Abstract. Lattice-based public-key encryption has a large number of design choices that can be combined in diverse ways to obtain different tradeoffs. One of these choices is the distribution from which secret keys are sampled. Numerous secret-key distributions exist in the state of the art, including (discrete) Gaussian, binomial, ternary, and fixed-weight ternary. Although the choice of the distribution impacts both the concrete security and performance of the schemes, it has not been compared explicitly how the choice of secret-key distribution affects this tradeoff. In this paper, we compare different aspects of secret-key distributions that appear in submissions to the NIST post-quantum standardization effort. We first consider their impact on concrete security (influenced by the entropy and variance of the distribution), on decryption failures and IND-CCA2 security (influenced by the probability of sampling keys with “non average, large” norm), and on the key sizes. Next, we select concrete parameters of an encryption scheme instantiated with the above distributions, optimized for key sizes, to identify which distribution(s) offer the best tradeoffs between security and performance.

We draw two main conclusions from the results of the above optimization. Firstly, fixed-weight ternary secret keys result in the smallest key sizes of the encryption scheme. Such secret keys reduce the decryption failure rate and hence allow for a higher noise-to-modulus ratio, alleviating the slight increase in lattice dimension required for countering specialized attacks that apply in this case. Secondly, fixed-weight ternary secret keys result in the scheme becoming more secure against decryption failure-based IND-CCA2 attacks, as compared to secret keys with independently sampled components.

1 Introduction

Recent advances in the development of quantum computers have made a long-standing threat against classical cryptography concrete.
At present, is not clear when a general-purpose quantum computer will become available and this threat will manifest [24,59]. Nevertheless, given the widely recognized difficulties of migrating to new cryptographic infrastructures [30] as well as the long-term confidentiality requirements on data currently exchanged, efforts towards the standardization [53,25] of post-quantum cryptography [14] have already begun. Lattice-based cryptography [54] has received significant attention [17,45] as a candidate for quantum-safe cryptography due to its well-understood mathematical foundations, efficiency, and flexibility. However, the design of lattice-based cryptosystems can be challenging as various tradeoffs and interactions between design aspects must be accounted for. In the design of lattice-based public-key encryption (PKE) schemes, aspects which must be considered include the choice of structure in the underlying lattice [57,49,46], the choice of independent or implicit noise [11], the choice of the noise distribution [15,50,6], and the choice of the secret-key distribution. All these affect the resulting security, operation and performance of the final scheme. Figure 1 summarizes the influence on these aspects of the choice of secret-key distribution, which is our focus in this paper.

Secret-key distributions can be characterised by their variance and entropy, which both impact on security. A secret key with low variance makes concrete attacks on the scheme easier [6,2,10]. For example, in attacks utilizing lattice reduction (such as the primal [6] and dual [2] attacks), the secret key is part of a short lattice vector that is recovered as the solution to a lattice problem formulated using the scheme’s public key (and ciphertext). These attacks are improved by taking into account the imbalance between the norms of the secret key and error vector [10]. The entropy of the secret-key distribution is relevant for combinatorial attacks (such as the hybrid attack [35], and the sparse variant of the dual attack [2]) in which part of the secret key is recovered by guessing. Secret keys with lower entropy are easier to guess.

The secret-key distribution influences chosen-ciphertext or active attacks [26] that exploit decryption failures, because the secret key is directly involved in

Fig. 1: The impact of a lattice-based encryption/key-encapsulation scheme’s secret-key distribution on various aspects of the scheme.
decryption and thus affects the probability of such failure events occurring. An attacker who witnesses these failure events can build up statistical information on the secret-key, making recovery of the secret easier [21,31]. Finally, the secret-key distribution also affects the computational performance of the scheme, through sampling of keys and (polynomial or matrix) multiplications.

The design of fully homomorphic encryption schemes [27] implicitly accounts for the security and performance tradeoffs resulting from the use of secrets having low variance and/or low entropy, which are essential for controlling the noise growth in such schemes. Indeed, a ternary [60], or fixed-weight ternary [32], secret-key distribution is typically chosen in implementations. Accordingly, the Homomorphic Encryption Security Standard [1] recommends secure parameters for several choices of secret-key distribution, including ternary. However, to the best of our knowledge, there exist no works explicitly analyzing the role played by the secret-key distribution in the tradeoffs between security and performance in lattice-based encryption schemes.

1.1 Our contributions

In this work, we focus on the choice of the secret-key distribution when designing a lattice-based public-key encryption scheme, analyzing how this choice affects the scheme’s security, operation and performance. Our contributions are:

1. We compare a number of secret-key distributions used in NIST post-quantum candidates [53] with respect to different criteria such as variance, entropy and resulting probability of decryption failure.
2. We analyze the performance of a lattice-based public-key encryption scheme for the above secret-key distributions. We show in Table 1 (details in Section 4.3) that fixed-weight ternary secret keys lead to minimum bandwidth requirements, while remaining secure. Despite allowing specialized attacks,
3. We extend the analysis in [21] on the impact of decryption failures on the chosen-ciphertext (IND-CCA2) security of lattice-based encryption schemes. We show in Figure 2 (details in Section 5) that using fixed-weight ternary secrets, rather than ternary secrets with independently drawn components, makes the scheme less prone to attacks of the above form, since sampling larger-than-expected secrets is impossible. Moreover, we show the same is true for fixed-weight secrets with a larger support, and that this is independent of the scheme’s chosen error distribution.

