Abstract

Secure Multi-party Computation (MPC) with small population and honest majority has drawn focus specifically due to customization in techniques and resulting efficiency that the constructions can offer. In this work, we investigate a wide range of security notions in the five-party setting, tolerating two active corruptions. Being constant-round, our protocols are best suited for real-time, high latency networks such as the Internet.

In a minimal setting of pairwise-private channels, we present efficient instantiations with unanimous abort (where either all honest parties obtain the output or none of them do) and fairness (where the adversary obtains its output only if all honest parties also receive it). With the presence of an additional broadcast channel (known to be necessary), we present a construction with guaranteed output delivery (where any adversarial behaviour cannot prevent the honest parties from receiving the output). The broadcast communication is minimal and independent of circuit size. In terms of performance (communication and run time), our protocols incur minimal overhead over the best known selective abort protocol of Chandran et al. (ACM CCS 2016) while retaining their round complexity. Further, our protocols for fairness and unanimous abort can be extended to \( n \)-parties with at most \( \sqrt{n} \) corruptions, similar to Chandran et al. Going beyond the most popular honest-majority setting of three parties with one corruption, our results demonstrate feasibility of attaining stronger security notions at an expense not too far from the least desired security of selective abort.

1 Introduction

Secure Multiparty Computation (MPC) [Yao82, GMW87, CDG87] is an area of cryptography that has evolved breathtakingly over the years in its attempt to secure data while computing on it. MPC focuses on the problem of enabling a set of $n$ mutually distrusting parties to perform joint computation on their private inputs in a way that no coalition of $t$ parties can affect the output of computation or learn any additional information beyond what is revealed by the output. In other words, MPC guarantees correctness of computation and privacy of inputs. The literature of MPC has witnessed plethora of works from a theoretical standpoint, however, the focus on building practice-oriented MPC [DPSZ12a, WRK17, BHKL18] constructs has gained momentum only in the recent years owing to the rising demand for efficiency in real-time networks such as the Internet. The vast literature of MPC can be broadly categorized into dishonest majority [GMW87, DO10, BDOZ11, DPSZ12b, AIL+12, NNOB12, LPSY15, WRK17] and honest majority [BGW88, RB89, BMR90, DN07, BH07, BH08, BFO12, MRZ15]. While both have received attention in the efficiency studies, designing practical MPC with honest majority is a captivating area of research [MRZ15, AFL+16, FLNW17, CGMV17, PR18, BJPR18] for the various reasons illustrated below.

The paramount benefit of having honest majority enables the computation to achieve stronger security goals such as fairness (adversary obtains output if and only if all honest parties do) and guaranteed output delivery (GOD) (any adversarial behaviour cannot prevent the honest parties from receiving the output) [Cle86]. These properties are desirable in real-life owing to limited time and resource availability, as they bind the parties to participate in the computation and thus keep the adversarial behaviour in check. Furthermore, lack of such strong guarantees can be detrimental in practice. For instance, in real-time applications such as e-commerce and e-auction, an adversary can always cause an abort if the outcome is not in its favour unless a stronger security notion is ensured. In e-voting, the adversary can abort the computation repeatedly, yet learn the outputs each time and use them to rig the election. Apart from enabling stronger security goals, honest-majority allows design of efficient protocols solely using symmetric-key functions. For instance, the necessity of a public-key primitive for realizing oblivious transfer can be replaced with symmetric-key primitives, as exhibited by our protocols and [CGMV17]. Further, this setting enables design of information-theoretic protocols [BGW88, RB89, BFO12, IKKP15], besides the computational ones. Thus, these strong notions have driven a lot of research. To elaborate, [DI05, DI06] show constant-round protocols with GOD. The round-optimality of these notions have been studied in [GIKR02, GLS15, PR18] and 3 rounds is proven to be necessary. Lately, round-optimal MPC protocols with GOD appeared in [GLS15, ACGJ18, BJMS18] relying on either Common Reference String (CRS) or public-key operations, in [ACGJ19, ABT19] under super-honest-majority $t < n/4$ and in [PR18] for the special case of 3-party solely from symmetric-key primitives. The work of [DOS18] shows how to compile honest majority MPC protocol for arithmetic circuits with abort (and several other constraints) into a protocol with fairness while preserving its efficiency. Interestingly, while [Cle86] rules out fairness in dishonest majority, [BK14, ADMM14, CGJ+17, PST17] demonstrate its feasibility relying on non-standard techniques such public bulletin boards, secure processors or penalties (via Bitcoin).

Since inception, the primary focus of MPC has been on generic constructions with $n$ parties. Yet, the regime of practical MPC has seen major breakthroughs in the small-party domain: 3-5. Real-time applications such as Danish Sugar-Beet Auction [BCD+09], statistical and financial data analysis [BTW12], email filtering [LADM14], distributed credential encryption [MRZ15], Kerberos [AFL+16], privacy-preserving machine learning [MRSV17], efficient MPC-frameworks such as VIFF [Gei07], Sharemind [BLW08] and ABY-Arithmetic Boolean Yao [MR18] are crafted for 3 parties with one corruption. The setting of 4, 5 parties with minority corrosion has been explored in [CGMV17, IKKP15, BJPR18]. The most popular setting of 3/4 parties with 1 active corruption brings to the table some eloquent custom-made tools such as the use of Yao’s garbled circuits [Yao82] to achieve malicious security [MRZ15, PR18, BJPR18], spending just 2-3 elements per party in arithmetic circuits [ABF+17] and sure-election of one honest party as a trusted party in case the adversary strikes [BJPR18, PR18]. These techniques rely on the adversary not having an accomplice to cause damage. However, the moment adversary has a collaborator (2 corruptions), these custom-made tools fall apart, thus elevating the challenge of achieving desired security with real-time efficiency. In this paper, we consider MPC for 5 parties (5PC) with 2 corruptions and treat it with securities of unanimous abort, fairness and GOD, at an expense that is not too far from the result of [CGMV17].
achieving least desired security of selective abort.

1.1 Related Work

The notable works on MPC for small parties come in two flavours– low-latency and high-throughput protocols. Relying on garbled circuits, the former offers constant-round protocols that serve better in high-latency networks such as the Internet. The latter, built on secret sharing tools, aim for low communication (bandwidth), but at the cost of rounds proportional to the depth of the circuit representing the desired function. These primarily cater to low-latency networks. We focus on the former category in our work.

The work most relevant to ours is [CGMV17] that proposes a 5PC protocol achieving the weak notion of selective abort against two malicious corruptions. Their customization for 5PC resulted in an efficient protocol for actively-secure distributed garbling of 4 parties, relying solely on the passively-secure scheme of [BLO16], saving 60% communication than [BLO16] with four corruptions. In the 3-party (3PC), 4-party (4PC) domain, [MRZ15, IKKP15] gave a 3PC with selective abort. [IKKP15] also gave a 2-round 4PC with GOD. Recently, [BJPR18] improved the state-of-the-art with efficient 3PC and 4PC achieving fairness and GOD with minimal overhead over [MRZ15]. Orthogonally, recent works [AFL\textsuperscript{+}16, ABF\textsuperscript{+}17, FLNW17, CCPS19, EOP\textsuperscript{+}19] in the high-throughput setting with non-constant rounds, show abort security in 3PC with one corruption. The works of [CGH\textsuperscript{+}18, NV18, DOS18, CCPS19] additionally include constructs attaining fairness.

1.2 Our Contribution

In the regime of low-latency protocols which is of interest to us, the known works [MRZ15, IKKP15, CGMV17], despite being in honest majority, trade efficiency for security and settle for weaker guarantees such as selective abort. With 3, 4 parties, [IKKP15, PR18, BJPR18] demonstrate that fairness, GOD are feasible goals and present protocols with minimal overhead over those achieving weaker notions. Our paper is yet another attempt in this direction, focused on the 5-party setting.

We present efficient, constant-round 5PC protocols with honest majority that achieve security notions ranging from unanimous abort to GOD, solely relying on symmetric-key primitives. Being efficient and constant-round, our protocols are best suited for high latency networks such as the Internet. Designed in the Boolean world, our protocols are built on the semi-honest variant of the distributed garbling scheme of [WRK17] while leveraging the techniques of seed distribution and Attested Oblivious Transfer of [CGMV17]. Our theoretical findings are backed with implementation results with the choice of benchmark circuits AES-128 and SHA-256.

5PC with Fairness and Unanimous Abort In a minimal network of pairwise-secure channels, we achieve fairness and unanimous abort in 5PC with performance almost on par with [CGMV17], all consuming 8 rounds. On a technical note, building on [CGMV17], we achieve fairness by ensuring a robust output computation phase even when the adversary chooses not to participate in the rest of the output computation on learning the output herself. This is realized using techniques which enforce that, in order to learn the output herself, the adversary must first aid at least one honest party compute the correct output. Further, we employ techniques to allow this honest party to release the output and convince about the correctness of the same to remaining honest parties. Our 5PC with unanimous abort is obtained by simplifying the fair construct such that the adversary can learn the output herself without any aid from honest parties, but if she helps at least one honest party get the output, then that honest party aids fellow honest parties to get the output (as in fair construct). Both our 5PC protocols with fairness and unanimous abort can be extended to $n$ parties under the constraint of $t = \sqrt{n}$ corruptions which was established in [CGMV17].

5PC with GOD Our protocol uses point-to-point channels and a broadcast channel. The latter is inevitable as we use optimal threshold [CL14]. As broadcast is expensive in real-time, we limit broadcast communication to be minimal and primarily, independent of circuit, input and output size. Our implementation uses a software broadcast based on Dolev-Strong protocol [DS83]. On the technical side, our protocol relies on 2-robust techniques– 4-party
2-private replicated secret sharing (RSS) scheme for input distribution and seed-distribution of [CGMV17] to ensure each party’s role is emulated by two other parties. These strategies ensure that each piece of intermediate data is with a 3-party committee and any wrong-doing by at most 2 parties will ensue conflict. When a conflict occurs, we determine a smaller instance of a 3PC with at most 1 corruption to compute the output robustly. Our technical innovations come from maintaining—(A) input privacy, while making two 3-party committees, one formed by RSS and one by seed-distribution, interact; (B) input consistency across the 3PC and outer 5PC. Due to the use of customized tools for small parties such as RSS, conflict identification and running a smaller 3PC instance, this protocol cannot be scaled to \( n \)-parties while retaining the goal of efficiency.

**Empirical Comparison.** A consolidated view of our results is presented below outlining the security achieved, rounds used, use of broadcast (BC) and empirical values. The values indicate the overhead in maximum runtime latency in LAN, WAN and total communication (CC) over [CGMV17] that offers selective abort in 8 rounds. The range is composed over the choice of circuits: AES-128 and SHA-256 and the left value in the range corresponds to AES, while the right value indicates SHA. AES is a smaller circuit, with 33616 gates, compared to 236112 gates of SHA. (*: the total number of rounds is calculated plugging in the state of the art robust 3PC [BJPR18]. The rounds for GOD is stated assuming broadcast channel availability in ours and [BJPR18]).

All protocols barring the one with GOD maintain the same circuit-dependent communication as [CGMV17]. The GOD protocol costs two circuit-dependent communication, one in 5PC and one in 3PC, the latter amongst a smaller instance of 3 parties. This is reflected in the cost of worst case run of our GOD protocol. For all other constructions, the overhead comes from extra communication (commitments to be precise) that is dependent only on the input, output size. Since SHA is a bigger circuit, its absolute overheads are more than AES in most cases but the percentage overheads are better for SHA than AES. The factor of additional communication overhead incurred by our protocols for SHA when compared to AES circuit is far less than the factor of increase in the total communication for SHA over AES in [CGMV17]. This indicates that the efficiency of our protocols improves for larger circuits.

## 2 Preliminaries

We consider a set of 5 parties \( P = \{ P_1, P_2, P_3, P_4, P_5 \} \), where each pair is connected by a pair-wise secure and authentic channel. The presence of a broadcast channel is assumed only for the GOD protocol where it is known to be necessary [CL14]. We model each party as a non-uniform probabilistic polynomial time (PPT) interactive Turing Machine. We consider a static security model with honest majority, where a PPT adversary \( A \) can corrupt at most 2 parties at the onset of protocol. Adversary \( A \) can be malicious in our setting i.e., the corrupt parties can arbitrarily deviate from the protocol specification. The computational security parameter is denoted by \( \kappa \).

A function \( \text{negl}(\kappa) \) is said to be *negligible* in \( \kappa \) if for every positive polynomial \( p(\cdot) \), there exists an \( n_0 \) such that for all \( n > n_0 \), it holds that \( \text{negl}(n) < \frac{1}{p(n)} \). A probability ensemble \( X = \{ X(a, n) \}_{a \in \{0, 1\}^*, n \in \mathbb{N}} \) is an infinite sequence of random variables indexed by \( a \) and \( n \in \mathbb{N} \). Two ensembles \( X = \{ X(a, n) \}_{a \in \{0, 1\}^*, n \in \mathbb{N}} \) and \( Y = \{ Y(a, n) \}_{a \in \{0, 1\}^*, n \in \mathbb{N}} \) are said to be *computationally indistinguishable*, denoted by \( X \approx Y \), if for every PPT algorithm \( D \), there exists a negligible function \( \text{negl}(\cdot) \) such that for every \( a \in \{0, 1\}^* \) and \( n \in \mathbb{N} \), \( |\Pr[D(X(a, n)) = 1] - \Pr[D(Y(a, n)) = 1]| \leq \text{negl}(n) \). The security of all our protocols is proved in the standard real/ideal world paradigm. Appendix A elaborates on the functionalities and security definitions. Below we discuss the primitives that we use.
Non-Interactive Commitment Schemes A Non-Interactive Commitment Scheme (NICOM) is characterized by two PPT algorithms (Com, Open) for the purpose of commitment and opening phase. The properties to be satisfied by a commitment scheme are: correctness (a commitment opens to the correct message), hiding (a corrupt receiver cannot derive any information about the message from the commitment alone) and binding (a corrupt committer cannot open a commitment to multiple messages). We use instantiations based on injective one-way functions that ensure a strong binding even if the public parameter is arbitrarily chosen by adversary.

For our fair protocol, we need an equivocal NICOM (eNICOM). An eNICOM is defined with four PPT algorithms (eCom, eOpen, eGen, Equiv). eCom, eOpen are defined as in NICOM and eGen, Equiv are used to provide the property of equivocation. The formal definitions and the instantiations appear in Appendix B.

Secret Sharing Schemes We use additive sharing and replicated secret sharing (RSS) [CDI05, ISN89]. For a value $x$, its $g$th additive share is noted as $x^g$. We now recall RSS. Consider a secret $x$, of some finite field $F$ to be shared among $n$ parties s.t only $> t$ parties can reconstruct $x$. A maximal unqualified set is the set of $t$ parties who together cannot reconstruct the secret. A dealer with secret $x$ splits it into additive shares s.t each share corresponds to one maximal unqualified set $T_l$, $l \in \{1, \ldots, \binom{n}{t}\}$. Formally, $x = \sum_{l \in \binom{I}{t}} x^l$. Each share $x^l$ is associated with $T_l$ (lexicographically wlog) and additive shares are random s.t they sum to $x$. Each party $P_i$, $i \in [n]$ gets all $x^l$ for $i \notin T_l$. This ensures that $t$ parties alone of any $T_l$ cannot retrieve $x$. We use a 4-party RSS with $t = 2$ where, each party gets 3 shares and each share is held by 3 parties including the dealer. Reconstruction is done by combining the shares held by any 3 parties. Given only shares of any two parties $\{P_i, P_j\}$, $x$ remains private as $x^l$ where $T_l = \{P_i, P_j\}$ is missing from the view.

3 Distributed Garbling and More

At the heart of our 5PC lies a 4-party distributed garbling (4DG) and a matching evaluation protocol tolerating arbitrary semi-honest corruptions. Garbling is done distributively amongst the garblers $\{P_1, P_2, P_3, P_4\}$ and $P_5$ enacts the sole evaluator. Our 4DG scheme is a direct simplification of the state-of-the-art actively-secure distributed garbling scheme of [WRK17]. The semi-honest scheme when combined with party-emulation idea of [CGMV17], achieves malicious security against 2 corruptions. Specifically, the role of each garbler in the underlying semi-honest 4DG scheme is also enacted by two other fellow garblers. This emulation is achieved via a unique seed distribution (SD) technique that ensures that the seed of a garbler is consistent with two other garblers and all the needed randomness for 4DG is generated from the seed. This helps to detect any wrong-doing by at most two garblers. Interestingly, the seed distribution can further be leveraged to replace the computationally-heavy public-key primitive Oblivious Transfer (OT) in [WRK17] with an inexpensive symmetric-key based alternative called attested OT [CGMV17]. While all our protocols for 5PC can be realized with any underlying passively-secure garbling scheme when used with SD and attested OT, we choose the current construction for efficiency. We start with the seed distribution technique.

3.1 Seed Distribution (SD)

In the 4DG, all randomness required by a garbler $P_i$ is generated using a random seed $s_i$. The SD technique involves distributing the seeds among 4 garblers s.t the seed $s_i$ generated by $P_i$ is held by two other garblers and no single garbler has the knowledge of all 4 seeds. Consequently, any data computed based on $s_i$ is done identically by 3 parties who own $s_i$ and thus, can be compared for correctness. With at least one honest party in this team of 3 parties, any wrong-doing by at most two parties is detected. The SD functionality $F_{SD}$ is depicted in Fig 1 and is realized differently in each of our protocols based on the required security guarantee (fairness or GOD).

We use $S_g$ to denote the set of indices of parties who hold $s_g$ as well as the set of indices of the seeds held by party $P_g$. Note that both these sets are identical– for instance, $S_1 = \{1, 3, 4\}$ indicates that parties $P_1, P_3, P_4$ hold $s_1$. $S_1$ also indicates that $P_1$ holds $s_1, s_3, s_4$. 

3.1 Seed Distribution (SD)
Let $S_i, i \in [4]$ be $S_1 = \{1, 3, 4\}, S_2 = \{2, 3, 4\}, S_3 = \{1, 2, 3\}, S_4 = \{1, 2, 4\}$. Let $C$ be the set of corrupt parties. Corrupted parties $P_j \in C$ may send the trusted party $(\text{Input, } s_j/\perp)$ as instructed by the adversary.

On message $(\text{Input, } *)$ from garbler $P_i, g \in [4] \setminus C$ and $(\text{Input, } \{s_j/\perp\}) \in C$ from adversary, sample $s_i$ on behalf of every honest $P_i$ and send $s_0$ (or $\perp$ as given by adversary) to each party in $S_g$.

### Figure 1: Functionality $F_{SD}$

#### 3.2 Attested Oblivious Transfer (AOT)

The AOT protocol [CGMV17] can be viewed as an OT between a sender and a receiver with an additional help from two other parties called “attesters”. These “attesters” aid in ensuring correctness of the OT protocol by attesting inputs of the sender and the receiver. AOT functionality is recalled in Fig 2.

