text{sign}, cm)\):
    - Compute \( \hat{b} \leftarrow h^x \prod_{i=1}^{f_i} b_i^{u_i} = g^x \prod_{i=1}^{f_i} h^{m_i u_i} \) and \( \hat{a} \leftarrow \prod_{i=1}^{f_i} a_i^{u_i} = u' \).
    - Call \( F_{\text{SMT}} \) with \((\text{send}, P, (\hat{a}, \hat{b}))\).
  - Upon receiving \((\text{sent}, C, m)\) from \( F_{\text{SMT}} \), receiver \( P \) proceeds as follows:
    - If \( m \) cannot be parsed as \( (\hat{a}, \hat{b}) \) in \( G_1^2 \) output \((\text{result} 1, \perp)\) and stop.
    - Compute \( h' \leftarrow \hat{b} u^{-z} \) and check \( e(h, X) \prod_{i=1}^{f_i} \tilde{y}_i^{m_i} = e(h', g) \). If the check fails, output \((\text{result} 1, \perp)\) and stop.

As in Coconut [47], we use a deterministic variant of Pointcheval-Sanders signatures. Namely, generator \( h \) is not selected randomly in \( G_1 \), rather it is computed as the hash of commitment \( cm \). The reason behind this slight modification is to enable a non-interactive distributed signature (i.e. signers do not need to interact), see Appendix D for further details. It is easy to show that the security of this variant holds in the random-oracle model, cf. [47].

C.4 Groth signatures

We use Groth’s structure preserving signatures [27] to bind a user public key to an auditor public key. The signature scheme operates in a pairing setting with groups \( G_1, G_2 \) and \( \mathbb{G}_T \), and messages in \( G_1 \). Let \( g \) and \( \overline{g} \) be random generators of \( G_1 \) and \( G_2 \) respectively. Key generation \( \text{keygen}(\lambda, t) \) selects a vector \( sk = (x, y_t, \ldots, y_1) \) and a random generator \( h \leftrightarrow G_1 \), and computes \( pk \leftrightarrow (h, X, Y_1, \ldots, Y_t) \) and \( e(s_i, X \prod_{j} \tilde{y}_j^{m_j}) = e(s_i, g) \).

C.4.1 Dodis-Yampolskiy VRF. We use the VRF of Dodis and Yampolskiy [20] that operates in the pairing setting. Key generation \( \text{keygen}(\lambda) \) chooses a random \( sk \leftrightarrow \mathbb{Z}_p \) and sets \( pk \leftrightarrow g^x \). Evaluation eval \((sk, x)\) aborts if \( x \not\in \mathbb{Z}_p \). It computes output \( y \leftarrow e(g, \overline{g})^1/(sk + x) \) and \( \pi \leftarrow g^1/(sk + x) \) in \( \mathbb{G}_T \). Verification check \( \text{check}(pk, x, y, \pi) \) checks whether \( e(g, \pi) = y \) and \( e(pk \cdot g^x, \pi) = e(g, \overline{g}) \); if so it outputs \( b = 1 \).

C.5 Groth-Sahai NIZK

Since all equations we have to verify — for the Pointcheval-Sanders signatures, the Pedersen commitments, the Groth signatures, and
the Dodis Yampolskiy VRF — are defined in terms of bilinear groups, we propose to use Groth-Sahai proofs [29] to instantiate $\mathcal{F}_\text{NIK}$ in our solution.

C.6 ElGamal public-key encryption

We use ElGamal encryption [21]. Key generation $\text{keygen}(\lambda)$ chooses a uniformly random exponent $sk \leftarrow \{1, \ldots, |\mathcal{G}|\}$ and computes $pk \leftarrow g^{sk}$. Encryption $\text{enc}(pk, m)$ chooses a uniformly random $r \leftarrow \{1, \ldots, |\mathcal{G}|\}$ and computes $c \leftarrow (g^r, pk^r m)$. Decryption $\text{dec}(sk, c)$ with $c = (c_1, c_2)$ computes $m = c_2 c_1^{-sk}$. The encryption scheme is semantically secure⁵ and key private under the decisional Diffie-Hellman assumption.

C.7 Range proofs

Our protocol requires range proofs to ensure that no field wrap-arounds are exploited to increase the quantity of tokens in a transfer. The range proof we use is based on the work of Camenisch, Chaabouni, and shelat [5], instantiated with Pointcheval-Sanders signatures.

D DISTRIBUTING CERTIFICATION

The Pointcheval-Sanders signature scheme can be extended into a non-interactive $t$-out-of-$n$ threshold signature scheme. Consider $n$ signers $C_1, \ldots, C_n$ from which a party $P$ collects at least $t$ signature shares that can be combined into a complete signature. We describe the process with a trusted key generation, however, notice that it is straightforward to convert the key generation mechanism into a multiparty computation between the signers (see e.g. [24]). We describe the key generation algorithm $\text{keygen}$ and the reconstruction algorithm $\text{recon}$ combine. The algorithm to produce a signature share is identical to original signing algorithm (taking secret key share as input instead of the overall secret key). That is, to sign a message $(m_1, \ldots, m_t)$, signer $C_j$ calls algorithm $(h, h') \leftarrow \text{sign}(sk_j, (m_1, \ldots, m_t))$ with $sk_j = (x_j, y_{i1j}, \ldots, y_{itj})$. The resulting signature share is a valid Pointcheval-Sanders signature for public key $pk_j = (X_j, Y_{1j}, \ldots, Y_{tj})$.

Algorithm $\text{keygen}(\lambda, n, t, \ell)$ computes $(sk_j, pk_j)_{j=1}^n$, $pk$ as follows:

- Compute Lagrange coefficients $\lambda_j = \prod_{i \in S \setminus j} \frac{\ell}{j-i}$ for all $j \in S$.
- Compute and output $(h, h' = \prod_{j \in S} h^{\lambda_j})$.

Protocol $\pi_{\text{BLINDSIG}}$ from Appendix C.3 has to be modified as follows:

- Instead of generating a key locally at $C$, all signers $C_1, \ldots, C_n$ together use $\mathcal{F}_\text{DKG}$ to generate the set of keys. Signer $C_1$ registers the public key $pk$ at $\mathcal{F}_\text{DKG}$.
- Requestor $P$ sends the request message to parties $C_1, \ldots, C_n$ until it has collected $t$ signatures that verify. It then uses combine to combine that into a single signature that verifies relatively to $pk$.

**Theorem D.1.** Let $n \in \mathbb{N}$ and $t < n$. The above-described variant of the protocol realizes the threshold variant of $\mathcal{F}_{\text{BLINDSIG}}$.

No further adaptations to the users’ protocol beyond the use of the threshold functionality are necessary, as the verification equation for the signatures remains the same.

---

⁵Our protocol only requires a semantically secure encryption thanks to transaction authentication via $\mathcal{F}_\text{auth}$. The latter ensures that the content of the transaction cannot be tampered with without detection.