1.2 Related work

The possibility of an attacker searching for ciphertexts that lead to a higher than expected probability of decryption failure in lattice-based public-key encryption was proposed by Jacob Alperin-Sheriff [7] and Mike Hamburg [33], as part of an
analysis of the NIST PQC candidate LAC \cite{47}. This was further analyzed by D’Anvers \textit{et al} in \cite{21}. Fixing the Hamming weight in the LAC cryptosystem was suggested by Hamburg \cite{33} as a possible countermeasure to the above attack, although a full analysis or rationale was not provided. Concurrent to this work, a subset of the techniques we propose – namely, fixing the (Hamming) weight of the secret-keys (and error vectors) – was independently used to stop the above attack \cite{7,33} in an updated version of LAC \cite{48, Section 1} submitted to the second round of the NIST PQC standardization process. However, the authors do not analyze how this technique stops the attack, nor do they generalize it to other schemes and distributions.

1.3 Organization

Section 2 introduces preliminaries and notation. Section 3 describes the secret-key distributions considered in this work. Section 4 first analyzes and compares the entropies, variances and probabilities of decryption failure for the different secret-key distributions in Sections 4.1 and 4.2. Next, Section 4.3 analyzes the (bandwidth) performance of a lattice (specifically, rounding)-based encryption scheme instantiated with the various secret-key distributions we consider, showing that fixed-weight ternary keys lead to the smallest bandwidth requirements. Section 5 analyzes the influence of the secret-key distribution on chosen-ciphertext (IND-CCA2) attacks that use decryption failures, showing that fixing the weight or number of secret key components makes such attacks harder. Section 6 concludes the paper.

2 Preliminaries

2.1 Notation

For each positive integer $a$, we denote the set of congruences modulo $a$ by $\mathbb{Z}_a$. We identify $\mathbb{Z}_a$ with the set \{0, 1, \ldots, a − 1\}. For a set $A$, we denote by $a \overset{\$}{\leftarrow} A$ that $a$ is drawn uniformly at random from $A$. For any polynomial $f(x)$, let $\mathcal{R}_f$ denote the polynomial ring $\mathbb{Z}[x]/f(x)$. For each positive integer $a$, we write $\mathcal{R}_{f,a}$ for the polynomials of degree less than that of $f(x)$, with all coefficients in $\mathbb{Z}_a$. We call a polynomial \textit{ternary} if all its coefficients are 0, 1 or $-1$. Throughout this document, regular font letters denote elements from a $\mathcal{R}_f$ defined for a polynomial $f(x)$. For any polynomial, its Hamming weight $h$ is defined as its number of non-zero coefficients. For $x \in \mathbb{Q}$, $\lfloor x \rfloor$ denotes rounding to the closest integer (with rounding up in case of a tie) respectively, and is extended coefficient-wise for elements (polynomials) of a defined $\mathcal{R}_f$.

2.2 Cryptographic, problem and scheme definitions

We follow the notation used in \cite{21}. A public-key encryption (PKE) scheme is defined as a triple of functions $\text{PKE} = (\text{Keygen}, \text{Enc}, \text{Dec})$ with message space
\( \mathcal{M} \), where given a security parameter \( \lambda \) \texttt{Keygen} returns a secret key \( sk \) and public key \( pk \), \texttt{Enc} encrypts a message \( m \in \mathcal{M} \) using \( pk \) to produce a ciphertext \( ct \), and \texttt{Dec} returns an estimate \( m' \) of \( m \) given \( ct \) and \( sk \).

The decisional Learning with Errors (LWE) \cite{56} problem involves distinguishing the uniform sample \((A, U) \leftarrow U(Z_{k_1 \times k_2} \times Z_{q})\) from the LWE sample \((A, B = \langle AS + E \rangle_q)\) where \( A \leftarrow U(Z_{k_1 \times k_2}) \) and where the secret key \( S \) and error \( E \) are generated from the secret and error distributions \( \chi_s(Z_{k_1 \times m}) \) and \( \chi_e(Z_{k_1 \times m}) \) respectively. The search problem is to recover \( S \) from the LWE sample.

As mentioned in \cite{21}, the above problem definitions can be generalized to Ring \cite{49} or Module \cite{46} (R/M)LWE by using vectors of polynomials. To further generalize the definition, independent reduction polynomials \( f_1(x) \) and \( f_2(x) \) can be considered, the first used to reduce the product of polynomial multiplications during key-generation and the second used similarly during encryption and decryption. The NIST PQC candidate Round5 \cite{9} uses such a construction with independent reduction polynomials. Then, the generalized problem is to distinguish the uniform sample \((A, U) \leftarrow U(R_{k_1 \times k_2} \times R_{k_1 \times m})\) from a generalized LWE sample \((A, B = \langle AS + E \rangle_{f_1})\) where \( A \leftarrow U(R_{k_1 \times k_2}) \), \( S \leftarrow \chi_s(R_{k_1 \times m}) \) and \( E \leftarrow \chi_e(R_{k_1 \times m}) \). The search problem is analogous to the LWE case.