$P_s$ acts as sender, $P_r$ acts as receiver and $P_{a1}, P_{a2}$ act as attesters.
- On input message $(\text{Sen, } m_0, m_1)$ from $P_s$, record $(m_0, m_1)$ and send $(\text{Sen, } m_0, m_1)$ to $P_{a1}$ and $P_{a2}$ and $\text{Sen}$ to the adversary.
- On input message $(\text{Rec, } b)$ from $P_r$, where $b \in \{0, 1\}$, record $b$ and send $(\text{Rec, } b)$ to $P_{a1}$ and $P_{a2}$ and Rec to the adversary.
- On input message $(\text{Att, } m_0^i, m_1^i, b^i)$ from $P_{a1}, i \in [2]$, if $(\text{Sen, } \text{sid, } *, *)$ and $(\text{Rec, } *)$ have not been recorded, ignore this message; otherwise, record $(m_0^i, m_1^i, b^i)$ and send $\text{Att}$ to the adversary.
- On input message $\text{Output}$ from the adversary, if $(m_0, m_1, b) \neq (m_0^i, m_1^i, b^i)$ or $(m_0, m_1, b) \neq (m_0^g, m_1^g, b_2)$, send $(\text{Output, } \perp)$ to $P_r$; else send $(\text{Output, } m_b)$ to $P_r$.
- On input message abort from the adversary, send $(\text{Output, } \perp)$ to $P_r$.

### Figure 2: Functionality $F_{AOT}(P_s, P_r, \{P_{a1}, P_{a2}\})$

#### 3.3 The semi-honest 4DG and Evaluation

A distributed garbled circuit (DGC) is prepared together by all garblers in a distributed manner. Each wire $w$ in our 4DG scheme is associated with a mask bit $\lambda_w \in \{0, 1\}$ and each garbler $P_g$ holds a share $\lambda_0^g$ s.t $\lambda_w = \oplus_{g \in [4]} \lambda_0^g$. Each $P_g$ samples two keys $k_{w,0}^g, k_{w,1}^g = k_{w,0}^g \oplus \Delta^g$ for each wire $w$, with global offset $\Delta^g$. Thus, each super-key of a wire has 4 keys contributed by 4 garblers.

**Definition 3.1.** A super-key of a wire is a set of 4 keys, each contributed by one garbler i.e., $\{k_{w,0}^g\}_{g \in [4]}$ indicates the 0-super-key on wire $w$ and $\{k_{w,1}^g\}_{g \in [4]}$ indicates the 1-super-key on $w$.

Free-XOR is enabled by setting the mask and keys for the output wire of an XOR gate as the XOR of masks and keys of its input wires. A garbled AND gate, on the other hand, comprises of a super-CT together would give the desired super-key on the output wire. In order to hide the actual output of intermediate gates from an evaluator, we enable point and permute. The mask bit $\lambda_w$ acts as the permutation bit for wire $w$. Thus, for an AND gate with input wires $u, v$, output wire $w$ and their corresponding masks $\lambda_u, \lambda_v, \lambda_w$, if $x_u, x_v$ denote the actual values on wires $u, v$ respectively, then the evaluator sees super-keys $k_{u,b_u}^g, k_{v,b_v}^g$ where $b_u, b_v$ defined as $(b_u = x_u \oplus \lambda_u), (b_v = x_v \oplus \lambda_v)$ denote the blinded bits. The evaluator then decrypts the super-CT positioned at row $(b_u, b_v)$ and obtains the output super-key $\{k_{w,0}^g \oplus \Delta^g(x_u x_v \oplus \lambda_w)\}_{g \in [4]}$ that corresponds to the blinded (masked) bit $x_u x_v \oplus \lambda_w$ on wire $w$.

**Definition 3.2.** A blinded or masked bit of a bit $x_w$ on a wire $w$ is the XOR of $x_w$ with mask bit $\lambda_w$ on wire $w$ i.e. $b_w = x_w \oplus \lambda_w$.

Interpreting row $(b_u, b_v)$ as $\gamma = 2b_u + b_v + 1$ and recasting the above, we see that the super-CT at row $\gamma$ for $\gamma \in [4]$ encrypts the super-key $\{k_{w,0}^g \oplus \Delta^g((b_u \oplus \lambda_u)(b_v \oplus \lambda_v) \oplus \lambda_w)\}_{g \in [4]}$. In 4DG, the super-CTs as above
for an AND gate are prepared distributed amongst the garblers, using the additive shares of the mask bits and keys held by each garbler corresponding to the input and output wires of the gate. We achieve this in a two-step process. First, we generate the additive sharing of each key belonging to the super-key to be encrypted in each row. Second, for each row, a garbler encrypts the additive shares it holds of each key of the corresponding super-key (obtained in the first step) in the CT that it contributes for the super-CT of that row. A CT for row \( \gamma \) has the format of one-time pad where the pad is calculated using a double-keyed PRF with keys corresponding to row \( \gamma \).

**Definition 3.3.** A super-ciphertext for a given row \( \gamma (\gamma = 2b_u + b_v + 1) \), of an AND gate with input wires \( u, v \), output wire \( w \), is a set of 4 CTs, \( \{ P_g \} \) \( g \in [4] \), where \( P_g \) contributes \( c_{\gamma}^g \) that encrypts its additive share of each key in \( \{k_{w,0}^g + \Delta^g((b_u + \lambda_v)(b_v + \lambda_u) \oplus \lambda_w)\} \) \( g \in [4] \).

To compute the additive sharing of super-key \( \{k_{w,0}^g + \Delta^g((b_u + \lambda_v)(b_v + \lambda_u) \oplus \lambda_w)\} \) \( g \in [4] \) for all rows (i.e. all possibilities of \((b_u, b_v)\)), we compute the additive sharing of the following in sequence, starting with the additive shares of \( \lambda_u, \lambda_v, \lambda_w \): (A) \( \lambda_u \lambda_v \) (for row 1 i.e. \( \gamma = 1 \) and \( b_u = b_v = 0 \)), \( \lambda_u \lambda_v \) (for \( \gamma = 2 \) and \( b_u = 0, b_v = 1 \)), \( \lambda_u \lambda_v \) (for \( \gamma = 3 \) and \( b_u = 1, b_v = 0 \)) and \( \lambda_u \lambda_v \) (for \( \gamma = 4 \) and \( b_u = 1, b_v = 1 \)); (B) \( \lambda_1 = \lambda_u \lambda_v + \lambda_w, \lambda_2 = \lambda_u \lambda_v + \lambda_w, \lambda_3 = \lambda_u \lambda_v + \lambda_w, \lambda_4 = \lambda_u \lambda_v + \lambda_w \); (C) \( \Delta^g \gamma \) for all \( g, \gamma \in [4] \) and \( \Delta^g \gamma \); (D) \( k_{w,0}^g + \Delta^g \gamma \) for all \( g, \gamma \in [4] \). (B) and (D) require linear operations, thus can be done locally by each garbler. However, for (A) and (C), additive sharing of a product needs to be computed which requires interaction among garblers. This is done via OTs, which we explain below. Also, in (A), it is known how to tweak shares of \( \lambda_u \lambda_v \) locally to get the shares of remaining products [BLO16], thus computing the sharing of \( \lambda_u \lambda_v \) alone suffices. We now explain how the additive sharing of 1) \( \lambda_u \lambda_v \), and 2) \( \Delta^g \gamma \) for any \( \gamma \in [4] \) is computed.

To compute 1), each garbler \( P_g \) locally computes \( \lambda_u \lambda_v \). In addition, each pair of parties \( P_g, P_{g'} \) for \( g \neq g' \) run an OT with \( P_g \) as sender, holding \((r, r \oplus \lambda_u^g)\) and \( P_{g'} \) as receiver, holding \( \lambda_u^g \) to generate 2-out-of-2 additive sharing of \( \lambda_u \lambda_v \). \( P_g \) outputs its share as \( r \) denoted by \([\lambda_u \lambda_v]_S \) and \( P_{g'} \) outputs its share as the OT output \( r \oplus \lambda_u^g \lambda_v^g \) denoted by \([\lambda_u \lambda_v]_R \) (We use \([\cdot]_S, [\cdot]_R \) to denote the shares of sender and receiver of OT respectively). Each garbler \( P_g \) now computes its share, \( \lambda_u \lambda_v \), of the product \( \lambda_u \lambda_v \) as the sum of its local product \( \lambda_u^g \lambda_v^g \) and the shares obtained from OTs either as a sender or as a receiver i.e., \( \lambda_u \lambda_v \lambda_w = \lambda_u^g \lambda_v^g \oplus (\oplus_{g \neq g'}[\lambda_u \lambda_v]_S) \oplus (\oplus_{g \neq g'}[\lambda_u \lambda_v]_R) \). Next, to compute 2), where \( \Delta^g \) belongs to \( P_g \) and \( \Delta^g \gamma = \Delta^g(\lambda_1 \oplus \lambda_2 \oplus \lambda_3 \oplus \lambda_4) \), each garbler \( P_g \) first locally computes \( \Delta^g \gamma \) and then for each cross-term \( \Delta^g \gamma, g \neq g' \), \( P_g \) acts as a sender with each \( P_{g'} \) as receiver in an OT to get their respective shares \([\Delta^g \lambda_{g'}]_S \) and \([\Delta^g \lambda_{g'}]_R \). Finally, the share of \( P_g \) for the product \( \Delta^g \lambda_{g'} \) is set to the following sum: \( \Delta^g \lambda_{g'} \oplus (\oplus_{g \neq g'}[\Delta^g \lambda_{g'}]_S) \) while the share of each \( P_{g'} \) is set to \([\Delta^g \lambda_{g'}]_R \). We now present the functionality \( F_{GC} \) (Fig 3). Partitioning the set of all super-CTs into its 4 constituent CTs, we can view the GC as \( GC^1 \ | \ GC^2 \ | \ GC^3 \ | \ GC^4 \) where \( g \)th partition is contributed by garbler \( P_g \).

**Evaluation of the DGC** Starting with the masked bits of all inputs and corresponding super-keys, \( P_b \) evaluates a DGC in topological order, with XOR gate evaluated using free-XOR. For an AND gate with input wires \( u, v \), \( P_b \) with input super-keys \( \{k_{u,0}^b, k_{v,0}^b\} \) \( g \in [4] \) and blinded input bits \( b_u, b_v \), decrypts \( (b_u, b_v) \)th row’s super-CT to obtain the super-key corresponding to blinded output bit \( u \oplus v \otimes w \) and the blinded output bit itself. The blinded bits for output wires give clear output when XORed with their respective masks.

### 3.4 Distributed Garbling with AOT and Seed distribution

As iterated before, we assume that all the randomness required by a party \( P_g \) for 4DG is generated using a random seed \( s_g \). The SD then enables a party-emulation technique where the seed \( s_g \) of \( P_g \) is available to exactly two other garblers in \( S_g \) who can now emulate the role of \( P_g \). Thus, each partition of GC, \( GC^g \) is generated by 3 garblers holding \( s_g \), offering security against at most two corrupt garblers. This also preserves input privacy as: (i) when two garblers are corrupt (and together hold all seeds), the evaluator is surely honest and protects the privacy of inputs; (ii) when a garbler and the evaluator are corrupt, one seed remains hidden, assuring input privacy. The SD results brings a prime gain in the underlying semi-honest 4DG— replacing standard OTs with 1-round AOTs:
Let $C$ be the circuit, $\kappa$, the security parameter and $F$, a double-keyed PRF [BLO16]. Each garbler $P_{g}$ prepares the private input set $\text{ISet}_{g}$ consisting of:
- An offset string $\Delta \in \{0, 1\}^{\kappa}$.
- A share $\lambda_{g}^{w} \in \{0, 1\}^{\kappa}$ of the masking bit for each wire $w$, barring the output wire of XOR gates.
- Keys $k_{g}^{w}$, $k_{w}^{g} \in \{0, 1\}^{\kappa}$ for every wire $w$ s.t. $k_{g}^{w} = k_{w}^{g} \oplus \Delta$, except the output wire of XOR gates.

**Input:** On receiving message (Input, $\text{ISet}_{g}$) from each garbler $P_{g}$, $g \in [4]$, compute super-keys and mask bits for all wires (those for XOR output wires are computed as per free-XOR). For every AND gate with input wires $u, v$, output wire $w$, the $g^{th}$ CT in the $\gamma^{th}$ super-CT for $g, \gamma \in [4]$ is computed as follows. For $a, b \in \{0, 1\}$, let $\gamma = 2a + b + 1, \lambda_{1} = \lambda_{a} \lambda_{b}, \lambda_{2} = \lambda_{a} \lambda_{v} \oplus \lambda_{u}, \lambda_{3} = \lambda_{a} \lambda_{v} \oplus \lambda_{u}, \lambda_{4} = \lambda_{a} \lambda_{v} \oplus \lambda_{u}, \lambda_{r} = \oplus_{g \in [4]} \lambda_{g}$ and $[\Delta^{g} \lambda_{g}]_{g}$ denote the $g^{th}$ additive share of $\Delta^{g} \lambda_{g}, g \in [4]$.

$$
eq\left\lceil_{\text{pad}} \frac{F_{\text{sk}, u, k_{u}^{g}}(u) \oplus (\lambda_{g}^{w} \oplus \left\lfloor ([\Delta^{g} \lambda_{g}]_{g})_{g} \neq g \right\rfloor || k_{w, 0}^{g} \right\rfloor \oplus [\Delta^{g} \lambda_{g}]_{g}}{P_{g}^{\text{pad}} \text{share of the output wire of } P_{g} \text{, } P_{g}^{\text{share of the output key of } P_{g}}}$$

**Output:** On receiving Output from parties, send $g^{th}$ partition $GC_{g}^{\gamma} = \{\{c_{\gamma}^{g}\}_{g \in [4]} \text{ AND gates}\} \{\text{H}(k_{w, 0}^{g})\}$ to $P_{g}$ where $H$ is the collision resistant hash (Appendix B).

**Figure 3:** Functionality $\mathcal{F}_{GC}$

The standard OTs used to compute each cross-term $\lambda_{u}^{w} \lambda_{v}^{g}, [\Delta^{g} \lambda_{v}]^{g}$ ($g \neq g'$) in the additive-sharing of $\lambda_{u} \lambda_{v}, \Delta^{g} \lambda_{v}$, respectively, are replaced with AOTs. The SD further enables each AOT to be run s.t. the attestors hold both seeds that the sender and receiver mutually-exclusively hold. This implies that the attestors are aware of the inputs of both sender and receiver at the onset, thus leading to a one-round instantiation of AOT (Appendix B). Note that the party-emulation technique does not increase the number of OTs required to three times the underlying semi-honest 4DG but instead keeps it the same, since SD ensures that, for each garbler $P_{1}$, OTs are needed in the computation of every $\lambda_{u}^{w} \lambda_{v}^{g}, [\Delta^{g} \lambda_{v}]^{g}$ ($g \neq g'$) only when one of $g, g'$ is not in $\mathcal{S}_{1}$.

For clarity, below we demonstrate, how a particular product share $\lambda_{u}^{w}$ (of $\lambda_{u}, \lambda_{v}$) is computed by parties in $\mathcal{S}_{1} (\{P_{1}, P_{3}, P_{4}\})$, utilizing AOT and SD. The share $\lambda_{u}^{w}$ consists of summands as listed in the first column of the table below. We explain how $P_{1}$ computes each summand. Except $\lambda_{u}^{w}, \lambda_{v}^{w}$, the remaining summands correspond to cross-terms that $P_{1}$ originally obtained via OT either as sender or receiver. Now, all summands that correspond to $P_{1}$ enacting a sender ($\lambda_{u}^{w} \lambda_{v}^{g}, g \neq 1$) can be sampled from $s_{1}, s_{2}$, as the sender’s share is a random bit. For the summands where $P_{1}$ enacts receiver ($\lambda_{u}^{w} \lambda_{v}^{g}, g \neq 1$), AOT is needed only for the summand, $\lambda_{u}^{w} \lambda_{v}^{w}$ that involves $s_{2}$ which $P_{1}$ does not own, while for other terms, $P_{1}$ can locally compute its share with the knowledge of both seeds. As for the AOT, $P_{1}$ acts as receiver with seed $s_{1}, P_{2}$ acts as sender with seed $s_{2}$, and $\{P_{3}, P_{4}\}$ act as attestors with $\{s_{1}, s_{2}\}$. Similarly, $\{P_{3}, P_{4}\}$ can compute the summands of $\lambda_{u}^{w}$ as indicated in the table.

Our final garbling and evaluation protocols appear in Figs 4-5. The correctness proof appears in Lemma 3.4.

**Efficiency of 4DG** Our 4DG is superior to the state-of-the-art [BLO16] computationally while retaining their communication efficiency. Concretely, for 4DG, [BLO16] needs 4 PRF computations per CT of the super-CT whereas our scheme needs 1 PRF computation per CT. Since, the number of PRFs computed depends on the number of parties, this difference is significant for large $n$. To elaborate, for $n$-party garbling, [BLO16] needs $n$
Common Inputs: Circuit $C$ that computes $f$.

Primitives and Notation: A double-keyed PRF $F$ [BLO16]. $S_g$ denotes the indices of parties who hold $s_g$ as well as the indices of seeds held by $P_g$.

Output: Each party $P_g, g \in [4]$ outputs $GC^j, j \in S_g$ or ⊥.

Sampling Phase: Each $P_g, g \in [4]$ samples $\Delta^j$ from $s_j, j \in S_g$. Also, the following is done for each wire $w$ in $C$ corresponding to seed $s_j$:

- If $w$ is not an output wire of XOR gate, sample $\lambda'_{w,0}$ from $s_j$. Set $k_{w,1} = k_{w,0} + \Delta^j$.
- If $w$ is an output wire of XOR gate with input wires $u, v$, set $\lambda_{u,v} = \lambda'_{u,0} + \lambda'_{v,0}$, $k_{u,v} = k_{v,0} + k_{v,0}$ and $k_{w,1} = k_{w,0} + \Delta^j$.

The mask and super-key pair for a wire $w$ is defined as $\lambda_w = \oplus_{g \in [4]} \lambda^g_w$ and $(\{k^g_{w,0}\}_{g \in [4]}, \{k^g_{w,1}\}_{g \in [4]})$. Run in parallel for every AND gate in $C$ with input wires $u, v$ and output wire $w$:

**R1: Product Phase I:** Define $\lambda_{uw} = \lambda_u \lambda_w \oplus \oplus_{g \in [4]} (\{\lambda_w^g\})_{\lambda_w}$. Likewise define $\lambda_{uw}, \lambda_{uv}, \lambda_{uw}$ that can be derived from shares of $\lambda_{uw}$. Each garbler $P_g$ computes $\lambda_{uw}^j$ of $\lambda_{uw}$ for every $j \in S_g$ as below:

- locally compute $\lambda_{uw}^{j\lambda}_w$. For each $k \neq j$, sample $[\lambda_{uw}^{j\lambda}w]_S$ from seed $s_j$.
- for every $k \in S_g$, locally compute $[\lambda_{uw}^{j\lambda}w]_R = [\lambda_{uw}^{j\lambda}w]_S + [\lambda_{uw}^{j\lambda}w]$ with the knowledge of $s_j$ and $s_k$.
- for every $k \notin S_g$, obtain $[\lambda_{uw}^{j\lambda}w]_R$ from $FGAOT$ acting as receiver with input $\lambda_{uw}^j$ and $P_k$ as the sender with inputs $([\lambda_{uw}^{j\lambda}w]_S, [\lambda_{uw}^{j\lambda}w]_S + [\lambda_{uw}^{j\lambda}w]$) derived from $s_k$.
- for each $k \notin S_g, j \neq g$, obtain $[\lambda_{uw}^{j\lambda}w]_R$ from $FGAOT$ acting as a receiver with input $\lambda_{uw}^j$, and sender $P_s, s = [4] \setminus \{g, j, k\}$ with inputs $([\lambda_{uw}^{j\lambda}w]_S, [\lambda_{uw}^{j\lambda}w]_S + [\lambda_{uw}^{j\lambda}w]$) derived from $s_k$.
- compute $\lambda_{uw}^{j\lambda}w = \lambda_{uw}^{j\lambda}w \oplus (\oplus_{j \neq} [\lambda_{uw}^{j\lambda}w]_R)$.