The decisional generalized Learning with Rounding (LWR) \cite{11} problem involves distinguishing the uniform sample \((A, U) \leftarrow U(R_{k_1 \times k_2} \times R_{k_1 \times m})\) from the generalized LWR sample \((A, B = \langle AS + E \rangle_{f_1})\) where \( A \leftarrow U(R_{k_1 \times k_2}) \), \( S \leftarrow \chi_s(R_{k_1 \times m}) \) and \( E \leftarrow \chi_e(R_{k_1 \times m}) \). Analogous to the LWE case, the search problem is to recover \( S \) from the generalized LWR sample.

Using the above generalized problem definitions, we define a generalized public-key encryption scheme in Algorithms 1, 2 and 3 similar to \cite[Sec. 2.4]{21}. Note the use of an additional \textit{ciphertext compression modulus} \( t \) in addition to the primary modulus \( q \) and the rounding modulus \( p \). The function \texttt{encode} transforms a message \( m \in \mathcal{M} \) into a polynomial representation, and \texttt{decode} is the inverse decoding function. Similar to as \cite[Sec. 2.4]{21} proposes, this generalized PKE framework can be instantiated to describe multiple NIST PQC schemes that are based on LWE/LWR \cite{15}, RLWE/RLWR \cite{6} or MLWE/MLWR \cite{16,23}.

### 3 State of the art: Secret-key distributions

This section presents definitions of the secret distributions analyzed in this paper. A number of, but not all, of these distributions feature in second-round NIST post-quantum cryptographic (PQC) candidates \cite{53}, this is summarized in Table 2. We start with distributions of secrets of length \( n \) obtained by drawing each of the \( n \) components independently from one single distribution. Then we describe distributions in which secrets are generated as a whole.
### Algorithm 1: Keygen()

1. \( A \leftarrow U(\mathbb{R}_1^{\ell \times t}) \)
2. \( S_A \leftarrow \chi_s(\mathbb{R}_q^{\ell \times m}) \), \( E_A \leftarrow \chi_e(\mathbb{R}_q^{\ell \times m}) \)
3. \( B = \left\lfloor \frac{p}{q} \cdot (AS_A + EA_f) \right\rfloor \)
4. return \((pk = (A, B), sk = S_A)\)

### Algorithm 2: Encrypt\((pk = (A, B), m)\)

1. \( S'_B \leftarrow \chi_s(\mathbb{R}_q^{\ell \times m}) \), \( E'_B \leftarrow \chi_e(\mathbb{R}_q^{\ell \times m}) \)
2. \( B' = \left\lfloor \frac{p}{q} \cdot (AS_A + E_A f_1) \right\rfloor \)
3. \( V' = \left\lfloor \frac{t}{q} \cdot (B'_T S_A + E'_B + \frac{q}{2} \text{encode}(m)) f_2 \right\rfloor \)
4. return \(ct = (B', V')\)

### Algorithm 3: Decrypt\((sk = S_A, ct = (B', V'))\)

1. \( m' = \left\lfloor \frac{1}{q} \left( \langle q/t \cdot V' \rangle - \langle q/p \cdot B' \cdot S_A \rangle f_2 \right) \right\rfloor \)
2. return \(\text{decode}(m)\)

### 3.1 Discrete Gaussian distribution

For schemes based on the (Ring [49]) Learning with Errors [56] ((R)LWE) problem, security reductions from worst-case lattice problems are feasible if the noise follows a sufficiently wide Gaussian distribution [56, 18], such as the Frodo scheme [15]. Variants in which the secret follows the same distribution as the error can be proven equivalent to the original problem by putting the system in systematic form, as done in [8]. Therefore, for schemes based on (R)-LWE, components of the secrets commonly (approximately) follow a discrete Gaussian distribution. For implementation reasons, the approximations have a finite support [15]. The discrete Gaussian probability distribution function \(D_{Z, \sigma}\) over \(Z\) with mean \(\mu = 0\) and parameter \(\sigma\) is defined as

\[
D_{Z, \sigma}(X = k) = \frac{1}{S} e^{-k^2/2\sigma^2}.
\]

Here \(X\) is the random variable over \(Z\), and \(S\) is the normalization constant \(\sum_{k=\infty} e^{-k^2/2\sigma^2}\). For \(\sigma \geq 0.5\), it holds that \(\text{var}(D_{Z, \sigma}) \approx \sigma^2\).

### 3.2 Centered binomial distribution

The centered binomial distribution was introduced in [6] as an easy-to-implement distribution that is a good approximation to a rounded continuous Gaussian distribution with the same variance. For each positive integer \(\eta\), the centered binomial distribution \(\text{bin}_{\eta}\) of width \(\eta\) has support \([-\eta, -\eta + 1, \ldots, -1, 0, 1, \ldots, \eta]\)
Table 2: NIST PQC candidates featuring secret-key distributions analyzed in this work.

</table>

and is defined as

\[ \text{bin}_\eta(k) = \left( \frac{2\eta}{k + \eta} \right) 2^{-2\eta} \text{ for } k \in [-\eta, \eta] \cap \mathbb{Z}. \]  

Clearly, \( \text{bin}_\eta \) is symmetric around zero and so has mean zero. By direct computation, it can be shown that the variance of this distribution is \( \text{var}(\text{bin}_\eta) = \frac{\eta}{2} \).

Sampling from \( \text{bin}_\eta \) can be done \(^3\) by computing \( \sum_{i=0}^{\eta-1} (b_i - b'_i) \) where the \( b_i, b'_i \in \{0, 1\} \) are uniform independent bits. The NewHope submission to the NIST standardization [55] uses \( \text{bin}_8 \) for generating noise and secrets. The Kyber [16] and Saber [22] submissions employ \( \text{bin}_\eta \) with \( \eta \in \{6, 8, 10\} \) for generating secrets in their three proposed parameter sets. The LAC [47] submission employs two unique \( \text{bin}_1 \) distributions for generating secrets and noise in its proposed parameter sets.

**Scaled version.** It is possible to define a generalized version of the centered binomial distribution \( \text{bin}_{\eta, \theta} \) of width \( \eta \) and with scaling factor \( \theta \) as

\[ \text{bin}_{\eta, \theta}(k) = \theta \cdot \text{bin}_\eta(k) \text{ for } k \in \mathbb{Z}, 1 \leq |k| \leq \eta, \text{ and } \text{bin}_{\eta, \theta}(0) = 1 - \theta(1 - \text{bin}_\eta(0)). \]  

In order that \( \text{bin}_{\eta, \theta} \) is a probability distribution, it is required that \( 0 \leq \theta \leq 1/(1 - \text{bin}_\eta(0)) \). As \( \text{bin}_{\eta, \theta} \) is symmetric around zero, its mean equals zero. Its variance satisfies

\[ \text{var}(\text{bin}_{\eta, \theta}) = \sum_{k \neq 0} k^2 \theta \cdot \text{bin}_\eta(k) = \theta \cdot \text{var}(\text{bin}_\eta) = \frac{\eta}{2} \theta \cdot \eta. \]  

By varying over both \( \eta \) and \( \theta \), the above, so-called scaled centered binomial distribution allows a wide range of trade-offs to be investigated. It has the centered binomial distribution (as \( \text{bin}_{\eta, 1} = \text{bin}_\eta \)) as a special case. We note that this generic distribution is not actually used in any NIST PQC candidate.

### 3.3 Symmetric ternary distribution

For \( 0 \leq \alpha \leq 1 \), the symmetric ternary distribution \( \mathcal{T}_\alpha \) with parameter \( \alpha \) is defined as

\[ \mathcal{T}_\alpha(0) = 1 - \alpha, \quad \mathcal{T}_\alpha(1) = \mathcal{T}_\alpha(-1) = \frac{1}{2} \alpha. \]  

---

\(^3\) The two submissions use different notations for the parameter \( \eta \).
Clearly, $T_\alpha$ has mean zero and variance $\alpha$. The Lizard submission to the NIST standardization [20] employs $T_{1/2}$ and $T_{1/4}$ for secret key generation in Lizard.CCA and Lizard.KEM. This distribution is another special case of the scaled centered binomial distribution defined in Section 3.2 (as $\text{bin}_{1,\theta} = T_{2\theta}$).

### 3.4 Fixed-weight ternary distribution

This distribution is not defined via a component-wise distribution, rather, the entire secret is generated as a whole, as in the NIST PQC candidates Round5 [9] and NTRUPrime [12]. For positive integers $n, h$ with $h$ even and $1 \leq h \leq n/2$, the fixed-weight ternary distribution $T_{n,h}$ is the uniform distribution on the set of all ternary vectors with $h/2$ ones, $h/2$ minus ones, and $n - h$ zeroes. There is a close relationship between fixed-weight ternary secrets and secrets generated according to a symmetric ternary distribution. The per-component distribution of vectors drawn according to $T_{n,h}$ equals $T_{h/n}$. Specifically, the per-component variance of vectors drawn according to $T_{n,h}$ equals $\frac{h}{n}$.

Conversely, by the law of large numbers, for large $n$, a vector of length $n$ with each component drawn independently according to $T_\alpha$ with high probability has approximately $\frac{1}{2} \alpha n$ ones, $\frac{1}{2} \alpha n$ minus ones, and $n(1 - \alpha)$ zeroes. However, as will be shown in Section 5, a certain active attack that utilizes decryption failures [21] is more powerful against secrets with independently generated components according to $T_{h/n}$ than against secrets generated according to $T_{n,h}$. The reason is that such an attacker can benefit from the (rare) occurrence of secrets of a weight considerably larger than $h$.

### 4 Analysis

We begin with a comparison of two fundamental properties of the distributions considered in Section 3, namely their entropies and variances. Next, we look more deeply into the interaction between a secret-key distribution and the underlying cryptographic scheme, and compare in Section 4.2 the probability of decryption failures when different secret-key distributions are considered. In Section 4.3, we compare the key sizes of a lattice-based public-key encryption scheme when instantiated with the different secret-key distributions considered in this work.

#### 4.1 Comparing entropy against variance

In this section, we consider the per-symbol entropy achieved by the secret-key distributions considered in this work, for a fixed variance. We note that the symmetric ternary (Section 3.3) and fixed-weight ternary (Section 3.4) distributions cannot have a variance that is greater than one. On the other hand, the centered binomial distribution (Section 3.2) cannot have a variance that is less than one. Finally, the discrete Gaussian distribution (Section 3.1) can be parametrized to have variances in both of these regimes.
Fig. 3: Comparison of the entropies and variances of the distributions considered in this work; solid green: fixed-weight ternary (with dimension 800 and weight of secret keys ranging from 8 till 792), dotted red: symmetric ternary with independently sampled components), blue (discrete Gaussian), black (centered binomial).