Define $\lambda_1 = \lambda_u \lambda_v \oplus \lambda_{uw}, \lambda_2 = \lambda_u \lambda_v \oplus \lambda_{uw}, \lambda_3 = \lambda_u \lambda_v \oplus \lambda_{uw}, \lambda_4 = \lambda_u \lambda_v \oplus \lambda_{uw}$. Every $P_g$ computes $j$th share $\lambda_{w,j}$ of $\lambda_w$ for all $j \in S_g$ as $\lambda_{uw}^j \lambda_{uv}^j \lambda_{uw}^j$. Similarly, it computes the shares for $\lambda_2, \lambda_3, \lambda_4$.

**R2: Product Phase II:** $P_g$ computes share $[\Delta^j \lambda_{w,j}^j]$ (jth additive share) of $\Delta^j \lambda_{w,j}$ for every $\gamma \in [4]$ and $j \in S_g$ as follows:

- locally compute $\Delta^j \lambda_{w,j}^j$. For every $k \neq j$, sample $[\Delta^j \lambda_{w,j}^j]_S$ from seed $s_j$.
- compute $[\Delta^j \lambda_{w,j}^j]_R = [\Delta^j \lambda_{w,j}^j]_S + [\Delta^j \lambda_{w,j}^j]$.

$P_g$ computes $[\Delta^j \lambda_{w,j}^j]$ of $\Delta^j \lambda_{w,j}$ for each $k \neq j$, $\gamma \in [4], j \in S_g$ as:

- For every $k \in S_g$, compute $[\Delta^j \lambda_{w,j}^j]_R = [\Delta^j \lambda_{w,j}^j]_S + [\Delta^j \lambda_{w,j}^j]$ locally from the knowledge of $s_j$ and $s_k$.
- For $k \notin S_g, j = g$, obtain $[\Delta^j \lambda_{w,j}^j]_R$ from $FGAOT$ acting as receiver with input $\lambda_{uw}^j$ and $P_k$ as sender whose inputs are $[\Delta^j \lambda_{w,j}^j]_S + [\Delta^j \lambda_{w,j}^j]$ derived from $s_k$. Set $[\Delta^j \lambda_{w,j}^j]_R = [\Delta^j \lambda_{w,j}^j]$.
- For $k \notin S_g, j \neq g$, obtain $[\Delta^j \lambda_{w,j}^j]_R$ from $FGAOT$ acting as receiver with input $\lambda_{uw}^j$ and $P_s, s = [4] \setminus \{g, j, k\}$ as sender with inputs $[\Delta^j \lambda_{w,j}^j]_S + [\Delta^j \lambda_{w,j}^j]$ (from $s_k$). Set $[\Delta^j \lambda_{w,j}^j]_R = [\Delta^j \lambda_{w,j}^j]_R$.

**Super-CT Construction Phase:** For each $j \in S_g, P_g$ constructs $c_j^g$ for $\gamma \in [4]$, as in $FGC$ (Fig 3) and outputs $GC^j = \{c_j^g\}_{\gamma \in [4]} \forall AND gates \{H(k_{w,0}), H(k_{w,1})\} \forall output wires w$.

**Figure 4: Protocol Garble()**

**Figure 5: Protocol Eval()**

PRF computations per CT of super-CT and hence a total of $O(n^2)$ PRF per super-CT, while our scheme still needs 1 PRF per CT (so total of $n$ PRFs for super-CT), thus saving $O(n)$ PRF computations over [BLO16]. The player-
emulation technique also impacts the performance of [BLO16] concretely, compared to our 4DG – 12 versus 3 for each CT which has 3 copies and thus, 48 versus 12 per super-CT and 192 versus 48 per AND gate.

3.5 Attested OT Instantiation

For the attested OT functionality $F_{4AOT}$ defined in Fig 2, we now provide a standalone instantiation. The sender of the AOT, $P_s$ having inputs $m_0, m_1$ samples random $r_0, r_1 \leftarrow \{0,1\}^k$ and generates the commitments: $(c_0, o_0) \leftarrow \text{Com}(pp, m_0)$, $(c_1, o_1) \leftarrow \text{Com}(pp, m_1)$. $P_s$ sends $(m_0, r_0, m_1, r_1)$ to the attesters and $(pp, c_0, c_1)$ to the receiver. The receiver $P_r$ sends the choice bit $b$ to the attesters. The attesters exchange the copy of message received from $P_s$, $P_r$ amongst themselves for correctness. If verified, they use $(m_0, r_0, m_1, r_1)$ to compute the commitments $(pp, c_0, c_1)$ and send the same to the receiver. One of the attesters, say $P_{a_1}$ also sends the opening corresponding to $c_0$ to $P_r$. If the verification fails, the attesters send $\perp$ to $P_r$. The receiver $P_r$ then checks if all the copies of commitments received are the same. If not, aborts. Else, $P_r$ uses the opening of $c_0$ to obtain $m_b$.

When coupled with seed distribution, the standalone realization of $F_{4AOT}$ can be simplified as follows: The attesters are chosen s.t they possess the inputs (derived from seed) of both sender and receiver. For instance, when $P_s = P_1, P_r = P_2$, the attesters are $P_3, P_4$ and the inputs of the sender are derived from the seed $s_1$, while the input of the receiver is derived from seed $s_2$ (both seeds are with $P_3, P_4$). Thus, $P_s$, now sends $(pp, c_0, c_1)$ to $P_r$ and the attesters send $H((pp, c_0, c_1))$ to $P_r$. Also, $P_{a_1}$ sends opening corresponding to commitment $c_0$. All these steps can be done in only one round and hence AOT in our garbling scheme needs only one round. $P_r$ then computes the output as in the standalone description. This process is formally depicted in Fig 6.

$P_s, P_r$ denote the sender and receiver respectively. $P_{a_1}, P_{a_2}$ are attesters. All are distinct parties.

**Inputs:** $P_s$ holds $m_0$, $m_1$, $P_r$ holds choice bit $b$.

**Output** $P_r$ outputs $m_b, \perp$.

**Primitives:** A secure NICOM (Com, Open) (Appendix B).

- $P_s$ samples $pp$ and random $r_0, r_1 \leftarrow \{0,1\}^k$ (derived from $s_i, i \in S_s \setminus S_r$) and computes $(c_0, o_0) \leftarrow \text{Com}(pp, m_0)$, $(c_1, o_1) \leftarrow \text{Com}(pp, m_1)$. $P_s$ sends $(pp, c_0, c_1)$ to $P_r$. $P_{a_1}, P_{a_2}$ who know $(r_0, r_1)$ (since they know $s_i$) also compute $(c_0, o_0) \leftarrow \text{Com}(pp, m_0)$, $(c_1, o_1) \leftarrow \text{Com}(pp, m_1)$ and each send $H((pp, c_0, c_1))$ to $P_r$.

- $P_r$ has $b$ (derived using $s_j, j \in S_r \setminus S_s$ which is known to $P_{a_1}, P_{a_2}$ (since they know $s_j$)). $P_{a_1}$ (wlog) sends $o_0$ to $P_r$.

**Local Computation by $P_r$:** If the commitment sent by $P_s$ and the hash values sent by $P_{a_1}, P_{a_2}$ do not match, then $P_r$ outputs $\perp$. Else, output $m_b = \text{Open}(c_0, o_0)$.

*The exact realization of the functionality $F_{4AOT}$ involves $P_s$ and $P_r$ sending $(r_0, m_0, m_1, r_1)$ and $b$ respectively to $P_{a_1}$ and $P_{a_2}$ who in turn exchange their copies received from $P_s, P_r$ for correctness.

![Figure 6: Protocol $\Pi_{AOT}(P_s, P_r, \{P_{a_1}, P_{a_2}\})$ for Garble](image)

The protocol realization specific to god5PC is presented in Fig 7. This protocol is same as $\Pi_{AOT}$, except that the sender’s and attesters’ messages are broadcast to enable the identification of conflict in case of mismatching messages. Thus the protocol either outputs the OT message to the receiver or identifies a 3PC $P^3$ for all.

3.6 Correctness and Security of 4DG

**Lemma 3.4.** The protocols Garble and Eval are correct.

**Proof.** To prove the lemma we argue that the super-key encrypted in the super-CT of a row decrypts to the correct super-key when evaluated on the blinded inputs corresponding to that row. Consider an AND gate with input wires $u, v$ and output wire $w$ with corresponding masks $\nu, \nu_v$ and $\lambda_w$ respectively. Let the blinded inputs $b_u, b_v$ received for evaluation have values $b_u = b_v = 0$. This means $\gamma = 1$ (row 1). We prove that $b_w$ and $\{k_{u,b_u}^y, k_{v,b_v}^y\} \exists \in [4]$ are correctly computed given $b_u, b_v$ and super-keys $\{(k_{u,b_u}^y, k_{v,b_v}^y)\} \exists \in [4]$. For simplicity we consider $\lambda_w = 0$. The values $b_u = b_v = 0$ imply $x_u = \lambda_u$ and $x_v = \lambda_v$. Since, $\lambda_w = 0$, $\nu = \nu_1 = \lambda_1 = \nu_2 \lambda_w$. This means that
\(P_s, P_r\) denote the sender and receiver respectively. \(P_{a_1}, P_{a_2}\) are attesters. \(P_a\) denotes the auditor. All are distinct parties.

**Inputs:** \(P_s\) holds \(m_0, m_1\), \(P_r\) holds choice bit \(b\).

**Notations** \(\mathcal{P}^3\) is the 3PC committee with at most 1 corruption.

**Output** \(P_r\) outputs \(m_b/\mathcal{P}^3\). All other parties output \(\perp/\mathcal{P}^3\).

**Primitives:** A secure NICOM (Com, Open) (Appendix B).

- \(P_s\) samples \(pp\) and random \(r_0, r_1 \rightarrow \{0, 1\}^s\) (derived from \(s_i, i \in S_s \setminus S_r\)) and computes \((c_0, o_0) \leftarrow \text{Com}(pp, m_0)\), \((c_1, o_1) \leftarrow \text{Com}(pp, m_1)\). \(P_s\) broadcasts \((pp, c_0, c_1)\). \(P_{a_1}, P_{a_2}\) who know \((r_0, r_1)\) (since they know \(s_i\)) also compute \((c_0, o_0) \leftarrow \text{Com}(pp, m_0), (c_1, o_1) \leftarrow \text{Com}(pp, m_1)\) and each broadcast \((c_0, c_1)\).

- \(P_r\) has \(b\) (derived using \(s_j, j \in S_r \setminus S_s\)) which is known to \(P_{a_1}, P_{a_2}\) (since they know \(s_j\)). \(P_{a_1}\) (wlog) sends \(o_0\) to \(P_r\).

If the broadcast values sent by \(P_s, P_{a_1}, P_{a_2}\) do not match, each \(P_r, \gamma \in [5]\) sets \(\mathcal{P}^3 := \{a_1, r, a\}\). Output \(\mathcal{P}^3\).

**(Computation by \(P_r\)):** If no \(o_0\) is received or \(\text{Open}(c_0, o_0) = \perp\), broadcast conflict with \(P_{a_1}, P_{a_2}\). All parties set \(\mathcal{P}^3 := \{s, a_2, a\}\) and output \(\mathcal{P}^3\). Else, \(P_r\) outputs \(m_b = \text{Open}(c_0, o_b)\) and the remaining parties output \(\perp\).

**Figure 7:** Protocol \(\Pi_{AOTGOD}(P_s, P_r, \{P_{a_1}, P_{a_2}\}, P_a)\)

\[g(\lambda_u, \lambda_v) = g(x_u, x_v)\text{ where }g\text{ is the AND gate function. Thus, the encrypted super-key must be }\{k_{w,g(x_u,x_v)}^\gamma\}_{\gamma \in [4]}\text{ as }\Delta^g\lambda_1 = \Delta^g g(x_u, x_v)\text{ (thus }\lambda_1 = g(x_u, x_v)\text{) for each garbler }P_g.\text{ Now, we show that on decryption of the super-CT in row }\gamma = 1,\text{ the evaluator obtains }\{k_{w,g(x_u,x_v)}^\gamma\}_{\gamma \in [4]}\text{. The plaintext of super-CT of row 1 on unmasking the one-time pad of PRF appears as follows:}

\[
\{ (\lambda_1^1) | | | | \{[\Delta^g\lambda_1^1]\}_{g\neq1} | | k_{w,0}^1 | | | [\Delta^1\lambda_1^1], \\
(\lambda_2^1) | | | | \{[\Delta^g\lambda_1^2]\}_{g\neq2} | | k_{w,0}^2 | | | [\Delta^2\lambda_1^2], \\
(\lambda_3^1) | | | | \{[\Delta^g\lambda_1^3]\}_{g\neq3} | | k_{w,0}^3 | | | [\Delta^3\lambda_1^3], \\
(\lambda_4^1) | | | | \{[\Delta^g\lambda_1^4]\}_{g\neq4} | | k_{w,0}^4 | | | [\Delta^4\lambda_1^4] \}
\]

The evaluator computes \(b_w = \bigoplus_{\gamma \in [4]} \lambda_\gamma^1 = g(x_u, x_v)\) and computes the super-key as \(\{k_{w,0}^\gamma \oplus \{[\Delta^g\lambda_1]\}_{\gamma}\}_{\gamma \in [4]} = \{k_{w,0}^\gamma \oplus \Delta^g\lambda_1\}_{\gamma \in [4]}\). Since \(\Delta^g\lambda_1 = \Delta g(x_u, x_v)\), the super-key reduces to \(\{k_{w,g(x_u,x_v)}^\gamma\}_{\gamma \in [4]}\) as desired. The correctness for the remaining rows of super-CT and for any choice of \(\lambda_u\) can be proved in a similar way.

\[\square\]

## 4 5PC with Fairness

Relying on pairwise-secure channels, we outline a symmetric-key based 5PC with fairness, tolerating 2 malicious corruptions with performance almost on par with the state-of-the-art [CGMV17] with selective-abort while maintaining a round complexity of 8. Starting with the overview of [CGMV17], we enumerate the challenges involved in introducing fairness into it and then describe techniques to tackle them.

In [CGMV17], the garblers perform a one-time SD, which can be used for multiple executions. The evaluator \(P_5\) splits her input additively among \(P_2, P_3, P_4\) who treat the shares as their own input. Garbling is done using the passively secure scheme of [BLO16] topped with the techniques of SD and AOT (Section 3). For the transfer of super-keys wrt every input wire \(w\) of each garbler \(P_g\), the remaining garblers send the mask shares not held by \(P_g\) \((\lambda_w, j \notin S_g)\) on \(w\) to \(P_g\) who after verifying the shares for correctness (applying the equality check), computes the blinded bit \(b_w = x_w \oplus \lambda_w\) \((x_w\) is the input on \(w\)). Now, \(P_g\) can send 3 out of 4 keys in the super-key for \(b_w\) to \(P_5\).

However, to enable \(P_5\) learn the fourth key for \(b_w\) that corresponds to the seed held by remaining co-garblers, \(P_g\) cannot simply send \(b_w\) to the co-garblers, as it would leak \(P_g\’s\) input when two of the garblers are corrupt (and hold all seeds and thus the mask \(\lambda_w\)). Hence, [CGMV17] overcomes this subtle case of masked input key as follows. \(P_g\) splits \(b_w\) as \(b_w = \bigoplus_{l \in [4] \setminus \{g\}} b_l\) and sends each share to exactly one co-garbler. Each co-garbler now sends key
for the share she received to \( P_5 \) who XORs the 3 key-shares to get the desired 4\(^{th} \) key. The property of free-XOR is crucial in ensuring that XOR of key-shares gives the key on blinded input. A breach in the above solution is that \( P_5 \) colluding with \( P_3 \) can learn both super-keys for \( w \) leading to multiple evaluations of \( f \). This is captured by the following attack: \( P_5 \) sets \( b_l = 0, b_r = 1 \) and sends them to co-garblers \( P_l, P_r \) respectively. As a result, \( P_5 \) receives 0-key from \( P_l \), 1-key from \( P_r \) and XOR of these values leaks the global offset and thus both keys corresponding to the seed \( P_5 \) does not own. Now \( P_5 \) who already owns 3 seeds can now use both 0-key and 1-key of the 4\(^{th} \) key to obtain multiple evaluations of \( f \). This is tackled by having \( P_5 \) and one of her co-garblers separately provide additive shares of 0\(^{st} \) that are XORed with key-shares before sending to \( P_5 \). Finally, \( P_5 \) assembles the XOR shares and uses the 4\(^{th} \) key for evaluation. On evaluation, \( P_5 \) sends the output super key \( Y \) to all garblers, who then compute the output using output mask shares, that are exchanged and verified at the end of garbling phase.

The prime challenge to introduce fairness in the protocol of [CGMV17] is for the case of a corrupt evaluator, who either sends \( Y \) selectively to garblers or sends an invalid/no \( Y \) after learning the output herself on successful evaluation of DGC. This can be tackled using the following natural techniques in the output phase: (a) The garblers withhold the shares of mask bits on the output wires until a valid output super-key is received from \( P_5 \). (b) To further prevent a corrupt \( P_5 \) from selectively sending \( Y \) to garblers, we enforce the garbler who received valid \( Y \) from \( P_5 \) to, in turn, send the same \( Y \) to her co-garblers. Nevertheless, both the above solutions can lead to unfair scenarios. In solution (a), a corrupt garbler can send an incorrect share of the mask bit on receiving \( Y \), thus creating chaos for the honest receiver who cannot decide the true value, while the corrupt garbler herself learns the output using the shares received from honest co-garblers. In solution (b), two colluding garblers can convince the honest garblers of any \( Y \) using their knowledge of all seeds, even if the honest \( P_5 \) aborts during evaluation. This is easily fixable with broadcast, however, without broadcast, a convincing strategy that \( Y \) indeed originated from \( P_5 \) is necessary.

We tackle the concerns in solution (a) using the commit-then-open technique. In detail, the garblers are forced to commit to the shares of mask bit on each output wire in advance to bar them from sending inconsistent values later and violating fairness. Three copies of each commitment are sent by the 3-parties who own the corresponding seed which are then compared for correctness by each receiver prior to evaluation. The collision-resistant property of hash is used as a proofing mechanism to tackle the concerns in solution (b). Concretely, \( P_5 \) computes hash on a random value proof in the garbling phase and sends the resulting hash, \( H(\text{proof}) \) to all garblers who in turn exchange \( H(\text{proof}) \) for consistency. The value proof is sent as a proof to the garblers along with \( Y \) post evaluation. This technique is reminiscent of the one used in [BIPR18]. The above techniques ensure that a colluding garbler and \( P_5 \) cannot compute the output \( y \) without the aid of at least one honest garbler. An honest garbler reveals shares on the mask bits owned by her only on the receipt of valid \( (Y, \text{proof}) \) from some party. This handles the concern in solution (b) by ensuring that \( Y \) was not imposter upon by two colluding garblers as they cannot forge a valid proof.

4.1 The construction

We present the formal protocol in Fig 8. The garblers perform a one-time SD as in [CGMV17], which can be used for multiple runs. Circuit garbling is done as in Fig 4. The input keys sent by garblers define their committed inputs. The case of evaluator’s input and transfer of input keys is dealt as in [CGMV17]. In addition, we enforce each garbler to generate commitments on the shares of output wire masks wrt each seed she owns and allow agreement on these commitments by all parties. Also, \( P_5 \) samples a random proof and sends \( H(\text{proof}) \) to the garblers who agree on the hash value or abort. Then, \( P_5 \) evaluates the GC and sends \( (Y, \text{proof}) \) to all. Each garbler checks if \( (Y, \text{proof}) \) is valid. If so, it sends \( (Y, \text{proof}) \) and the openings corresponding to the commitments on mask bit shares of output wires to all. Finally, when a garbler has enough valid openings for commitments on mask bit shares of output wires, she computes the required output.

The equivocal commitment eNICOM is used to commit on the output mask shares to handle a technicality that arises in the proof. Namely, when one garbler and \( P_5 \) are corrupt, the adversary, on behalf of \( P_5 \), can decide to abort as late as when \( Y \) needs to be sent to garblers. Hence, the simulator is also forced to act on the adversary’s behalf and invoke the functionality after this step. Nevertheless, the simulator needs to simulate the prior rounds
Inputs: Party $P_i \in \mathcal{P}$ has $x_i$.
Common Inputs: The circuit $C(x_1, x_2, x_3, x_4, \oplus_j \in \{2, 3, 4\} x_5^j)$ that computes $f(x_1, x_2, x_3, x_4, x_5)$ and takes $x_1, x_2, x_3, x_4$, and shares $\{x_5^j\}_{j \in \{2, 3, 4\}}$ as inputs, each input, their shares are from $\{0, 1\}$ (instead of $\{0, 1\}^\ell$ for simplicity) and output is of the form $\{0, 1\}^\ell$.
Notation: $S_i$ denotes indices of the parties who hold $x_i$ as well as indices of the seeds held by $P_i$.
Output: $y = C(x_1, x_2, x_3, x_4, x_5)$ or $\perp$.
Primitives: A NICOM (Com, Open), an eNICOM (eGen, eCom, eOpen, Equiv), Garble (Fig 4), Eval (Fig 5), Collision Resistant Hash H (Appendix B).

Seed Distribution Phase (one-time): $P_g$ chooses random seed $s_g \in \{0, 1\}^\ell$, and sends $s_g$ to the other two parties in $S_g$ who in turn exchange with each other and abort if their versions do not match.

Evaluator’s Input sharing Phase: $P_5$ secret shares its input as $x_5 = x_5^{52} \oplus x_5^{53} \oplus x_5^{54}$. $P_5$ sends $x_5^j$ to $P_5$ (wlog).

Proof Establishment Phase: $P_5$ chooses proof from the domain of hash function $H$ computes and sends $H($proof$)$ to each garbler $P_g, g \in \{4\}$. $P_g$ in turn sends the copy of $H($proof$)$ received from $P_5$ to her co-garbler. $P_g$ aborts if $H($proof$)$ received from a co-garbler does not match with her own copy received from $P_5$. Else, $P_g$ accepts $H($proof$)$ to be the agreed upon hash.

Setup of public parameter for Equivocal Commitment. For $\text{epp}^g, g \in \{4\}$ of eNICOM, each $P_j, j \in S_g$ samples $\text{epp}^g$ from fresh randomness (not from any of the seeds he holds) and sends to all. $P_5$ additionally samples $\text{epp}^g, l \in \{4\} \setminus S_g$ and sends to all. Each party computes $\text{epp}^g = \oplus_{j \in \{4\}} \text{epp}^g$. $P_i \in \mathcal{P}$ forwards $\text{epp}^g, g \in \{4\}$ to all. Each $P_i \in \mathcal{P}$ aborts if any of $\text{epp}^g$ received mismatch.

Transfer of Equivocal Commitments.
- Each $P_g, g \in \{4\}$ runs the Sampling Phase of Garble($C$) and computes the following commitments for every circuit output wire $w$ using randomness from $S_j, j \in S_g$: $\{(c_{w,j}, \alpha_{w,j}) \leftarrow \text{eCom}(\text{epp}^j, \lambda_{w,j})\}_{j \in S_g}$, $P_g$ sends $\{(\text{epp}^j, c_{w,j})\}_{j \in S_g}$ to all.

Garbling, Masked input bit and Key Transfer Phase.
- For circuit input wire $w$ held by $P_g, g \in \{4\}$ corresponding to input bit $w$, each $P_i, i \in \{4\} \setminus \{g\}$ sends $\lambda_{w,j}, j \in S_i$ to $P_g$. $P_g$ aborts if it receives mismatched copies for some $\lambda_{w,j}$. Else, $P_g$ computes $\lambda_{w,j} = \oplus_{j \in \{4\}} \lambda_{w,j}$ and $b_w = x_w \oplus \lambda_{w,j}$. $P_g$ sends $(b_w, \{k_{w,b_w,\{j\}}\}_{j \in S_g})$ to $P_5$. To send $k_{w,b_w,\{j\}}$, $j \in \{4\} \setminus S_g$ (not held by $P_g$) to $P_5$, it does the following (The case for the key of $P_5$’s input share if held by $P_g$ is handled similarly):
- $P_g$ chooses random bits $b_l$ and random output $0^\ell = \oplus_{l \in \{4\} \setminus \{g\}} \beta_l$. $P_g$ sends $b_l, \beta_l$ to $P_l$.
- One garbler other than $P_g$ chooses $\delta_l \in \{0, 1\}^\ell$ s.t. $0^\ell = \oplus_{l \in \{4\} \setminus \{g\}} \delta_l$ and sends $\delta_l$ to $P_l$.
- $P_i$ sends $K_i = k_{w,b_w,\{j\}} \oplus \beta_l \oplus \delta_l$ to $P_5$ who sets $k_{w,b_w,\{j\}} = k_{w,b_w,\{j\}}$.
- For input wire $w$ corresponding to $P_5$’s input shares, let $\{\text{epp}^g, k_{w,b_w,\{j\}}\}_{g \in \{4\}}$ be the keys derived from seeds $\{S_j\}_{j \in \{4\}}$.
- Each $P_g, g \in \{4\}$ computes commitments on these as: for $b_l \in \{0, 1\}$, $j \in S_g$, $(c_{w,b_l,j}, \alpha_{w,b_l,j}) \leftarrow \text{Com}(\text{pp}^j, k_{w,b_l,j})$ using $\text{pp}^j$ and randomness derived from $S_j$ and sends $\{(\text{pp}^j, c_{w,b_l,j})\}_{j \in S_g}$ to $P_5$. $P_g$ also sends $\alpha_{w,b_l,j}$ to $P_5$ if it holds $b_{w,l}$. $P_5$ aborts if it receives either different copies of commitments or invalid opening for any wire. Otherwise, $P_5$ recovers the super-keys for $b_{w,l}$, namely, $\{k_{w,b_w,\{j\}}\}_{g \in \{4\}}$. Let $X$ to be the set of super-keys obtained.
- Garble($C$) is run. Each $P_g, g \in \{4\}$ sends $\{\text{GC}^g\}_{j \in S_g}$ to $P_5$. If $P_5$ finds conflicting copies, it aborts.

Evaluation and Output Phase.
- $P_5$ runs Eval to evaluate $GC$ using $X$ and obtains $Y$ and $(y_w \oplus \lambda_w)$ for all output wires $w$. $P_5$ sends $(Y, \text{proof})$ to all.
- For $g \in \{4\}, j \in S_s$, if $k_{w,b_w,\{j\}} \in X$ for some output wire $w$ does not match with either $(k_{w,0,j}, k_{w,1,j})$ or the three keys $k_{w,b_w,\{j\}}$ in $Y$ do not match to the same $b_w$ or if proof does not verify with previously received $H($proof$)$, $P_g$ does nothing. Else, $P_g$ sends $(Y, \text{proof})$ to all other garblers and $\{\alpha_{w,j}\}_{j \in S_s}$ to all. $P_5$ checks if valid $\{\alpha_{w,j}\}_{j \in S_s}$ received from each $P_g$. If so, $P_5$ computes $y_w = (y_w \oplus \lambda_w) \oplus \oplus_{l \in \{4\}} \lambda_{w,j}$ for output wire $w$ and thus outputs $y$.
- If received valid $(Y, \text{proof})$ and $\{\alpha_{w,j}\}_{j \in S_s}$ from a co-garbler $P_g$, $P_g, \alpha \in \{4\}$ computes $y$ by unmasking all $\lambda_w$.
- Also, if sent nothing before, send $(Y, \text{proof})$ to co-garbler, $(\alpha_{w,j}, \alpha_{w,j})_{j \in S_s, j \in S_s}$ to all. If no $y$ computed yet and received valid $(Y, \text{proof}), \{\alpha_{w,j}\}_{j \in S_s, j \in S_s}$ from co-garbler $\alpha$, $(\alpha_{w,j})$, was sent by $P_g$ to $\alpha$ before, compute $y$ upon unmasking all $\lambda_w$. Likewise, if $P_5$ has not computed $y$ yet and received valid $\{\alpha_{w,j}\}_{j \in S_s, j \in S_s}$ from $P_\alpha (\alpha_{w,j})$ was sent by $P_g$ to $P_\alpha$ before), $P_5$ computes $y$ by unmasking all $\lambda_w$.

Figure 8: Protocol fair5PC
with no clue of the output, which includes transfer of DGC, super-keys, commitments on output mask shares. To
tackle this, the simulator uses eNICOM to commit to dummy values at the start and later equivocates to output
mask shares (set based on the output obtained after invoking the functionality) if the corrupt $P_5$ sends $Y$ to at least
one honest garbler. Elaborate details are given in Appendix C.

To keep the eNICOM trapdoor hidden from the adversary and available to the simulator, we need it to be
distributed among 3 parties. Although convenient, the public parameter for eNICOM cannot be derived from the
seeds, as it would trivially arm a corrupt garbler (with the knowledge of 3 seeds) to equivocate. Further, due to the
symmetry of eNICOM, equivocation seems infeasible for the simulator if the trapdoor is distributed into only three
parts. Hence, we distribute the trapdoor and thus public parameter into four parts (held by three parties) to keep
the binding property intact in the real world while allowing the simulator (acting on behalf of 3 honest parties) to
perform equivocation. We demonstrate below for each $g \in [4]$, how $\text{epp}^{\theta}(= \oplus_{i \in [4]} \text{epp}^{\theta_i})$ for the output mask bits
corresponding to $s_g$ is chosen by the parties. We note that we could opt for a random-oracle based scheme and use
its programmability to enable equivocality. But this would make the proof rely on non-standard assumption, and
not injective one-way functions.

**n-party Extension** The technique of achieving fairness for 5 parties can be extended to $n$ parties tolerating $t < \sqrt{n}$ corruptions by modifying only the output phase of fair5PC (Fig 8). The technical overview and the formal
protocol appear in Fig 9 (Section 4.3).

**Optimizations** We propose the optimizations below to boost the efficiency of fair5PC: all optimizations of
[CGMV17] can be applied to our protocol. More concretely, majority of communication in the garbling phase
is due to the number of AOT invocations. This is optimized with the use of batch AOTs. Batch AOTs allow
the sender to send both commitments while the attesters send only hash on all the commitments. The NICOM
instantiation (Appendix B) based on the ideal cipher model can be used to obtain faster commitments in practice.
Each $GC^g$, $g \in [4]$, is sent by exactly one owner while the rest send only $H(GC^g)$. $P_5$ verifies the hash values
before evaluation. For implementation, eNICOM, NICOM are instantiated with random-oracle based commitment.
Also, communication in eNICOM is saved by generating commitment on the concatenation of mask bit shares of
all wires rather than on each bit individually.

### 4.2 Properties

**Lemma 4.1.** The protocol fair5PC is correct.

**Proof.** The input of $P_5$ is well defined by the shares sent to $P_2$, $P_3$, $P_4$. The 3 keys for each input wire owned
by the garblers, along with the $4^{th}$ key sent as XOR shares, define their committed inputs. Evaluation is done
on committed inputs. The correctness of $Y$ and thus $y$ follows from the correctness of garbling and evaluation
(Figs 4, 5). \qed

**Theorem 4.2.** Our fair5PC protocol consumes at most 8 rounds.

**Proof.** The proof establishment phase and setting up of public parameter for eNICOM consume 2 rounds each
and can be overlapped. Further, round 1 of these two phases can be overlapped with distribution of $P_5$’s input and
round 1 of masked input bit computation and key transfer phase. These together consume a total of 3 rounds. The
key transfer is started prior to Garble. More precisely, garbling can begin alongside round 3 of key transfer phase. The transfer of GC and keys to $P_5$ take 1 round. Finally, evaluation and output phase need at most 3 rounds, thus settling the protocol in 8 rounds. If $Y$ is received by all honest garblers in round 1 of output phase itself, then 7 rounds suffice. The seed distribution phase is one-time and hence is not counted for round complexity.

**Theorem 4.3.** Assuming one-way permutations, the protocol of fair5PC securely realizes $F_{\text{fair}}$ (Fig. 17) in the standard model against a malicious adversary that corrupts at most two parties.

The formal security proof appears in Appendix. C.

We give the intuition of fairness for completeness. For fairness, we need to guarantee that if the adversary learns the output, then so do honest parties and converse. We first argue in the forward direction. Suppose an adversary gets the output. We consider two corruption cases: Firstly, when $P_1$ and $P_5$ are corrupt, the adversary obtains the output only if at least one honest garbler say $P_2$ receives a valid $(Y, o)$ from $P_5$ or $P_1$ (valid shares of output wire mask bits also from $P_1$). $P_2$ sends the received message along with the masking bit shares she owns to all, allowing other parties to compute the output. The recipient garblers further send out their valid masking bit shares to allow any residual party to compute the output. Secondly, when two garblers $P_1, P_2$ are corrupt, an honest $P_5$ sends $(Y, o)$ to all, on successfully evaluating GC. $P_1, P_2$, knowing all the seeds, can construct the output themselves. The honest garblers send the masking bit shares they hold to all. Thus, every party obtains the output in both cases.

To prove the converse case, suppose the honest parties get the output. We consider the same corruption cases as above. In the first case, it must be true that at least one of the honest garblers say $P_2$, received a valid $(Y, o)$ who then sends the masking bit shares it owns along with $(Y, o)$ to all. Thus, the honest recipients compute the output using $(Y, o)$ and the masking bit shares from $P_2$. If $P_2$ received $Y$ from $P_5$, then $P_2$ uses the masking bit shares sent by $P_3, P_4$ (once they obtain output) to compute $y$. Else, $P_2$ must have received valid $(Y, o)$ and the masking bit shares from $P_1$, which is sufficient to compute $y$. For the case of corrupt $P_1, P_2$, suppose $P_5$ gets the output. This implies that all garblers must have obtained the output using valid $(Y, o)$ sent by $P_5$ and the masking bit shares received from co-garblers. Consequently, $P_5$ obtains the output using the masking bit shares sent by honest garblers. This summarizes the intuition.

### 4.3 n-party Extension of fair5PC

**n-party Extension** We first recall the conditions involved in seed distribution for n-parties elaborated in [CGMV17] to better understand the extension tolerating $t = \sqrt{n}$ corruptions. The seed distribution needs to satisfy the following properties:

**Privacy:** No $t - 1$ garblers should hold all the seeds. This is to ensure input privacy of honest garblers when $t - 1$ garblers and the evaluator collude.

**Attested OT** For each pair of seeds $s_i, s_j$, there must be a garbler who holds both $s_i, s_j$. This party will act as an attester in the corresponding AOT.

**Correctness** Every seed should be held by at least $t + 1$ garblers. This is necessary for correctness of the computed DGC.

All the above properties collectively imply that for any corruption scenario, the honest garblers together must hold all the seeds. Specifically, from correctness: each seed $s_i$ that is supposed to be held by at least $t + 1$ garblers is sure to end up in the hands of an honest garbler in the worst case corruption scenario of $t$ corrupt garblers. To achieve fairness for the case of $n$ parties, all steps of the protocol fair5PC remain the same except the output phase. For the extension, we consider that $P_1, ..., P_{n-1}$ are garblers and $P_n$ is the evaluator. On a high level, the output phase involves 3 rounds where in round 1, $P_n$ sends $(Y, proof)$ to all garblers and the remaining two rounds are used to exchange $(Y, proof)$ with co-garblers and openings for the commitments on mask-shares belonging to output wires with all and thus fairly compute the output.
Each honest party computes the output only if openings for commitments wrt every seed is received by the end of round 3. A naive way to distribute the openings in the last two rounds is to allow an honest garbler to forward the openings possessed by her (and if received any other) when a valid \((Y, proof)\) is received. This technique however, leads to fairness violation in the following scenario: suppose the evaluator and \(t - 1\) garblers are corrupt and \(P_a\) does not communicate with any honest garbler in round 1. However in round 2, few of the corrupt garblers send \((Y, proof)\) to one set of honest parties (chosen selectively s.t the openings of this set of honest parties and those held by the adversary are enough to compute the output). These honest parties forward all the accumulated openings in round 3 and thus the adversary gets the output. Further, in round 3, the adversary can also choose to send the openings to the other complementary set of honest parties on behalf of all the corrupt parties who have not sent anything yet, thus ensuring that other complimentary set gets the output while the first set aborts. To tackle this, we impose a restriction on the garbler \(P_g\) who communicates for the first time in round 3 of the output phase as: forward the openings accumulated until round 2 only if, the openings received in round 2 together with those held by \(P_g\) are sufficient to reconstruct the output. This condition eliminates the dependency of \(P_g\) on shares received in round 3 to compute the output and ensures that the adversary, in order to compute the output herself, must aid at least one honest party compute the output. Thus, even if one honest party is able to compute the output at the end of round 2, then that honest party releases all the openings in round 3 sufficient to help all honest parties compute the output. This concludes the intuition. The formal protocol is presented in Fig 9.

| Round 1: | The evaluator sends \((Y, proof)\) to the garblers. |
| Round 2: | If the received \((Y, proof)\) from the evaluator is valid, each garbler \(P_g\) forwards \((Y, proof)\) and openings for the commitments on output mask shares wrt the seeds she holds. |
| Round 3: | If received valid \((Y, proof)\) and valid openings from subset of garblers s.t the openings received and the output mask shares already present with party \(P_a\) are sufficient to reconstruct \(\lambda_w\) for every output wire \(w\), then \(P_a\) computes output \(y\) using the output masks. If sent nothing before, \(P_a\) forwards \((Y, proof)\) and the accumulated openings to all. |
| Local Computation: | If no \(y\) computed yet and received valid \((Y, proof)\) and openings from subset of garblers that are sufficient to reconstruct \(\lambda_w\) for every output wire \(w\), then party \(P_\beta\) computes output \(y\) using the output masks. |