The comparison of these distributions with respect to entropy achieved for a fixed variance is shown in Figure 3. The per-symbol entropy of the fixed-weight ternary distribution with parameters \( n \) (dimension/length) and \( h \) (weight) is 
\[
\log_2 \left( \binom{n}{h} \frac{h}{h/2} \right) / n,
\]
since there are exactly \( \binom{n}{h} \frac{h}{h/2} \) \( n \)-long ternary vectors containing exactly \( h/2 +1 \)'s and exactly \( h/2 -1 \)'s. It can be shown by Stirling’s approximation that for large \( n \), this entropy is the same as that of the symmetric ternary distribution. In Figure 3, we fix \( n = 800 \), and compute the variance as \( h/n \), and entropy as above for Hamming weights \( h \) ranging from 8 till 792. It can be seen that in the so-called “low-variance” regime (i.e., for variances less than approximately 0.4), the ternary distributions achieve entropies almost as high as that of the discrete Gaussian distribution, which is known to maximize the entropy for a given variance [41]. Such regimes can be imagined to be desirable for low probabilities of decryption failure, since a low variance implies a lower probability of (a) large component(s) being sampled in the secret key that can increase the failure probability. The ternary distributions may have other benefits, namely more efficient cryptographic computations and easier sampling, that we do not discuss here.

For such low variances however, the centered binomial distribution cannot be defined and thus cannot be compared with either the discrete Gaussian or
the ternary distributions. We must thus consider variances that are greater than one, and there it can be seen in Figure 3 that the entropy of the centered binomial distribution for such variances is lower than that of the discrete Gaussian distribution.

4.2 Comparing failure probability against variance

We discuss the impact of the secret distribution choice on the decryption failure rate of the generalized lattice-based public-key encryption scheme described in Section 2, algorithms 1, 2 and 3. For concreteness and simplicity, we consider a Ring Learning with Rounding based instantiation of it, i.e., we choose \( l = 1, E_A = E'_B = E''_B = 0 \). To prevent the polynomial degree from being restricted to only powers of 2, we choose the key-generation reduction polynomial \( f_1(x) = \Phi_{n+1}(x) = x^n + x^{n-1} + \ldots + 1 \), the \((n+1)\)-th cyclotomic polynomial for \( n+1 \) a prime. To avoid correlated errors due to the use of this specific \( f_1(x) \) and also to reduce decryption failure rates to the level achieved by power-of-2 cyclotomic polynomials, we choose the encryption reduction polynomial \( f_2(x) = x^{n+1} - 1 \). We refer to [9] for details on this technique, noting that it requires the polynomials in \( S_A \) and \( S'_B \) to have a factor \((x - 1)\).

Section 4.1 mentioned that the (fixed-weight and symmetric) ternary distributions can only have variance at most one, while the centered binomial distribution can only have variance at least one. This complicates a direct (i.e., with variances equalized) comparison of the failure rates resulting from these distributions. Instead, in this section we analyze the effect of fixing the composition of the secrets on the decryption failure rate, i.e., the effect of fixing the exact number or weight of secret key components for each possible component value. In other words, we will compare the failure rate of the above-mentioned public-key encryption scheme when instantiated with the symmetric ternary distribution as opposed to the fixed-weight ternary distribution. Next, we will do the same and compare the centered binomial distribution bin \( \eta \) with a fixed-weight variant of it, i.e., with the uniform distribution on the set of all vectors in \( \{-\eta, \ldots, \eta\}^n \) with exactly \( \left\lfloor \frac{2^n}{k+\eta} \right\rfloor 2^{-2n} \) components equal to \( k \) (for \( k \in \{-\eta, \ldots, \eta\} \setminus \{0\}) \), and the remaining components are zero.

For fixed scheme parameters \( n = 800, q = 2^{11}, p = 2^9, t = 2^7 \), Figure 4 compares the failure rates achieved by the above scheme for the symmetric ternary and fixed-weight ternary distributions. In the former case, the failure probability can be computed by iteratively convolving the symmetric ternary secret distribution and that of the “rounding” error, similar to [23]. In case of fixed-weight ternary secrets, assuming independence, the failure probability can be computed similarly as in [9] Sec. 4.3 where one term in the decryption error polynomial is distributed as the sum of exactly \( h \) independent uniform random variables on \( (-q/2p, q/2p) \cap \mathbb{Z} \), minus the sum of \( h \) independent uniform random variables on \( (-q/2p, q/2p) \cap \mathbb{Z} \).

Figure 4 shows that the use of fixed-weight ternary secrets in the encryption scheme reduces its decryption failure rates. Secret keys sampled from the symmetric ternary distribution may have a Hamming weight that is higher than
expected. On the other hand, fixed-weight ternary secret keys can never have weight higher than \( h \). Generalizing this, it is possible to strictly bound the Euclidean norm of secret keys sampled from distributions that assign fixed-weights to non-zero components of the secret key.

Conversely, there also exists a non-negligible probability that secrets sampled from the symmetric ternary distribution have a weight that is lower than expected, which leads to the possibility of a multi-target attack along the lines of [33] that reduces the cost of key recovery attacks such as [36,2]. In this attack, the attacker can perform a one-time precomputation in order to find an encryption randomness that results in higher than expected probability of decryption failure, use this to compute ciphertexts for multiple targets, out of which targets with secret keys that have smaller than expected weight can be identified if decryption unexpectedly succeeds. Fixing the weight of the secret keys, in addition to improving the decryption failure rate, also stops this attack.

The same result as for the ternary distributions can be seen again in Figure 5 that compares the decryption failure rate of the encryption scheme for the centered binomial distribution and its fixed-weight variant introduced above. The comparison is done for the fixed parameters \( n = 828, q = 2^{14}, p = 2^{10}, t = 2^4 \). It is again seen that fixing the weight of the non-zero components reduces the failure rate, since it strictly limits the number of non-zero components that are sampled in the secret key, as well as removing the possibility of sampling very large components.
4.3 Comparing security and performance trade-offs

The variance, entropy, failure probability and computational performance can be computed given a type of secret distribution. However, it is not possible to derive a conclusion about the overall system looking at them only individually, since their effect is interlinked, as shown in Figure 1. While a secret distribution aspect (e.g., low variance) can have a positive impact on the encryption scheme, e.g., low decryption failure, it can also have a negative impact, e.g., lower concrete security. Therefore, we choose to analyze the eventual effect of this interaction on the final scheme, by performing a parameter search with the aim of minimizing the bandwidth requirements, chosen as the metric since it improves performance of security protocols. Our chosen scheme is the same Ring Learning with Rounding based instantiation of the generalized PKE scheme of Section 2 that we instantiated in Section 4.2 i.e., by choosing \( l = 1 \), \( E_A = E'_B = E''_B = 0 \) \( f_1(x) = \Phi_{n+1}(x) \) \( f_2(x) = N_{n+1}(x) \). Parameters are chosen to encrypt a 192-bit message, while offering a minimum targeted security level (NIST security category 3 [53]) and ensuring a negligibly low decryption failure rate so that standard transformations [35] can be applied on the scheme to obtain an IND-CCA2 secure scheme.

While choosing parameters, concrete security is analyzed considering the best known current attacks, which are ones that utilize lattice basis reduction, under
the conservative core-sieving model [6] assuming sieving [43] as the underlying SVP oracle in basis reduction. Although the exact cost of lattice reduction is considered unclear in the literature [19,34,51,3], it is dominated by that of running the SVP oracle on $b$-dimensional lattices. Ignoring asymptotic factors, this cost is estimated as $2^{0.292b}$ and $2^{0.265b}$ [32,44,43] respectively, depending on whether a quantum speedup by Grover’s algorithm [29] is assumed or not. Attacks considered include the primal or decoding attack [6], and the dual or distinguishing attack [2], extended to utilize lattice rescaling [9,10,2], to exploit the fact that a number of secret-key distributions in this work are relatively narrower than the error, and result in unbalanced short lattice vectors. To further account for such narrow secret-key distributions, specialized or combinatorial attacks such as the hybrid lattice reduction and meet-in-the-middle attack [36], and a sparse-secret attack [2] are also considered.

Table 1 summarizes the computed parameters and compares the achieved performance. The first row shows parameters related to the secret distribution, namely $\eta$, $\theta$, and $h$ where applicable, as defined in Section 3, and variance $\sigma^2$ of the distribution. For schemes with fixed-weight secret-key distributions, the parameter $h$ represents a list of weights of non-zero components that appear in the secret key, ignoring the sign of the component. For example, $h = [h_1, h_2, \ldots, h_\eta]$ implies that the secret key contains $h_1$ components that are $\pm 1$, $h_2$ that are $\pm 2$, and so on till $h_\eta$ that are $\pm \eta$. The second row includes the size $n$ of the reduction polynomial and the moduli – $q$, $p$, and $t$ – involved in the Ring Learning with Rounding (RLWR) problem [11]. We observe that all configurations achieve a classical level of at least 192 bits of security, and a failure rate of at most $2^{-170}$.

The conclusion from the comparison in Table 1 is that for similar security and decryption failure rate targets, a rounding-based public-key encryption scheme with smallest bandwidth requirements is obtained when the secret keys are sampled from a fixed-weight ternary distribution. While such secret keys open up the possibility of specialized attacks [36,2], they also enable stronger noise tolerance and a higher noise-to-modulus ratio, improving security. The observation from Table 1 is that the combination of these two competing effects while optimizing parameters of the encryption scheme, leads to smaller key sizes.

5 Resistance against decryption failure-based chosen-ciphertext attacks

An important aspect to consider while designing public-key encryption and encapsulation schemes is their security against active or chosen-ciphertext attacks, formalized in the notion of IND-CCA2 security. Lattice-based encryption and encapsulation schemes typically have a probability of decryption failure, which depends on the instantiation of the secret key and noise of both parties. In case of schemes based on (Ring) Learning with Rounding [11], it depends only on the secret keys since the noise is determined based on the secret keys and the public parameter. One possible attack against such schemes in the IND-CCA2 model involves an attacker who chooses ciphertexts with the goal of causing a
decryption failure, and hopes to gain information on the decryptor’s secret key by observing such failure events.