Figure 9: Output Phase for \(n\)-party fairness

5 5PC with Unanimous Abort

5.1 The construction

By simplifying fair5PC, we present a 5PC achieving unanimous abort, relying on a network of pairwise-private channels with performance on par with [CGMV17] and maintaining the round complexity to 8. Specifically, we eliminate the stronger primitive of eNICOM used to commit on output mask shares in fair5PC, owing to weaker security. However, we still need to address the case of a corrupt \(P_5\) selectively sending \(Y\) to honest garblers. Unanimous abort can be trivially achieved if \(Y\) is broadcast by \(P_5\) instead of being sent privately but since broadcast increases assumptions and is expensive in real-time networks, we enforce the garbler who receives a valid \(Y\) from \(P_5\) to forward the same to her co-garbblers. However, this technique does not suffice on its own, since in case of a colluding garbler and the evaluator, \(P_5\) may not send \(Y\) to any honest party and at the same time, the corrupt garbler may send \(Y\) only in the last round, to one honest garbler, thus violating unanimity. To tackle this, we ensure that an honest garbler accepts \(Y\) in the last round of output phase from a co-garbler only if the co-garbler gives a valid proof that she received \(Y\) from \(P_5\) only in the previous round. This is realized by having each garbler sample a random value and circulate its hash for agreement prior to evaluation of GC. Later in the output phase, if received \(Y\) from \(P_5\), each garbler sends this random value along with \(Y\) to the co-garbblers. However, if a garbler \(P_g\) who did not receive any message from \(P_5\), receives valid \(Y\) and random value from the co-garbler, then \(P_g\) sends her random value along with the \(Y\) and random value of the co-garbler to all. The number of random values received along with \(Y\) from a garbler \(P_g\) serve as proof as in which round of output phase \(P_g\) received \(Y\). Further, to ensure that \(Y\) indeed originated from \(P_5\) (and was not forged by two corrupt garblers), we reuse the technique described
in fair5PC. The formal protocol (Fig 10), proof of correctness are presented below. Similar to our fair protocol, this protocol can also be extended for arbitrary $n$ parties by modifying the output phase of uAbort5PC (Fig 10) as in Fig 11 (Section 5.3).

| Inputs, Common Inputs, Output and Notation | Same as in fair5PC(). |
| Primitives | A secure NICOM (Com, Open) (Section 2), Garble4 (Figs. 4), Eval4 (Fig. 5). |
| Seed Distribution Phase | (one-time)and Evaluator’s Input Sharing Phase are same as in fair5PC(). |
| Proof Establishment Phase | $P_i, i \in [5]$ chooses $proof_i$ from the domain of a hash function $H$, computes and sends $H(proof_i)$ to all parties. Each party, $P_i, j \in [5] \setminus \{i\}$ in turn sends the copy of $H(proof_j)$ received to the remaining parties. $P_i$ aborts if the $H(proof_j)$ received from the remaining parties does not match with her own copy received from $P_j$. Else, $P_i$ accepts $H(proof_j)$ to be the agreed upon hash. |
| Setup of public parameter and Transfer of Equivocal Commitments | are not present in this protocol but instead for each output wire $w$, each $P_j, j \in S_g$ sends $\lambda^0_w$ in clear to all. Each party $P_i \in P$ aborts if the three copies of $\lambda^0_w$ received do not match. Else, $P_i$ computes $\lambda_w = \oplus_{g \in [4]} \lambda^g_w$. |
| Garbling, Masked input bit and Key Transfer Phase | are same as in fair5PC(). |
| Evaluation and Output Phase | $P_3$ runs Eval4 to evaluate GC using $X$ and obtains $Y$ and $(y_w \oplus \lambda_w)$ for all output wires $w$. $P_3$ sends $(Y, proof)$ to all. $P_3$ locally computes $y_w = (y_w \oplus \lambda_w) \oplus_{i \in [4]} \lambda^i_w$ for each output wire $w$. |
| | For each $P_g, g \in [4], j \in S_g$, if the received $k^g_w_{w,bw}$ of $Y$ for some output wire $w$ does not match with either $(k^0_w,0,1)$ or the three keys $k^g_w_{w,bw}, j \in S_g$ in $Y$ do not map to the same $b_w$ or proof$_g$ fails, then do nothing. Else for each output wire $w$, compute $y_w$, unmasking $\lambda_w$. Send $(Y, proof_5, proof_g)$ to the co-garblers. |
| | If received valid $(Y, proof_5, proof_g)$ from a co-garbler $P_g, P_\alpha, \alpha \in [4]$ computes $y$ unmasking $\lambda_w$. Also if sent nothing before, send $(Y, proof_5, proof_g, proof_\alpha)$ to all. If no output $y$ is computed yet and received valid $(Y, proof_5, proof_g, proof_\alpha)$ from co-garbler $P_\alpha$ (proof$_g$ indicates $(Y, proof_5, proof_g)$ was received from $P_g$), garbler $P_i$ obtains $(y_w \oplus \lambda_w)$ from $Y$, unmask $\lambda_w$ and computes $y$. |

Figure 10: Protocol uAbort5PC

Optimizations. The efficiency of uAbort5PC protocol can be boosted similar to fair5PC in both the garbling phase and communication of GC.

5.2 Properties

Lemma 5.1. The uAbort5PC protocol is correct.

Proof. The input of the evaluator, $P_3$ is defined to be committed based on the shares sent to $P_2, P_3, P_4$ in Round 1. The keys communicated by the garblers for their own input define their committed inputs. Evaluation is performed using the committed inputs. The correctness of the output super-key $Y$ and thus $y$ follows from the correctness of garbling and evaluation (Figs 4, 5). □

Theorem 5.2. Our uAbort5PC protocol runs in at most 8 rounds.

Proof. The proof follows from the proof of Theorem 4.2. □

Theorem 5.3. Assuming one-way permutations, our protocol uAbort5PC securely realizes the functionality $F_{uAbort}$ (Fig. 18) in the standard model against a malicious adversary that corrupts at most two parties.

The security proof is provided in Appendix D.
5.3 $n$-party Extension of uAbort5PC

To achieve unanimous abort for the case of $n$ parties, all steps of the protocol uAbort5PC remain the same except the output phase. The seed-distribution is done as explained in Section 4.3. For the extension, we consider that $P_1,...,P_{n-1}$ are garblers and $P_n$ is the evaluator. On a high level, the output phase involves 3 rounds where in round 1, $P_n$ sends $(Y, proof_n)$ to all garblers and the remaining two rounds are used to exchange the $Y$ and proofs to compute the output.

Each honest party computes the output only if $t + 1$ proofs are received by the end of round 3. This is done to prevent the adversary from remaining silent in first two rounds but selectively sending $Y$ to few honest parties only in the last round and them naively accepting the output without any confirmation about fellow honest parties. Thus, an honest garbler who has not sent anything until the end of round 2, forwards $Y$ and the received proofs (along with own proof) in round 3 only if at least $t$ valid proofs are received by the end of round 2. This ensures that all honest parties are in agreement about the output acceptance at the end of round 3. In detail, if one honest party decides to accept the output by the end of round 2 due to the availability of $t$ proofs, then all honest parties will also accept the output at the end of round 3 due to the availability of at least $t + 1$ proofs which implies that an honest party has accepted $Y$ in round 2. This completes the intuition. We formally present the $n$-party extension for unanimous abort in Fig 11.

Let $P_n$ be the evaluator and $P_g, g \in [n-1]$ be the garblers.

Round 1: The evaluator sends $(Y, proof_n)$ to the garblers.

Round 2: If the received $(Y, proof_n)$ from the evaluator is valid, each garbler $P_g$ forwards $(Y, proof_n, proof_g)$ to all.

Round 3: If received valid $(Y, proof_n, \{proof_g\}_{g \in G})$ where $G$ is a subset of garblers, if the total number of $proof_g$’s and $proof_n$ is at least $t$, then party $P_g$ outputs $y$ and if sent nothing before, $P_n$ forwards $(Y, proof_n, \{proof_g\}_{g \in G}, proof_n)$ to all.

Local Computation: If no $y$ output yet and received valid $(Y, proof_n, \{proof_g\}_{g \in G}, proof_n)$ s.t the total number of $proof_g$’s, $proof_n$ and $proof_n$ together is at least $(t + 1)$, then party $P_g$ outputs $y$ using the output super-key and output wire masks for each output wire.

Figure 11: $n$-party Extension: Output Phase for $n$-party unanimous abort

6 5PC with Guaranteed Output Delivery (GOD)

With fair5PC as the starting point, we elevate the security and present a constant-round 5PC with GOD relying only on symmetric-key primitives. We assume a necessary broadcast channel besides pairwise-private channels for our corruption threshold owing to the result of [CL14]. Our protocol reduces to an honest-majority 3PC with GOD in some cases. With the assumption of broadcast channel, our protocol takes 6 rounds when no 3PC is invoked and stretches up to 12 rounds when packed with the 3PC of [BJPR18] in the worst case.

6.1 The Construction

We achieve GOD by tackling the scenarios leading to abort when the parties are in conflict. Specifically, we eliminate a corrupt party and transit to a smaller world of 3 parties with at most one corruption to complete computation in such cases. We retain the setup of four garblers $\{P_1, P_2, P_3, P_4\}$ and $P_5$ as the evaluator. On a high level, our protocol starts with a robust input and (one-time) SD, followed by the garbling phase, transfer of the GC, blinded inputs and corresponding super-keys to the evaluator and concludes with the circuit evaluation by the evaluator and output computation by all. The key technique in achieving a robust computation lies in the use of tools such as 4-party 2-private RSS and SD to ensure that each phase of the protocol is robust against any malicious wrongdoing. While using a passively-secure 4DG as the underlying building block, there exist scenarios where it seems improbable to publicly identify and eliminate a corrupt party due to the presence of 2 active corruptions. Instead, when the adversary strikes, we establish and eliminate the parties in conflict publicly (of which one is
ensure to be corrupt) and rely on the remaining parties with at most one corruption to robustly compute the output. The essence of our protocol lies in tackling the threats to input privacy and correctness that arise during the transfer of masked inputs and corresponding super-keys due to the presence of distinct committees.

To begin with, the input and seed distributions are robust. Each input-share/seed is owned by a committee of 3 parties (as dictated by RSS/seed-distribution). To ensure consistent distribution, we force the dealer (of input-share/seed) to commit to the data publicly and open privately rather than relying on private communication alone. Parties who receive the same RSS share/seed cross-check with each other to agree either on a publicly committed value or a default value when no correct openings are dealt. The shares distributed as per RSS in input distribution parties (as dictated by RSS/seed-distribution). To ensure consistent distribution, we force the dealer (of input-share/seed) to commit to the data publicly and open privately rather than relying on private communication alone. Each of these values can be broadcasted by the honest parties about the wrongdoing. Further, input privacy is preserved when masked input is broadcast in case (d) for the shares not owned by evaluator (instead owned by 3 garblers), since the adversary (corrupting the evaluator and one garbler) lacks knowledge of one seed needed to learn the underlying input-share.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{protocol_inputGOD.png}
\caption{Protocol inputGOD_i}
\end{figure}

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{protocol_seedGOD.png}
\caption{Protocol seedGOD_g}
\end{figure}

Inputs: \(P_i\) has input \(x_i\).

Output: \(P_j, j \in [6]\) denotes the two size maximal unqualified subset (\(|T_j| = 2\)) of the parties in the lexicographic order. Each party \(P_k \in \mathcal{P}\) outputs \((c_{ij}, x^{il})\), \((o_{il}, r^{il})\) where \((c_{il}, o_{il})\) denote the commitment and opening of the shares \((x^{il} \oplus r^{il})\), \(r^{il}\) respectively.

\textbf{Primitives:} A NICOM (Com, Open) (Appendix B), a 4-party 2-private RSS.

\textbf{R1:} \(P_i\) does the following:
- shares its input as \(x_i = \oplus_{j \in [6]} x_{ij}\) and a random input \(r_i \in \{0, 1\}\) as \(r_i = \oplus_{j \in [6]} r_{ij}\).
- samples \(pp_i\) and for \(j \in [6]\), computes commitments on \((x^{ij} \oplus r^{ij})\), \(r^{ij}\) as: \((c_{ij}, o_{ij}) \gets \text{Com}(pp_i, (x^{ij} \oplus r^{ij}))\) and \((c_{ij}', o_{ij}') \gets \text{Com}(pp_i, r^{ij})\).
- broadcasts \((pp_i, c_{ij}, o_{ij}); \text{ sends } (o_{ij}, o_{ij}')\) privately to each \(P_l, l \notin T_j\).

Define \(X_{ij}\) to be the set of parties holding the shares \(x^{ij} \oplus r^{ij}\) and \(r^{ij}\). \(P_i\) by default belongs to every \(X_{ij}\).

\textbf{R2:} For \(\{pp_i, (c_{ij}, o_{ij})\}_{j \in [6]}\) and \(\{o_{ij}, o_{ij}'\}\) received from \(P_i\), \(P_k\) sets the opening information to \(\bot\) when they are invalid and forwards \((o_{ij}, o_{ij}')\) to \(P_l \notin T_j\).

\textbf{Local computation by } \(P_k\): \(P_k\) resets its opening data on receiving valid openings from fellow parties (if set to \(\bot\) earlier). If any opening still remains \(\bot\), set agreed-upon default value of \((x^{ij} \oplus r^{ij})\) and \(r^{ij}\).

The techniques to identify a pair of conflicting parties (in order to eliminate a corrupt party) differ based on the communication being either public or private. Public data sent by a party involves the transfer of: (a) GC partition wrt each seed owned by the party, (b) shares of output wire masks wrt each seed owned by the party, (c) shares of input wire masks wrt the seeds not owned by the wire owner, (d) masked input values when no correct openings are dealt. Each of these values can be broadcasted by the 3 parties owning the respective seed (for cases (a)-(c)) or input-share (for case (d)). Any mismatch in the 3 broadcasted copies leads to election of a 3-party committee \(\mathcal{P}^3\) that becomes the custodian for completing computation. The primary reason for adopting broadcast in the above cases is to aid in unanimous agreement about the conflicting parties. Else, if we rely on private communication alone, an honest receiver may always receive mismatching copies and fail to convince all honest parties about the wrongdoing. Further, input privacy is preserved when masked input is broadcast in case (d) for the shares not owned by evaluator (instead owned by 3 garblers), since the adversary (corrupting the evaluator and one garbler) lacks knowledge of one seed needed to learn the underlying input-share.
Private communication includes the transfer of super-key for input wires wrt masked input shares to $P_3$. The natural solution is to have the garblers, owning the respective input share, send keys privately to $P_3$ corresponding to the seeds they own. The private transfer alone, however, allows corrupt parties to send incorrect keys which goes undetected by $P_5$. We resolve this using the standard trick of commit-then-open. All garblers publicly commit to both keys on each input wire for the seeds they possess, where any conflict is dealt as in the public message. The commitments wrt each seed are generated by the three seed owners using randomness derived from the same seed, turning public verification to plain equality checking. When no public conflict arises, only the garblers holding the actual input share send the relevant openings to $P_5$. Since each input-share is owned by at least two garblers (the other may be the evaluator), they together hold all parts of the correct super-key to be opened, hence all openings can be communicated. However, this step may not be robust in case of a corrupt garbler sending incorrect (or no) opening privately which can be realised only by $P_5$. In such case, $P_5$ raises a conflict against the garbler who sent a faulty opening and a 3-party set is identified for 3PC which excludes $P_5$ and the conflicting garbler.

Further, input consistency is threatened when the adversary gets the output in the 5PC, yet makes the honest parties receive output via 3PC which now needs to adhere to the inputs committed in the outer 5PC protocol. This occurs when a corrupt $P_5$ computes the output, yet does not disclose to the garblers and the related 3PC instance invoked must ensure input consistency to bar the adversary from learning multiple evaluations of $f$. This creates a subtle issue when in the elected 3PC, only one party say $P_\alpha$ holds a share $x^{\alpha j}$ (the other two owners of $x^{\beta i}$ are eliminated). A potentially corrupt $P_\alpha$ can use a different $x^{\alpha j}$ causing the 3PC to compute on a different input $x_j$ of $P_1$ than what was used in the 5PC, thus obtaining multiple evaluations of $f$. Custom-made to the robust 3PC of [BJPR18], we tackle this having the RSS dealer $P_1$ distribute $x^{ij} + r^{ij}$ and $r^{ij}$ instead of just $x^{ij}$ for each share in the input-distribution phase. When a 3PC is invoked, the 3-parties who hold opening of $x^{ij} + r^{ij}$ and $r^{ij}$ hand them over respectively to the two parties in the 3PC who do not hold $x^{ij}$. With such a modification, now each input share in the elected 3PC is either held by at least two parties or by one party in which case it is XOR-shared between the remaining two. This is in line with the 3PC of [BJPR18] that offers consistency for inputs, either held by at least two parties or by one party in which case it is XOR-shared between the remaining two. In the 3PC of [BJPR18], two parties, say $P_\alpha, P_\beta$ act as garblers and the third party, say $P_\gamma$ acts as an evaluator. The garblers use common randomness to construct the same Yao’s GC [BHR12] individually. Since at most one party can be corrupt, a comparison of GCs received from the garblers allows $P_\gamma$ to conclude its correctness. For key transfer, the garblers perform commitments on all keys for the input wires in a permuted order and send openings for the shares they own to $P_\gamma$. This suffices since, for an input share not held by $P_\gamma$, it is available with both garblers and thus, $P_\gamma$ can verify if both the openings received for such a share are same. The use of permutation here further ensures that $P_\gamma$ does not learn the actual value of the input key that she has the opening for. However, for input shares held by $P_\gamma$, no permutation is used to allow $P_\gamma$ to verify if the correct opening has been received. The diagram and an example depicting this process appears in Fig 25 (Appendix F).

In 5PC, it is easy to check that the evaluator colluding with a garbler can’t cheat with a wrong super-key for the output, as no single garbler possesses all seeds. The AOT protocol, used in Garble, is aptly modified to tackle conflicts and elect a 3PC instance (Fig. 7). Our 3PC appears in Fig. 14. The main protocol appears in Fig. 15.

**Optimizations** To improve efficiency, the garbling process is optimized similar to fair5PC. When a conflict is identified prior to the sending of GC, identification of the 3PC instance and its execution are set in motion immediately, thus enabling the protocol to terminate faster. To minimize the overhead of broadcast and make it independent of input, output and circuit size, we replace each broadcast message $m$ with the collision-resistant hash of the message, $H(m)$, while sending $m$ privately to the recipient. For instance, in DGC, $H(GC^i)$, $i \in [4]$ is broadcasted by parties who own $GC^i$ whereas, $GC^i$ is sent to the evaluator by one of the parties in $S_i$ privately. Similarly, for sending output super-key, $H(Y)$ is broadcasted by $P_5$ and $Y$ is sent via pairwise channels and so on. With this optimization in broadcast, we elaborate how any conflict will be resolved with the following examples (all our broadcast messages fall under one of these examples):

Example 1: Consider a message $m$ to be broadcasted where $m$ is the GC fragment $GC^1$. This fragment is held by $P_1, P_3, P_4$ due to seed distribution. Each of $P_1, P_3, P_4$ broadcasts $H(GC^1)$. If the hashes mismatch for two parties say $P_1, P_3$, then a 3PC instance is formed with $P_2, P_4, P_5$. Else, if all the broadcast hashes are in
agreement, then $P_1$ will send $GC^1$ privately to $P_5$. Now if $P_5$ is honest and finds that the received $GC^1$ is not consistent with the hash that was successfully broadcasted and agreed, then $P_3$ broadcasts a conflict with $P_1$ and a 3PC instance with $P_2, P_3, P_4$ is chosen. Else if $P_5$ is corrupt and raises a false conflict with $P_1$, even then the 3PC with $P_2, P_3, P_4$ is run. In both the cases, one corrupt party is surely eliminated and the 3PC contains at most one corruption.