D’Anvers et al. [21] present an attack framework of this form on a number of NIST post-quantum standardization candidates, and compare how the different schemes fare against it. However, the roles played by different aspects of the schemes’ designs in withstanding active attacks of the above form are not completely studied. In this section we analyze the role played by the secret-key distribution of a scheme in this attack. We analyze and quantify the cost of the above-mentioned decryption failure-based attack [21] against each of the secret-key distributions considered in this paper, in the context of the rounding-based encryption scheme we introduced in Section 4.2. We show that fixing the weight of the (non-zero) secret key components makes the attack harder, independent of any other scheme parameters such as the error distribution.

We first recall the basic intuition behind the attack: Typically, most lattice-based public-key encryption schemes consist of a core building block that is an IND-CPA secure public-key encryption scheme. Applying a KEM variant [35] of the Fujisaki-Okamoto transform on this scheme yields an IND-CCA2 secure scheme, whose security can be proven in the random oracle model. A core component of the above transform is a reencryption step that intuitively requires the encryptor to prove knowledge of the message that is being encrypted/encapsulated. Thus, an active or chosen ciphertext attacker can do no better than exhaustively search for messages that result in so-called “weak” ciphertexts [21] which cause a decryption failure with probability higher than a threshold \( f_t \) — this is a parameter chosen by the attacker. The probability of finding such weak ciphertexts is denoted in [21] by the parameter \( \alpha \), and the (increased) decryption failure rate resulting from them is denoted by the parameter \( \beta \). Assuming that the attacker has no quantum access to the decryption oracle, the overall attack cost of this so-called failure boosting attack, is thus \((\alpha \beta)^{-1}\) (using a classical computer) or \((\sqrt{\alpha \beta})^{-1}\) (with a quantum speedup [29]). Once weak ciphertexts are found, the attacker uses information gained by observing decryption failure events to speed up standard secret key recovery attacks [6,36].

We recall some notation from [21] before proceeding to the analysis of the attack and our extension of it. In the context of the generalized public-key encryption scheme described in Section 2, algorithms 1, 2 and 3, we define the errors introduced by the rounding operation (if applicable) as:

\[
U_A = A S_A + E_A - B_r, \quad U'_B = A^T S'_B + E'_B - B'_r, \\
U''_B = B'_T S'_B + E''_B + \left\lfloor \frac{q}{2} m \right\rfloor - V'_r. \tag{6}
\]

Further, let

\[
S = \left( -S_A \atop E_A + U_A \right), \quad C = \left( E_B + U'_B \atop S'_B \right), \quad G = E''_B + U''_B \tag{7}
\]

The above-mentioned attack cost of failure boosting can be minimized by the attacker over the choice of the failure probability threshold \( f_t \). This minimization
requires obtaining the (distribution of the) variance of the coefficients of the polynomial $S^T C_{ij}$ [21, Eq. 8] (where $i, j$ are used to vary over the coefficients of the polynomials in $S^T C$):

$$\text{var}(S^T C_{ijk}) = \| (E'_B + U'_{B,j}) \|_2^2 \text{var}(\chi_s) + \| (S'_{B,j}) \|_2^2 \text{var}(\chi_e + u)$$

Computing the (distribution of) this variance is an essential step towards modeling the failure probability in each component of the polynomials involved in the decryption error term that is represented by $S^T C + G$. $(C, G)$ can be chosen by the attacker with the eventual goal of finding a “weak” ciphertext that causes a higher than expected probability of decryption failure.

Computing the distribution of the failure probability in each component of the decryption error eventually allows determining whether the attacker succeeds in causing the probability of the decryption failure rate in each component of the above polynomials to be greater than the chosen $f_t$, for a chosen $(C, G)$ pair – this qualifies as an attack success. This involves computing the resulting $\alpha$ and $\beta$ parameters, and thus the overall attack cost. A key assumption made by [21] in the above computations is that the coefficients of $S^T C$ are normally distributed. This assumption also allows applying this analysis to a number of different schemes with varying secret-key and noise distributions. However, as mentioned by the authors themselves in [21, Section 3.1], this assumption is also the source of potential inaccuracies in the analysis. In the following section we show that this inaccuracy exists for specific distributions, and can be removed by refining the analysis of [21] for said distributions.

5.1 Adapting failure boosting to fixed-weight secrets

It is possible to refine the existing analysis of failure boosting [21] when considering schemes which have secret keys with fixed-weight components, i.e., where the number of components that are equal to $i \in [1, \ldots, \eta]$ (positive and negative components taken together) is exactly $h_i$. Specifically, the Gaussian approximation step involved in computing the distribution of the decryption failure probabilities per component of $S^T C + G$ can be made more precise for such schemes. This allows for a more accurate computation of the distribution of the coefficients in the polynomials comprising $S^T C$, improving the analysis of [21].