Example 2: Consider a message $m$ to be broadcasted where $m$ is the mask share $\lambda^1_w$ on output wire $w$. The mask-share $\lambda^1_w$ is held by $P_1, P_3, P_4$ due to seed distribution. Each of $P_1, P_3, P_4$ broadcasts $H(\lambda^1_w)$. If the hashes mismatch for two parties say $P_1, P_3$, then a 3PC instance is formed amongst the remaining parties, $P_2, P_4, P_5$. If, else if all the hashes are in agreement, then $P_1, P_3, P_4$ privately send $\lambda^1_w$ to each party. We consider the receiver $P_2$ for explanation. This step is robust since if the hashes are in agreement, there will always exist one valid preimage among the private messages received by $P_2$. This is because, even if two of the three senders $P_1, P_3$ are corrupt and send inconsistent preimage, $P_4$ will send valid $\lambda^1_w$ which will be consistent with the agreed upon hash. Hence $P_2$ uses the value sent by $P_4$ and proceeds for computation.

6.2 Properties

**Lemma 6.1.** An elected 3PC has at most one corruption.

**Proof.** We argue that a corrupt party is eliminated in a conflict. Suppose $P_i, P_j$ are in conflict. This could be due to either (i) mismatch in the public message broadcast by $P_i, P_j$ or (ii) one of $P_i, P_j$ raised a conflict against the other for an incorrect private message. In case (i), each message is result of either robust input or seed distribution and hence if both were honest, the broadcast messages would be identical. In case (ii), each message involves an opening for the commitments agreed on in public message and neither $P_i$ nor $P_j$ would raise a conflict if valid
Lemma 6.2. In case of conflict in $P$, that at least one of further and thus the conflict could not have been the result of adversary’s doing in the previous steps. This implies

Inputs and Output: Party $P_i \in \mathcal{P}$ has $x_i$. Each party outputs $y = C(x_1, x_2, x_3, x_4, x_5)$.

Common Inputs: The circuit $C(\oplus_{j \in \{0, 1\}} x_{ij}, \oplus_{j \in \{0, 1\}} x_{ij})$ that takes the RSS shares as inputs and computes $f(x_1, x_2, x_3, x_4, x_5)$, each input, their shares are from $\{0, 1\}$ (instead of $\{0, 1\}^\ell$ for simplicity) and output is from $\{0, 1\}$.

Notation: $S_i$ denotes the indices of the parties who hold $s_i$ as well as the indices of the seeds held by $P_i$. $X_{ij}$ denotes the set of parties that holds the $j^{th}$ share of $P_i$’s input $x_{ij}$. $\mathcal{P}^3$ is the identified 3PC committee.

Primitives: A NICOM (Com, Open), inputGOD (Fig. 12), seedGOD (Fig. 13), Garble (Fig. 4), Eval (Fig. 5) and $\Pi_{\text{AOTGOD}}$ (Fig. 7).

Input and Seed Distribution Phase. Run inputGOD and seedGOD for every $P_i \in \mathcal{P}$ and $P_g, g \in [4]$ respectively in parallel.

Garbling Phase. Garble($C$) is run where $\Pi_{\text{AOTGOD}}$ (Fig. 7) is used instead of $\mathcal{F}_{\text{AOT}}$. Each $P_g, g \in [4]$ broadcasts $\{GC\}_i \in S_i$. Each party runs god3PC with $\mathcal{P}^3$ when any instance of $\Pi_{\text{AOTGOD}}$ returns $\mathcal{P}^3$ or when $\mathcal{P}^3 = \mathcal{P} \setminus \{P_1, P_3\}$ when $(P_\alpha, P_\beta)$ with $\alpha, \beta \in S_g$ for some $g \in [4]$ broadcasts different $GC_g$ (in the optimized version, we broadcast only a hash of GC).

Masked input bit and Key Transfer Phase.

- In parallel to the R1 of Garbling phase.
  - For every input wire $w$, $P_g, g \in [4]$ broadcasts $\lambda_i^w, j \in S_g$. Every party runs god3PC with $\mathcal{P}^3 = \mathcal{P} \setminus \{P_\alpha, P_\beta\}$, if parties $P_\alpha, P_\beta$ holding seed $s_i$, i.e. $\{\alpha, \beta\} \in S_i$, broadcast different copies of $\lambda_i^w$ for some output wire $w$ and $g$. (Tie break deterministically if multiple pairs are in conflict.) Otherwise, every party reconstructs $\lambda_i^w = \oplus_{g \in [4]} \lambda_i^w$ for every output wire $w$.

- For every output wire $w$ corresponding to input $x_u = x_{ij}$ held by three garblers, for each $P_j \in X_{ij}$: each garbler $P_j, h \neq g$, broadcasts $\lambda_i^w, l \in S_h \setminus S_j$. (If $X_{ij}$ includes evaluator, then each garbler $P_j, h \in [4]$ broadcasts $\lambda_i^w, l \in S_h$). Every party runs god3PC with $\mathcal{P}^3 = \mathcal{P} \setminus \{P_\alpha, P_\beta\}$, if there are parties $P_\alpha, P_\beta$ with $\{\alpha, \beta\} \in S_i$, broadcasting different copies $\lambda_i^w$ for some wire $w$. Otherwise, $P_g$, the owner of the input wire $w$ uses $\lambda_i^w$, to compute $\lambda_i^w = \oplus_{l \in [4]} \lambda_i^w$.

- In parallel to R2 of Garbling phase, for every output wire $w$ corresponding to input $x_u = x_{ij}$ held by two garblers and $P_\alpha$, $P_\beta$ already knows $b_u$ as $\lambda_i^w$ was computed by $P_\beta$ in the previous step.

- For every initial input wire $w$, the process for all seeds $s_j, j \in [4]$, computes commitments as: for $b \in \{0, 1\}, j \in S_g$, $(c_j^w, o_j^w, b) \leftarrow \text{Com}(pp_j, k_j^w, b)$ and broadcasts $\{pp_j, c_j^w, o_j^w\}$. $P_g$ sends the opening $o_j^w, b$ to $P_j$ if it also holds $b$. Every party runs god3PC with $\mathcal{P}^3 = \mathcal{P} \setminus \{P_\alpha, P_\beta\}$ if $(P_\alpha, P_\beta)$ with $\alpha, \beta \in S_i$, for some $i$ and input wire $w$ broadcast different commitments. Otherwise, $P_g$ tries to recover the super-key for $b_u$, namely, $(k_g^w, b_u), g \in [4]$ using the openings received. If no valid openings received for some key, $P_g$ broadcasts a conflict with a garbler who sent invalid opening and subsequently every party runs god3PC with the remaining three parties as $\mathcal{P}^3$. Otherwise, let $X$ be the set of super-keys obtained.

Evaluation and Output Phase.

- $P_3$ runs Eval to evaluate $C$ using $X$ and obtains $Y$ and $(y_u \oplus \lambda_u)$ for all output wires $w$. For each output wire $w$, $P_3$ runs god3PC with $\mathcal{P}^3 = \mathcal{P} \setminus \{P_1, P_3\}$ if $k_{w,b_u}$ of $Y$ for some output wire $w$ and index $j \in S_g$ does not map to either $(k_{w,0}^j, k_{w,1}^j)$ or the three keys $k_{w,b_u}, j \in S_g$ in $Y$ do not map to the same $b_u$. Otherwise, each garbler $P_j$ obtains $(y_u \oplus \lambda_u)$ by comparing each key in $Y$ with the two key labels for each $w$ and computes $y_u = (y_u \oplus \lambda_u) \oplus_g [4] \lambda_u$. Finally, $P_g$ outputs $y$.

Figure 15: Protocol god5PC

opening was received. Also, in both the above cases, each message is checked for correctness before proceeding further and thus the conflict could not have been the result of adversary’s doing in the previous steps. This implies that at least one of $P_1, P_3$ is corrupt. Thus, an elected 3PC in either case would contain parties $\mathcal{P}^3 = \mathcal{P} \setminus \{P_1, P_3\}$. Since one of $P_1, P_3$ is surely corrupt, at most one corrupt party can be present in $\mathcal{P}^3$.

Lemma 6.2. The output $y$ computed in the god3PC instance corresponds to the committed inputs.

Proof. In case of conflict in god5PC, a 3PC instance with at most one corruption is formed (Lemma 6.1). To
ensure the input consistency in the 3PC, every agreed upon RSS share $x^{ij}$ in inputGOD, is made available in 3PC to at least two parties or when held by one party, it is XOR shared between the remaining two. With this arrangement of input shares, the robust 3PC of [BJPR18] is guaranteed to preserve input consistency. This ensures that computation in 3PC is performed on the inputs committed in inputGOD.

**Theorem 6.3.** The protocol god5PC is correct.

*Proof.* We argue that the output $y$ computed corresponds to the unique inputs committed by each $P_i, i \in [5]$ in inputGOD. A corrupt party either commits to an input or a default value is assumed as per inputGOD. The honest parties are established to have committed to their inputs by the end of round 1 in inputGOD. An honest $P_\alpha$ obtains the output either by decoding the output super-key $Y$ or via the output of god3PC (as a participant in god3PC or recipient from the 3PC committee). In the latter case, correctness follows from Lemma 6.2 and correctness of god3PC. We argue for the former case. Let an honest $P_\alpha$ obtains output from $Y$ broadcast by $P_5$. This implies that the adversary behaved honestly in the entire execution and the input keys opened by a corrupt garbler correspond to committed inputs only. Otherwise, a conflict would be raised to elect a 3PC, which contradicts our assumption that the output was obtained on decoding $Y$. Thus, the output always corresponds to the committed inputs in inputGOD. The correctness of evaluation follows from the correctness of the garbling scheme.

**Theorem 6.4.** Assuming one-way permutations, protocol god5PC securely realizes the functionality $F_{\text{god}}$ (Fig. 16) in the standard model against an active adversary that corrupts at most two parties.

The security proof is presented in Appendix E. Since the inputs are defined prior to the garbling phase in god5PC, we do not require the adaptive notion of the proof. The same is true for all our protocols.

Although, the formal security proof appears in Appendix E, here, we provide intuition of GOD for completeness. The routine inputGOD binds the adversary to commit to an input or a default value. If a conflict is identified at any point during the execution, then an elected 3PC committee runs robust 3PC of [BJPR18] to obtain the output $y$. Otherwise, computation proceeds as per the honest run and each party receives the output using the $Y$ broadcasted by $P_5$. If $Y$ is valid, then all parties compute $y$ using $Y$ to conclude the execution. Else if $Y$ is invalid or not received, a 3PC instance is identified among the garblers to compute $y$. In both the above cases (lemma 6.3), inputs committed in inputGOD alone are used to obtain the output $y$ thus concluding the intuition.

## 7 Empirical Results

In this section, we elaborate the empirical results of our protocols. We use the circuits of AES-128 and SHA-256 as benchmarks. We begin with the details of the setup environment, both hardware and software and then give a detailed comparison of efficiency.

### Hardware Details

We provide experimental results both in LAN and WAN (high latency) settings. For the purpose of LAN, our system specifications include a 32GB RAM; an Intel Core i7 – 7700 – 4690 octa-core CPU with 3.6 GHz processing speed with AES-NI support from the hardware. For WAN, we have employed Microsoft Azure D4s_v3 cloud machines with instances located in West US, South India, East Australia, South UK and East Japan. The average bandwidth measured using the `iperf` testing tool corresponds to 169Mbps. The slowest link has a round trip time of 277 ms between East Australia and South UK. RTT denotes the time required to send a packet from source to destination and subsequently an acknowledgment back from destination to source. But the transfer of a packet involves only one way communication from source to destination. So the delay that we consider is half of RTT which is 138.5 ms for our slowest link (present between garblers $P_3 - P_4$). The following are the maximum delays for each garbler for one way communication: $P_1$: 102 ms, $P_2$: 101 ms, $P_3$: 138 ms, $P_4$: 138.5 ms. For the evaluator, the maximum delay is close to 112 ms. The tables indicate the average delay for the role of garbler which turns out to be between 114 – 120 ms.
Software Details. For efficiency, the technique of free-XOR is enabled and the implementation is carried out using libgarble library licensed under GNU GPL license. This library leverages the use of AES-NI instructions provided by the underlying hardware. We additionally use OpenSSL 1.0.2g library for SHA to instantiate our commitments. The operating system used is Ubuntu 16.04 (64-bit). Our code follows the standards of C++11 and multi-threading is enabled on all cores for improved results. Communication is done using sockets whose maximum size is set to 1 MB and a connection is established between every pair of parties to emulate a network consisting of pair-wise private channels.

We compare our results in the high-latency network with the relevant ones. The state of the art in 3PC [MRZ15, BJRPR18] and 4PC [BJRPR18] with honest majority achieving various notions of security, incur significantly less overhead compared to our setting since they tolerate one corruption which aids in usage of inexpensive Yao’s garbled circuits [BHR12] and fewer rounds. Thus, the closest result to our setting is [CGMV17] and below we make a detailed comparison with it.

For fair analysis, we instantiate the protocol of [CGMV17] in our environment and use the semi-honest 4DG scheme of [BLO16] that they rely on. However, we also instantiate [CGMV17] with the 4DG scheme of [BLO16] to emphasize the saving in computation time that occurs with the use of Garble in place of the scheme of [BLO16]. We highlight the following parameters for analysis: computation time (CT)– the time spent computing across all cores, runtime (CT + network time) in terms of LAN, WAN and communication (CC). The network time emphasizes the influence of rounds and communication size taking into account the proximity of servers. The tables highlight average values distinctly for the role of a garbler ($P_g$, $g \in [4]$) and the evaluator ($P_e$). The results for [CGMV17], uAbort5PC, fair5PC appear in Table 1. Table 2 depicts the results for god5PC. While having the round complexity of 8 as in [CGMV17] and achieving stronger security, uAbort5PC and fair5PC incur an overhead of at most 0.2 MB overall for both circuits over [CGMV17]. The overhead in both protocols is a result of the proof of origin of output super-key $Y$ and exchange of $Y$ among garblers. Additionally, in fair5PC, the commit-then-open trick on output mask bits constitutes extra communication. For the necessary robust broadcast channel in god5PC, we use Dolev Strong [DS83] to implement authenticated broadcast and fast
Table 3: The total computation time (Total CT), maximum latency in LAN run-time (LAN) and WAN run-time (WAN) and total communication (Total CC) of all parties for [CGMV17] and our protocols using Garble. The figures in brackets indicate the increase for the worst case run of god5PC.

elliptic-curve based schemes [BDL⁺12] to realize public-key signatures therein. These signatures have a one-time setup to establish public-key, private-key for each party. We do the same for robust 3PC of [BJPR18] for empirical purposes.

When instantiated with DS broadcast, the round complexity for honest run of GOD is 12 (in the presence of 4 broadcasts) and the shown WAN overhead in Table 2 over [CGMV17] captures this inflation in rounds. For the sake of implementation of all protocols (including [CGMV17] for fair comparison), we have adopted parallelization wherever possible. Next, if we observe god5PC, Table 2 indicates that the pairwise communication (CC) of god5PC protocol is almost on par with that of [CGMV17] in Table 1 (and less than fair5PC). This is because, the honest run of our god5PC is almost same as [CGMV17] except for the input commit routine and the use of broadcast. The input commit routine can be parallelized with the process of garbling to minimize number of interactions. This implies that the majority overhead is mainly due to the use of broadcast. The implementation of DS broadcast protocol is done by first setting up public-key, private key pair for each party involved. Each message sent by the broadcast sender is then agreed upon by the parties by running 3 (+1) rounds. If multiple independent broadcasts exist in one round, they are run parallelly. Also, any private communication that can be sent along with the broadcast data is also parallelized for improved round complexity.

The broadcast communication is kept minimal and independent of the circuit, input and output size. As a result, the total data to be broadcasted constitutes only 1.73 KB of the total communication. In the honest run, when the adversary does not strike, the overall overhead amounts to a value of at most 1.2 s in WAN over [CGMV17]. The worst case run in god5PC occurs when the adversary behaves honestly throughout but only strikes in the final broadcast of Y and a 3PC instance is run from that point. In this case, the overall WAN overhead is at most 2.5 s over [CGMV17]. This overhead is justified considering the strength of security that the protocol offers when compared to [CGMV17]. Also, the overheads in LAN and communication are quite reasonable.

In the fair5PC, the higher overhead of 0.2 KB than honest run of god5PC is the result of commitments on output wire masks and circulation of Y and proof of origin of Y in the output phase as explained above. Also, fair5PC protocol involves 3 sequential rounds for output phase compared to single communication of Y by P5 in [CGMV17] and in god5PC. Note that in the LAN setting, the RTT is of the order of microseconds for one packet send. Our observations show that, in the LAN setting, the RTT sensitively scales with the communication size whereas in WAN, the RTT hardly varies for small increase in communication. For instance, we have noted that, in LAN, the average RTT for 1 KB, 8 KB, 20 KB, 80 KB is 280µs, 391µs, 832µs, 1400µs respectively, whereas in WAN the RTT for these communication sizes does not vary. This implies that two transfers of 1 KB data consumes less time than a single transfer of 20 KB data in LAN. All the above reasons collectively justify the slight difference in the LAN time. Having said that, we believe that WAN being a better comparison measure in terms of both communication data and round complexity, aptly depicts the overhead of all our protocols over [CGMV17].

Table 3 provides a unified view of the overall maximum latency in terms of each parameter and total communication of all protocols implemented with Garble. The bracketed values indicate the additional overhead involved in the worst case run of god5PC. Note that the overhead for SHA-256 is higher compared to AES-128. This difference maps to the circuit dependent communication involving the inputs and output. Since SHA is a huge circuit compared to AES, the increase is justified. However, the percentage overheads get better for SHA compared to AES. Besides, the factor of additional communication overhead incurred by our protocols for SHA when compared to AES is far less than the factor of increase in the total communication for SHA over AES in [CGMV17] thus implying that the performance of our protocols improves with larger circuits. Further, based on our observation and in [CGMV17], using AOT instead of OT extension eliminates the expensive public key operations needed even
for the seed OTs between every pair of garblers. Further, AOT needs just 1 round whereas OT extension needs more. All these factors lead to the improvement of our Garble over [WRK17] which relies on large number of Tiny OTs [NNOB12] to perform authentication.

A Functionalities and Security Model

The security of our protocols is proven based on the standard real/ideal world paradigm i.e. it is examined by comparing the adversary’s behaviour in a real execution to that of an ideal execution considered to be secure by definition (in presence of an incorruptible trusted third party (TTP)). In an ideal execution, each participating party sends its input to the TTP over a perfectly secure channel, the TTP computes the function using these inputs and sends respective output to each party. Informally, a protocol is said to be secure if an adversary’s behaviour in the real protocol (where no TTP exists) can be simulated in the above described ideal computation.
Each honest party $P_i$ ($i \in [5]$) sends its input $x_i$ to the functionality. Corrupted parties may send arbitrary inputs.

**Input:** On message $(\text{Input}, x_i)$ from a party $P_i$ ($i \in [5]$), do the following: if $(\text{Input}, \ast)$ message was already received from $P_i$, then ignore. Else record $x_i' = x_i$ internally. If $x_i'$ is outside of the domain for $P_i$, set $x_i'$ to be some predetermined default value.

**Output:** Compute $y = f(x_1', x_2', x_3', x_4', x_5')$ and send $(\text{Output}, y)$ to party $P_i$ for every $i \in [5]$.