The decryption failure probability $f_{ijk}$ in the $ijk$-th component of $S^T C + G$, given a chosen pair $(C, G)$ is computed in [21, Eq. 11] as:

$$f_{ijk} = \Pr \left( |(S^T C + G)_{ijk}| > q_t |G, C \right) \approx \Pr \left( |x + G_{ijk}| > q_t |G, x \leftarrow \mathcal{N} \left( 0, \text{var}(S^T C_{ijk}) \right) \right).$$

$q_t = q/2^B$ is a decryption threshold, where $q$ is the system modulus and $B$ bits of information are extracted from each component of the shared secret. The previously mentioned assumption made by [21] that the coefficients of $S^T C$ are normally distributed results in the approximation in the second step of the
above equation. We refine this approximation by first noting that (recalling the definitions of $S$, $C$ and $G$ in Eq. 7):

$$S^T C = (-S^T_A (E_A^T + U_A^T)) \left( E_B + U_B' \right)$$

$$= -S^T_A (E_B + U_B') + (E_A^T + U_A^T) S_B'$$

$$= S_A E_B + E_A S_B$$

(10)

Rewriting $S^T C$ in the above manner makes it clear that the computation of $f_{ijk}$ in Eq. 9 can be refined as follows:

$$f_{ijk} \approx \text{Pr} (\lvert x_1 + x_2 + G_{ijk} \rvert > q_t \mid G, x_1 \leftarrow N(0, \text{var}(S_A E_B)_{ijk}), x_2 \leftarrow \chi_{e+a_s})$$

(11)

where firstly, $\text{var}(S_A E_B)_{ijk}$ is adapted from $\text{var}(S^T C_{ijk})$ in Eq. 8 as:

$$\text{var}(S_A E_B)_{ijk} = \| (E_B' + U_B') \|^2 \text{var}(\chi_s)$$

(12)

and secondly, $\chi_{e+a_s}$ is the distribution of each component in the polynomial product $(E_A S_B)_{ij}$, where polynomials in $S_B$ have components chosen from $\{-\eta, \ldots, \eta\}$, with exactly $h_i$ components that are equal to $i \in [1, \ldots, \eta]$ (positive and negative components taken together). The variable $x_2$ is thus distributed as $\sum_{i=1}^{\eta} \sum_{j=1}^{h_i} X_{i,j}$, where the random variables $X_{i,j}$ for $1 \leq i \leq \eta$ and $1 \leq j \leq h_i$ are independently drawn from $\chi_{e+u}$. This distribution can be computed by convolving, over all $i \in [1, \ldots, \eta]$, the $h_i$-fold iterative convolution of $\chi_{e+u}$ scaled with a factor $i$. Equations 11 and 12 thus summarize our adaptation to the analysis of the failure boosting phase of the decryption failure-based active attack in [21].

5.2 Results of our adaptation

Applying our above adapted analysis, Figure 2 depicts the cost $(\alpha \beta)^{-1}$ of applying failure boosting to find a weak ciphertext on a classical computer, for a number of NIST post-quantum standardization candidates, and the rounding-based public-key encryption scheme we defined in Section 4.2 – instantiated with both fixed-weight and non fixed-weight ternary secrets. The parameters used for these are the same as computed in Section 4.3. Note that the construction of the encryption scheme using these distributions is similar to some instantiations of the NIST PQC candidate Round5 [9], albeit a version that does not use error correction and uses non fixed-weight ternary secrets for the latter. The results clearly indicate that fixing the weight makes the attack harder.

To further demonstrate this, and to show that the results of our adaptation also carry over to schemes using independent errors (instead of only rounding-based errors), we include results for fixed-weight variants of the NIST PQC candidates Saber [22] – that uses rounding errors, and Kyber [16] – that uses independently sampled errors. These fixed-weight variants sample their secret keys from centered binomial distributions [6] analogous to the original schemes,
however the weights of the non-zero components are fixed in a manner similar to that mentioned in Section 4.2. Figure 2 shows that the cost of the failure boosting attack increases visibly faster for these fixed-weight variants of Saber and Kyber than the original schemes. Since these schemes were originally designed to use secret key components that are larger than 1, fixing the weight of non-zero secret key components provides them with an even greater security benefit against the failure boosting attack of [21] than schemes using secret keys with components that are only ternary.

6 Conclusions and future work

Of all the different design aspects involved in the construction of lattice-based public-key encryption schemes, an important one that has so far not been analyzed in depth in the literature is the role played by the secret-key distribution in the tradeoff between performance and security of the scheme. We initiate study in this area by comparing a number of secret-key distributions currently being considered as part of candidates to the NIST post-quantum standardization process, with respect to different criteria such as variance, entropy, resulting probability of decryption failure, and resistance against chosen-ciphertext attacks based on decryption failures.

Our results indicate that out of the secret-key distributions considered in this work: firstly, fixed-weight ternary secrets reduce the decryption failure rate of the encryption scheme and allow for a higher noise-to-modulus ratio while ensuring a large enough dimension secure against concrete attacks, thus leading to the smallest key sizes when parameters are optimized for bandwidth. Secondly, fixing the weight of non-zero components in the secret key increases security against decryption failure-based chosen-ciphertext attacks, as compared to secrets with independently sampled components. An interesting area of further research is to analyze the effect of similarly fixing the weight of components in the error vector, on the security and performance of the encryption scheme.

Acknowledgements

We thank Thijs Laarhoven for helpful discussions on comparing the entropy and variance of the fixed-weight and symmetric ternary distributions, and for pointing out the possibility of multi-target attacks on schemes using the latter. We thank Jan-Pieter D’Anvers for providing helpful insights on the analysis of the “failure boosting” technique in [21]. The research of Player was supported by the European Union PROMETHEUS project (Horizon 2020 Research and Innovation Program, grant 780701).