Figure 16: Ideal Functionality $\mathcal{F}_{\text{god}}$

Each honest party $P_i$ ($i \in [5]$) sends its input $x_i$ to the functionality. Corrupted parties may send arbitrary inputs as instructed by the adversary. When sending the inputs to the functionality, the adversary is allowed to send a special abort command as well.

**Input:** On message $(\text{Input}, x_i)$ from $P_i$, do the following: if $(\text{Input}, \ast)$ message was received from $P_i$, then ignore. Otherwise record $x_i' = x_i$ internally. If $x_i'$ is outside of the domain for $P_i$, consider $x_i' = \text{abort}$.

**Output:** If there exists $i \in [5]$ such that $x_i' = \text{abort}$, send $(\text{Output}, \bot)$ to all the parties. Else, send $(\text{Output}, y)$ to party $P_i$ for every $i \in [5]$, where $y = f(x_1', x_2', x_3', x_4', x_5')$.

Figure 17: Ideal Functionality $\mathcal{F}_{\text{fair}}$

Each honest party $P_i$ ($i \in [5]$) sends its input $x_i$ to the functionality. Corrupted parties may send arbitrary inputs as instructed by the adversary. When sending the inputs to the trusted party, the adversary is allowed to send a special abort command as well.

**Input:** On message $(\text{Input}, x_i)$ from $P_i$, do the following: if $(\text{Input}, \ast)$ message was received from $P_i$, then ignore. Otherwise record $x_i' = x_i$ internally. If $x_i'$ is outside of the domain for $P_i$, consider $x_i' = \text{abort}$.

**Output to the adversary:** If there exists $i \in [5]$ such that $x_i' = \text{abort}$, send $(\text{Output}, \bot)$ to all the parties. Else, send $(\text{Output}, y)$ to the adversary, where $y = f(x_1', x_2', x_3', x_4', x_5')$.

**Output to honest parties:** Receive either continue or abort from the adversary. In case of continue, send $y$ to all honest parties. In case of abort send $\bot$ to all honest parties.

Figure 18: Ideal Functionality $\mathcal{F}_{\text{uAbort}}$

### B Primitives

#### B.1 Non-Interactive Commitment Scheme

We use Non-Interactive Commitment Scheme (NICOM) characterized by two PPT algorithms ($\text{Com}$, $\text{Open}$) and are defined as:

- $\text{Com}$ outputs commitment $c$ and corresponding opening information $o$, given a security parameter $\kappa$, a common public parameter $\text{pp}$, message $x$ and random coins $r$.
- $\text{Open}$ outputs the message $x$ given $\kappa$, $\text{pp}$, a commitment $c$ and corresponding opening information $o$.

The commitment scheme should satisfy the following properties:

- **Correctness:** For all values of public parameter $\text{pp}$, message $x \in \mathcal{M}$ and randomness $r \in \mathcal{R}$, if $(c, o) \leftarrow \text{Com}(x; r)$ then $\text{Open}(c, o) = x$.

- **Hiding:** For all PPT adversaries $\mathcal{A}$, all values of $\text{pp}$, and all $x, x' \in \mathcal{M}$, the difference $|\Pr_{(c, o) \leftarrow \text{Com}(x)}[\mathcal{A}(c) = 1] - \Pr_{(c, o) \leftarrow \text{Com}(x')}[\mathcal{A}(c) = 1]|$ is negligible.

- **Binding:** A PPT adversary $\mathcal{A}$ outputs $(c, o, o')$ such that $\text{Open}(c, o) \neq \text{Open}(c, o')$ and $\bot \notin \{\text{Open}(c, o), \text{Open}(c, o')\}$ with negligible probability over uniform choice of $\text{pp}$ and random coins of $\mathcal{A}$.

**Instantiations** In the random oracle model, the commitment scheme is:

- $\text{Com}(x; r)$ sets $c = H(x||r)$, $o = (x||r)$ where $c, o$ refer to the commitment and opening respectively. The $\text{pp}$ can be empty.
– $\text{Open}(c, o = (x||r))$ returns $x$ if $H(o) = c$ and ⊥ otherwise.

For the purpose of all empirical results, the random oracle can be instantiated using a hash function. Alternatively, based on one-way permutation, we present an instantiation of NICOM(Com, Open) used theoretically in our protocols as: Let $f : \{0, 1\}^n \rightarrow \{0, 1\}^n$ be a one-way permutation and $h : \{0, 1\}^n \rightarrow \{0, 1\}$ be a hard-core predicate for $f$. Then the bit-commitment scheme for $x$ is:

– $\text{Com}(x, r)$ sets $c = (f(r), x \oplus h(r))$ where $r \in R \{0, 1\}^n$ and $o = (x||r)$.
– $\text{Open}(c, o = (x||r))$ returns $x$ if $c = (f(r), x \oplus h(r))$, else ⊥.

We provide bit and string based instantiations for NICOM(Com, Open) [CGMV17] based on block ciphers that are secure in the ideal cipher model [Sha49, HKT11, Bla06] that are used in our AOT protocols for efficiency. The bit commitment scheme is as follows:

– $\text{Com}(b, r)$ sets $c = F_k(r) \oplus r \oplus b^o$ where $b^o = ||_{i \in [n]} b$ and $F : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}^n$ is a random permutation parametrized by key $k$. Also, $o = (r||b)$.
– $\text{Open}(c, o = (r||b))$ returns $b$ if $c = F_k(r) \oplus r \oplus b^o$ and ⊥ otherwise.

However, this bit commitment scheme is not secure for string commitments. Hence we describe the following secure instantiation:

– $\text{Com}(m, r)$ sets $c = F_k(r) \oplus r \oplus F_k(m) \oplus m$ s.t $F : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}^n$ is a random permutation parametrized by key $k$ and $o = (r||m)$.
– $\text{Open}(c, o = (r||m))$ returns $b$ if $c = F_k(r) \oplus r \oplus F_k(m) \oplus m$, else ⊥.

### B.2 Equivocal Commitment Scheme

For the fair protocol, we use an Equivocal Non-Interactive Commitment Scheme (eNICOM) characterized by four PPT algorithms (eCom, eOpen, eGen, Equiv). The algorithms eCom, eOpen are as defined in NICOM. The algorithms eGen, Equiv are defined as:

– eGen(1^n) returns a public parameter and a corresponding trapdoor (epp, t). The parameter epp is used by both eCom and eOpen and trapdoor $t$ is used for equivocation.
– Equiv(c, o’, x, t) returns an $o$ s.t $x \leftarrow \text{eOpen}(\text{epp}, c, o)$ when invoked on commitment $c$, its opening $o’$, the desired message $x$ (to which equivocation is required) and the trapdoor $t$.

An eNICOM should satisfy the following properties:

– **Correctness:** For all pairs of public parameter and trapdoor, $(\text{epp}, t) \leftarrow \text{eGen}(1^n)$, message $x \in \mathcal{M}$ and randomness $r \in \mathcal{R}$, if $(c, o) \leftarrow \text{eCom}(x; r)$ then $\text{eOpen}(c, o) = x$.

– **Hiding:** For all $(\text{epp}, t) \leftarrow \text{eGen}(1^n)$, all PPT adversaries $\mathcal{A}$ and all $x, x' \in \mathcal{M}$, the difference $|\Pr_{(c, o) \leftarrow \text{eCom}(x)}[A(c, o) = 1] - \Pr_{(c, o) \leftarrow \text{eCom}(x), o \leftarrow \text{Equiv}(c, x, t)}[A(c, o) = 1]|$ is negligible.

– **Binding:** For all $(\text{epp}, t) \leftarrow \text{eGen}(1^n)$, a PPT adversary $\mathcal{A}$ outputs $(c, o, o')$ s.t $\text{eOpen}(c, o) \neq \text{eOpen}(c, o')$ and $\bot \notin \{\text{eOpen}(c, o), \text{eOpen}(c, o')\}$ with negligible probability.

**Instantiation:** We can use the equivocal bit commitment scheme of [CIO98] in the standard model, based on Naor’s commitment scheme [Nao91] for bits. Let $G : \{0, 1\}^n \rightarrow \{0, 1\}^{4n}$ be a pseudorandom generator. The commitment scheme for bit $b$ is:

– eGen(1^n) sets $(\text{epp}, t_1, t_2, t_3, t_4) = ((\sigma, G(r_1), G(r_2), G(r_3), G(r_4)), r_1, r_2, r_3, r_4)$, where $\sigma = G(r_1) \oplus G(r_2) \oplus G(r_3) \oplus G(r_4)$. $t = ||_{i \in [4]} t_i$ is the trapdoor.
- eCom\((x; r)\) sets \(c = G(s_1) \oplus G(s_2)\) if \(x = 0\), else \(c = G(s_1) \oplus G(s_2) \oplus \sigma\) and sets \(o = (x||r)\) where \(r = s_1||s_2\).
- eOpen\((c, o = (x||r))\) returns \(x\) if \(c = G(s_1) \oplus G(s_2) \oplus x \cdot \sigma\) (where \(\cdot\) denotes multiplication by a constant), else returns \(\bot\).
- \(\text{Equiv}(c = G(r_1) \oplus G(r_2), \bot, x, (t_1, t_2, t_3, t_4))\) returns \(o = (x||r)\) where \(r = t_1||t_2\) if \(x = 0\), else \(r = t_3||t_4\).

The entire trapdoor \(t = (t_1, t_2, t_3, t_4)\) is required for equivocation.

For empirical purposes, we rely on the random oracle based scheme presented before with the property of equivocation and is realized using a hash function.

B.3 Collision Resistant Hash

Consider a hash function family \(H = \mathcal{K} \times \mathcal{L} \rightarrow \mathcal{Y}\). The hash function \(H\) is said to be collision resistant [RS04] if for all probabilistic polynomial-time adversaries \(A\), given the description of \(H_k\) where \(k \in_R \mathcal{K}\), there exists a negligible function \(\text{negl}(\cdot)\) such that
\[
\Pr[(x_1, x_2) \leftarrow A(k) : (x_1 \neq x_2) \land H_k(x_1) = H_k(x_2)] \leq \text{negl}(\kappa),
\]
where \(m = \text{poly}(\kappa)\) and \(x_1, x_2 \in_R \{0,1\}^m\).

C Security Proof of fair5PC

We now outline the complete security proof of Theorem 4.3 that describes the security of the fair5PC protocol relative to its ideal functionality in the standard security model.

Proof. We describe the simulator \(S_{\text{fair5PC}}\) for the following two cases: First, when two garblers say \(P_1\) and \(P_2\) are corrupt. Second, when one garbler say \(P_1\) and the evaluator \(P_5\) are corrupt. The simulator acts on behalf of all the honest parties in the execution. The corruption of any two garblers is symmetric to the case when \(P_1, P_2\) are corrupt and the corruption of any one garbler and evaluator corrupt is symmetric to the case of \(P_1, P_5\) corrupt.

We briefly highlight the need for equivocal commitment scheme (eNICOM) for the shares of output masking bits in our fair protocol as follows: The adversary can decide to abort the execution as late as when \(Y\) needs to be sent (in the worst case). Consequently, this enforces the simulator to make this decision on behalf of the adversary at the end of Round 5 when calling the functionality. Hence, the simulator needs a mechanism to simulate the earlier rounds appropriately such as sending the GC and committing to the shares of the output masking bits, without the knowledge of whether the execution will result in a valid output or not (with no information about the output). The sending of distributed GC is handled as in any standard distributed garbling proof. To tackle the commitment on shares of output masking bits, the simulator commits to dummy bits for the seed completely under its control. At a later point if the execution results in invoking \(F_{\text{fair}}\) and obtaining \(y\), the simulator equivocates the commitments to desired share bits such that each output wire \(w\) decodes to correct \(y_w\). The trapdoor and public parameter for our eNICOM scheme are derived from relevant seeds as described in the protocol.

We provide a high level view of the simulation in distributed garbling and evaluation for completeness. First, in the case of corrupt \(P_1, P_2\), the evaluator is honest. Hence correctness is required from the DGC. The simulator behaves as an honest \(P_i, i \in \{3,4\}\) following the protocol steps and instructing the functionality to abort in case of any cheating throughout the garbling since all seeds are known to the adversary. If no cheating is detected throughout the DGC construction, then the GC is generated as per the Garble4 procedure. The inputs of corrupt parties are extracted during the garbled input communication. The simulator sends abort to the functionality if the GC partition sent by \(P_1, P_2\) is not same as the one generated by honest parties.

Second, in the case of corrupt \(P_3, P_5\), the simulator knows the seeds held by the adversary. In addition the simulator has complete control over the part of GC generated using seed \(s_2\). Since the simulator does not know the output in advance, the masking bit share \(\lambda_w^2\) corresponding to output wires \(w\) cannot be set in advance. As a result, a fake GC is constructed using \(s_2\) that always evaluates to the same output super-key for the extracted and random inputs that are known to the simulator. If the evaluation goes through and \(Y\) is received on behalf of the honest parties, then the simulator invokes the functionality to obtain \(y\), aptly programs the masking bit share under
its control by setting $\lambda_w^2 = y \oplus (\oplus_{i \in \{4\}, i \neq 2}) \lambda_w^i$ for each output wire, performs equivocation on the commitment made for share $\lambda_w^2$ and sends the corresponding decommitment to the corrupt parties thus completing simulation. We describe the simulator steps in detail in Figures 19, 20.

$$S_{\text{fairSPC}}^{12} (P_1^*, P_2^* \text{ are corrupt})$$

**Seed Distribution Phase (one-time):**
- Receive $s_y, g \in [2]$ from $P_g^*$ on behalf of both $P_3, P_4$. If the copies of $s_y$ received mismatch, then invoke $F_{\text{fair}}$ with $(\text{Input, } \perp)$ on behalf of $P_g^*$ and set $y = \perp$.
- Sample random $s_3, s_4$ and send $s_3 \to P_1^*, P_2^*$ on behalf of $P_3$ and $s_4$ on behalf of $P_4 \to P_1^*, P_2^*$.

**Evaluator’s Input sharing Phase:**
- Sample a random $x^{52} \in \{0,1\}^\ell$ as input share of $P_5$ and send $x^{52}$ to $P_2^*$ on behalf of $P_5$.

**Proof Establishment Phase:**
- Sample proof from the domain of hash function $H$ and send $H(proof)$ on behalf of $P_5 \to P_1^*, P_2^*$.
- Send $H(proof)$ on behalf of $P_3, P_4 \to P_2^*, g \in [2]$. Also receive $H(proof)$ from $P_g^*$ on behalf of $P_3, P_4$. If the received hash value from $P_g^*$ does not match with the hash value $H(proof)$ that was created originally on behalf of $P_5$, then invoke $F_{\text{fair}}$ with $(\text{Input, } \perp)$ on behalf of $P_g^*$ and set $y = \perp$.

**Setup of public parameter for Equivocal Commitment.**
- For eNICOM, receive $epp^{g, i}, g \in [2], j \in |S_g|, epp^{g, l} \in [4] \\setminus S_g$ from $P_g^*$ on behalf of the honest parties. Also send $epp^{l, i} \in \{3,4\}, j \in |S|, epp^{l, l} \in [4] \\setminus |S|$ on behalf of $P_1$ to each $P_g^*$. Compute $epp^\alpha = \oplus_{i \in [4]} epp^{g, i}$ based on the values received from $P_g^*$. If $epp^\alpha$ does not match with the $epp^{g, i} = \oplus_{i \in [4]} epp^{\alpha, i}$ computed on behalf of the honest parties, then invoke $F_{\text{fair}}$ with $(\text{Input, } \perp)$ on behalf of $P_g^*$ and set $y = \perp$. Else forward $epp^{l, i} \in [4]$ to $P_1^*, P_2^*$ on behalf of the honest parties.

**Transfer of Equivocal Commitments.**
- For each circuit output wire $w$, create equivocal commitments for masking bit shares as per the protocol. Send \{$(epp^i, c_w^i)\}_{i \in |S|}$ on behalf of $P_i, i \in \{3,4\}$ to $P_1^*, P_2^*$. Also, receive \{$(epp^j, c_w^j)\}_{i \in |S|}$ from $P_g^*, g \in [2]$ on behalf of the honest parties. For any output wire $w$, if the received $(epp^j, c_w^j)$ from $P_g^*$ does not correspond to the one generated using $s_3$, then invoke $F_{\text{fair}}$ with $(\text{Input, } \perp)$ on behalf of $P_g^*$ and set $y = \perp$.

**Garbling, Masked input bit and Key Transfer Phase.**
- For circuit input wires $w$ corresponding to input $x_i, i \in [2]$ held by $P_i^*$, send $\lambda_w^l, l \in |S|$ on behalf of $P_j, j \in \{3,4\}$ to $P_1^*$. Similarly, for input corresponding to honest $P_j$, receive $\lambda_w^l, l \in |S|$ from $P_i^*$ on behalf of $P_j$. Invoke $F_{\text{fair}}$ with $(\text{Input, } \perp)$ on behalf of $P_i^*$ and set $y = \perp$.
- Sample random bits $b_1, b_2$ for input wires $w$ of honest $P_i, i \in \{3,4\}$ (including the shares of $P_j$ that $P_i$ should hold). Send $b_1, b_2$ to $P_1^*, P_2^*$ respectively on behalf of $P_i$. For the masked input $b_w$ on wire $w$ of $P_1^*, j \in [2]$, perform the steps as per the protocol to compute $K_i, l \in [4] \\setminus \{j\}$.
- For every input wire $w$ belonging to $P_i$’s input share, where \{$(k_{w,b,ib}^i, k_{w,ib}^i)\}_{g \in [4]}$ denote the super-key derived from seeds $(s_g)_{g \in [4]}$ received, receive \{$(c_{w,b}^j)_{b \in \{0,1\}}$\} sent by $P_i^*, i \in [2] \cap |S|$ on behalf of $P_3$. If the commitment received for any $w$ from $P_i^*$ does not match with the one originally created, then invoke $F_{\text{fair}}$ with $(\text{Input, } \perp)$ on behalf of $P_i^*$ and set $y = \perp$.
- For simulation of Round 1 of Garble1, it is necessary to ensure correctness of the circuit. Behave as honest $P_i, l \in \{3,4\}$ using the seeds chosen in Round 1 and instruct the functionality to abort in case of any cheating detected on behalf of honest $P_i$ based on the messages sent by $P_i^*, i \in [2]$. If an instance of $F_{\text{AOT}}$ returns $\perp$ (due to inconsistent messages from $P_i^*, i \in [2]$), then invoke $F_{\text{fair}}$ with $(\text{Input, } \perp)$ on behalf of $P_i^*$ and set $y = \perp$.
- For simulation of Round 2 of Garble1, behave as honest $P_i, l \in \{3,4\}$. If an instance of $F_{\text{AOT}}$ returns $\perp$ (due to inconsistent messages from $P_i^*, i \in [2]$ or $i \in |S|$ for some $j \in [4]$ sends different $GC^j$, then invoke $F_{\text{fair}}$ with $(\text{Input, } \perp)$ on behalf of $P_i^*$ and set $y = \perp$. If there is no abort, then the garble circuit (described in ??) will be the output of honest parties.
- Input $x_i$ of $P_i^*, i \in [2]$ is extracted by unmasking $\lambda_w$ from $b_w = x_i \oplus \lambda_w$ (sent to $P_3$) for each wire $w$ corresponding to the input of $P_i^*$. Invoke $F_{\text{fair}}$ with $(\text{Input, } x_1), (\text{Input, } x_2)$ to get the output $y$.

**Evaluation and Output Phase.**
- Compute $Y$ such that for all output wires $w$, each key in $Y$ maps to $(y_w \oplus \lambda_w)$. Send $(Y, \text{proof})$ to $P_i^*, i \in [2]$ on behalf of $P_5$.
- Send $(Y, \text{proof}, \sigma_w^i), j \in |S|$ for all output wires $w$ on behalf of $P_i, l \in \{3,4\}$ to $P_i^*, i \in [2]$. Also, receive the openings sent by $P_g^*$ similarly. This completes the simulation.
Figure 19: Simulator $S_{\text{fair5PC}}^{12}$ for fair5PC with actively corrupt $P_1^*$, $P_2^*$

The hybrid arguments are as follows:

Security against corrupt $P_1^*, P_2^*$: We now argue that $\text{IDEAL}_{\mathcal{F}_{\text{fair5PC}}}^{\frac{1}{5}S_{\text{fair5PC}}} \approx \text{REAL}_{\text{fair5PC},A}$ when an adversary $A$ corrupts $P_1, P_2$. The views are shown to be indistinguishable via a series of intermediate hybrids.

- **HYB0**: Same as $\text{REAL}_{\text{fair5PC},A}$.
- **HYB1**: Same as HYB0 except that $P_3$ aborts if any decommitment for $\{k_{w,0}, k_{w,1}\}_{g \in [4]}$ corresponding to a committed share $x^{52}$ opens to a value other than what was originally committed and held by $P_2^*$.
- **HYB2**: Same as HYB1 except that $Y$ is computed as $Y = \{k_{w,yw,\oplus \lambda_{w_i}}\}_{g \in [4]}$ for each output wire $w$ instead of running the Evaluation Phase of garbling.
- **HYB3**: Same as HYB2 except that $P_i, i \in \{3, 4\}$ outputs $\perp$ if distributed GC cannot be successfully evaluated by $P_3$.

HYB3 $= \text{IDEAL}_{\mathcal{F}_{\text{fair5PC}}}^{\frac{1}{5}S_{\text{fair5PC}}}$. To sum up the proof, we show that each pair of hybrids is computationally indistinguishable as follows:

**HYB0** $\approx$ **HYB1**: The primary difference between the hybrids is that in HYB0, $P_3$ aborts if the decommitments sent by $P_2$ corresponding to the share $x^{52}$ output $\perp$ whereas in HYB1, $P_3$ aborts if the decommitments sent by $P_2^*$ open to any value other than what was originally committed. Since the commitment scheme Com is strong binding, $P_2$ could have decommitted successfully to a different valid input label than what was originally committed, only with negligible probability.

**HYB1** $\approx$ **HYB2**: The only difference between the hybrids is that, in HYB2, $Y$ is computed as $Y = \{k_{w,yw,\oplus \lambda_{w_i}}\}_{g \in [4]}$ instead of running the Evaluation Phase of the garbling. The indistinguishability follows from the correctness of the garbling scheme since $Y$ computed using $Y = \{k_{w,yw,\oplus \lambda_{w_i}}\}_{g \in [4]}$ is equivalent to that computed using the standard Evaluation Phase of garbling.

**HYB2** $\approx$ **HYB3**: The only difference between the hybrids is that in HYB2, $P_i, i \in \{3, 4\}$ can possibly output $y$ which is non-$\perp$ in case it receives a valid proof’ such that $H(\text{proof}) = H(\text{proof})$ from $P_1^*$ or $P_2^*$ although $P_3$ was unable to evaluate the GC successfully, whereas in HYB3, $P_i$ outputs $\perp$ in this case. Due to the collision resistant property of the hash function, $P_1^*/P_2^*$ could have a proof’ that can be valid pre-image of $H(\text{proof})$ only with negligible probability.

### Seed Distribution Phase (one-time):
- Receive $s_1$ from $P_i^*$ on behalf of both $P_3, P_4$. If the copies of $s_1$ received mismatch, then invoke $\mathcal{F}_{\text{fair}}$ with $(\text{Input}, \perp)$ on behalf of $P_i^*$ and set $y = \perp$.
- Sample random $s_3, s_4$ and send $s_3$ to $P_i^*$ on behalf of $P_3$ and $s_4$ on behalf of $P_4$.

### Evaluator’s Input sharing Phase:
- Receive $x^{52}, x^{53}, x^{54}$ on behalf of $P_2, P_3, P_4$ respectively. Compute $x_5 = \oplus_{j \in \{2,3,4\}} x^{5j}$.

### Proof Establishment Phase:
- Receive $H(\text{proof})$ on behalf of $P_i, i \in \{2,3,4\}$ from $P_5^*$. If the received copies of $H(\text{proof})$ are not consistent, then invoke $\mathcal{F}_{\text{fair}}$ with $(\text{Input}, \perp)$ on behalf of $P_i^*$ and set $y = \perp$.
- Send $H(\text{proof})$ to $P_i^*$ on behalf of $P_i$. Also receive $H(\text{proof})$ from $P_1^*$ on behalf of $P_1$. If the copy of the hash value sent by $P_1^*$ is not consistent from that sent by $P_2^*$, then invoke $\mathcal{F}_{\text{fair}}$ with $(\text{Input}, \perp)$ on behalf of $P_i^*$ and set $y = \perp$.

### Setup of public parameter for Equivocal Commitment:
- For eNICOM, receive $\text{epp}_j^i, j \in S_1, \text{epp}_j^{12}$ from $P_i^*$ on behalf of the honest parties. Also send $\text{epp}_j^i, i \in \{2,3,4\}, j \in$
Security against corrupt $P_1^*, P_5^*$: We now argue that $\text{IDEAL}_{\mathcal{F}_{\text{fair}},s^{15}_{\text{fair},5PC}} \approx \text{REAL}_{\text{fair},5PC,A}$ when an adversary $A$ corrupts $P_1, P_5$. The views are shown to be indistinguishable via a series of intermediate hybrids.

- **HYB**: Same as $\text{REAL}_{\text{fair},5PC,A}$.
- **HYB**: Same as HYB0 except that some of the commitments of input wire labels sent by $P_2, P_3, P_4$ wrt seed $s_2$, which will not be opened are replaced with commitments of dummy values. These commitments correspond to the labels that do not correspond to any input share.
– HYB₂: Same as HYB₁ except that the GC is created as simulated one with the knowledge of s₂.
– HYB₃: Same as HYB₂ except that,
  • HYB₃₁: When the execution results in abort, the commitment to λₖᵢ for each output wire w is created for a dummy value.
  • HYB₃₂: When the execution results in output y, the commitment cₖᵢ for each output wire w is created for a dummy value and later equivocated to λₖᵢ using oₖᵢ computed via where oₖᵢ = Equiv(cₖᵢ, oₖᵢ, λₖᵢ, t) where t is the trapdoor for the commitment cₖᵢ.
– HYB₄: Same as HYB₃ except that the protocol results in abort if the received Y does not correspond to the Y resulting from the simulated GC.

HYB₄ = IDEAL_{F_{uAbort}, S_{uAbort}^{12}}. To conclude the proof we show that every consecutive pair of hybrids is computationally indistinguishable as follows:

HYB₀ ≈ HYB₁: The only difference between the hybrids is that some of the commitments of the input labels in HYB₀ corresponding to P₅’s input shares that will not be opened are replaced with commitments of dummy values in HYB₁. The indistinguishability follows via reduction to the hiding property of Com.

HYB₁ ≈ HYB₂: The only difference between the hybrids is that in HYB₂, the GC is constructed as a simulated one using the seed s₂ instead of a real GC. More concretely, In HYB₁, Rounds 1, 2 are run as per Garble₁ procedure, which gives \( |G| \times 4 \). In HYB₂, it is generated as a simulated circuit such that it always evaluates to the same Y. Indistinguishability follows from the reduction to the security of distributed garbling and in turn the double-keyed PRF F property.

HYB₂ ≈ HYB₃₁: The difference between the hybrids is that the commitment to λₖᵢ for each output wire w, is created for a dummy value in HYB₃₁. The indistinguishability follows via reduction to the hiding property of eCom.

HYB₂ ≈ HYB₃₂: The difference between the hybrids is that in HYB₃₂, commitment to λₖᵢ for each output wire w, is created for a dummy value and later equivocated using oₖᵢ computed via where oₖᵢ = Equiv(cₖᵢ, oₖᵢ, λₖᵢ, t) where t is the trapdoor for the commitment cₖᵢ. Indistinguishability follows via reduction to the hiding property of eCom.

HYB₃ ≈ HYB₄: The only difference between the hybrids is that, in HYB₃, the protocol aborts if for some output wire w and index j ∈ Sₜ, k_w,j of the received Y does not match with either (k_w,0, k_w,1) or the keys \( \{k_w,j\}_{j \in S_t} \) in Y do not map to the same b_w whereas in HYB₄, the protocol results in abort if the received Y does not match the one created with simulated GC. By security of the garbling scheme, P₅ could have forged such a Y only with negligible probability.

\[ \square \]

D Security Proof of uAbort5PC

Proof. We present the proof of Theorem 5.3 relative to its ideal functionality \( F_{uAbort} \) (Figure ??). We only outline the sketch of the proof, since it is very similar to the security proof of Theorem 4.3, explained in detail in Section C.

We consider two corruption cases: First, when two garblers P₁, P₂ are corrupt and second, when one garbler P₁ and the evaluator P₅ are corrupt. The cases of any two corrupt garblers and one garbler one evaluator corrupt are analogous to the first and second case respectively. The simulator, \( S_{uAbort}^{12} \) is described for the first case of corruption as follows: When P₁, P₂ are corrupt, \( S_{uAbort}^{12} \) acts on behalf of the honest parties. To begin with, \( S_{uAbort}^{12} \) receives sᵢ, i ∈ [2] from Pᵢ* on behalf of Pᵢ, P₅. If the copies of sᵢ received mismatch, then \( S_{uAbort}^{12} \) invokes the functionality \( F_{uAbort} \) on behalf of Pᵢ* with input ⊥. Else, it samples s_j, j ∈ {3, 4} and sends s_j to P₁*, P₂* on behalf of P_j. A random x⁵₂ is also sent by \( S_{uAbort}^{12} \) on behalf of P₅ to P₂*. \( S_{uAbort}^{12} \) behaves according to the protocol steps in the masked input bit and Key Transfer Phase. The inputs of corrupt parties
are extracted similar to our fair protocol. For garbling, since \( P_1, P_2 \) are corrupt, correctness must be ensured. \( S_\text{uAbort5PC}^{12} \) behaves as an honest \( P_i, i \in \{3, 4\} \) instructing the functionality to abort in case of any cheating during garbling since all seeds are known to the adversary. If no cheating occurs in the GC construction, then a GC is generated as per the Garble procedure. If transfer of keys and masked inputs proceed without any adversarial action, \( S_\text{uAbort5PC}^{12} \) then sends \( x_1, x_2 \) to \( F_\text{uAbort} \) to obtain \( y \) which is the output of GC evaluation. \( S_\text{uAbort5PC}^{12} \) then computes \( Y \) such that for all output wires \( w \), each key in \( Y \) maps to \((y_w \oplus \lambda_w)\). \( S_\text{uAbort5PC}^{12} \) sends continue to \( F_\text{uAbort} \) and sends \((Y, \text{proof}_g)\) on behalf of \( P_5 \) and send \((Y, \text{proof}_5, \text{proof}_g)\) on behalf of every honest garbler \( P_g \) in the next round to complete the execution.

For the case of a corrupt garbler \( P_1 \) and the evaluator \( P_5 \), we describe the simulator, \( S_\text{uAbort5PC}^{15} \) as follows: To begin with, \( S_\text{uAbort5PC}^{15} \) receives \( s_1 \) from \( P_1^{5} \) on behalf of \( P_3, P_4 \). If the copies of \( s_1 \) received mismatch, then \( S_\text{uAbort5PC}^{15} \) invokes the functionality \( F_\text{uAbort} \) on behalf of \( P_1^{5} \) with input \( \bot \). Else, it samples \( s_j, j \in \{3, 4\} \) and sends \( s_j \) to \( P_1^{5} \) on behalf of \( P_j \). \( S_\text{uAbort5PC}^{15} \) has the freedom to choose \( s_2 \). \( S_\text{uAbort5PC}^{15} \) behaves according to the protocol steps in the masked input bit and Key Transfer Phase. The input of \( P_5^{5} \) is extracted using the shares disclosed by her to the parties with indices in \( \{2, 3, 4\} \). The input of \( P_1^{5} \) is extracted in garbled input generation similar to our fair protocol. \( S_\text{uAbort5PC}^{15} \) the invokes the functionality to obtain the output \( y \). Construct a fake garbled circuit using \( s_2 \) and the knowledge of \( y \) that always evaluates to the same output super-key \( Y \), which corresponds to the evaluation performed using the extracted inputs of the adversary and the inputs of the honest parties. Consequently, the evaluator evaluates the GC to obtain \( Y' \) which is communicated to the garblers. If the labels in \( Y, Y' \) differ, then \( S_\text{uAbort5PC}^{15} \) instructs the functionality to abort. However, the probability this event is negligible since the adversary can only one row of the CT for each gate corresponding to the seed not held by her. This makes the distributions indistinguishable. Finally, if \( S_\text{uAbort5PC}^{15} \) receives a valid pair \((Y, \text{proof}_g)\) from \( P_5^{5} \) on behalf of honest \( P_i, i \in \{2, 3, 4\} \), then \( S_\text{uAbort5PC}^{15} \) sends continue to \( F_\text{uAbort} \) and sends \((Y, \text{proof}_5, \text{proof}_1)\) to \( P_1^{5} \) on behalf of \( P_i \). Else if valid \((Y, \text{proof}_5, \text{proof}_1)\) is received from \( P_1^{5} \) in round 2 of the output phase on behalf of honest \( P_i \), then \( S_\text{uAbort5PC}^{15} \) sends continue to \( F_\text{Abort} \). Else, \( S_\text{uAbort5PC}^{15} \) sends abort to the \( F_\text{uAbort} \) to complete the simulation. \( \square \)

### E Security Proof of god5PC

In this section, we outline the complete security proof of Theorem 6.4 that describes the security of our god5PC protocol relative to its ideal functionality in the standard security model.

**Proof.** We describe the simulator \( S_\text{god5PC} \) for two cases which exhaustively cover the corruption scenarios: First, when \( P_1 \) and \( P_2 \) are corrupt. Second, when \( P_1 \) and \( P_5 \) are corrupt. The corruption of any two garblers is symmetric to the case when \( P_1, P_2 \) are corrupt and the corruption of any one garbler and evaluator is symmetric to the case of \( P_1, P_5 \) corrupt. The simulator acts on behalf of all honest parties in the execution. For better understanding we separate out the simulation for the subroutine inputGOD from the simulation of main protocol. In the inputGOD routine, we outline the simulator for the case of corrupt \( P_1, P_2 \) describing inputGOD for \( P_1 \)'s input \( x_1 \) and inputGOD for honest party's input \( x_3 \). The simulation of inputGOD routine for the case of corrupt \( P_1, P_5 \) is identical to the case of corrupt \( P_1, P_2 \). The inputs of corrupt parties are extracted in the inputGOD routine.

We give a high level view of the simulation of garbling and output computation as follows: First, in the case of \( P_1^{5}, P_5^{5} \) corrupt, the evaluator \( P_5 \) is honest. Hence, in this case, correctness is required from the distributed GC. The simulator behaves as an honest \( P_i, i \in \{3, 4\} \) by raising conflicts as per the protocol in case of any cheating throughout the garbling phase, since all seeds are known to the adversary. If no cheating is detected throughout the GC construction, then a GC is generated as per the Garble procedure. Else a 3PC instance is identified and the simulator in turn invokes the simulator of 3PC guaranteed output delivery protocol to complete the simulation. Second, in the case of \( P_1^{5}, P_5^{5} \) corrupt, the simulator knows the seeds held by the adversary. In addition the simulator has complete control over the part of GC generated using the seed \( s_2 \). Since input extraction is done in the inputGOD routine, the simulator can invoke the functionality to obtain \( y \) in advance at the time of garbling. As a result with the knowledge of \( y \), a fake garbled circuit is constructed by the simulator using \( s_2 \) that always evaluates to the same output keys forming the output super-key \( Y \), which corresponds to the evaluation performed using the extracted inputs of the adversary and the inputs of the honest parties. The output masking bit share \( \lambda_w \).
for each output wire \( w \) is broadcasted after setting it to \( (y \oplus (\oplus_{i \in [4],i \neq 2} \lambda_{i,w})) \) in the garbling phase itself since the simulator knows \( y \) and all masking bit shares in advance. Finally, if \( Y \) is received from \( P^*_2 \) on behalf of honest parties then the simulation terminates, else a 3PC instance is identified according to the protocol and the simulator runs the simulator of the 3PC instance sub-routine to complete the simulation. (Since the simulator for 3PC is already well-described in [BJPR18], we do not provide details of it).

We describe the simulator steps in detail for \text{inputGOD}() below in Figs 21.

**Input and Seed Distribution Phase.**
- Simulation of \( S^{12}_{\text{inputGOD}_i} \), \( i \in [5] \) instances for input \( x_1 \). Invoke \( F_{\text{god}} \) with \((\text{input}, x_1), (\text{input}, x_2)\) on behalf of \( P^*_1, P^*_2 \) to obtain \( y \).
- For simulation of \text{seedGOD}_g, \( g \in [2] \), receive \((\text{pp}^g, c_g)\) from \( P^{g}_g \) on behalf of all honest parties. Receive \( o_g \) on behalf of \( P_3 \) and \( P_4 \) from \( P^{g}_g \). If a valid opening \( o_g \) is received on behalf of at least one of \( P_3, P_4 \), use the corresponding valid opening to obtain \( s_g \). Else assume a default value for \( s_g \).
- For simulation of \text{seedGOD}_g, \( g \in \{3,4\} \), sample random \( s_g \) and compute \((c_g, o_g) \leftarrow \text{Com} (\text{pp}^g, s_g)\). Broadcast \((\text{pp}^g, c_g)\) on behalf of \( P_g \) and send \( o_g \) on behalf of \( P_g \) to \( P^*_1, P^*_2 \).

**Garbling Phase.**
- For simulation of Round 1 of Garble\(_4\), it is necessary to ensure correctness of the circuit. Behave as honest \( P_g, g \in \{3,4\} \) using the seeds chosen in Round 1. Simulate each instance of \( \Pi_{\text{AOTGOD}} \) by acting as an honest party. If a \( \Pi_{\text{AOTGOD}} \) instance returns \( P^3 \) (due to inconsistent messages from either \( P^*_1 \) or \( P^*_2 \)), invoke \( S_{\text{god3PC}} \) (Simulator for 3PC in [BJPR18]) and send the output \( y \) to all received from the simulation of \text{god3PC} on behalf of honest parties in \( P^3 \) to complete the simulation.
- For simulation of Round 2 of Garble\(_4\), behave as honest \( P_o, g \in \{3,4\} \). If a \( \Pi_{\text{AOTGOD}} \) instance returns \( P^3 \) (due to inconsistent messages from either \( P^*_1 \) or \( P^*_2 \)) or \( P^3 = P \setminus \{P^*_o, P^*_3\} \) is identified when \((P_o, P^*_3)\) with \( \alpha, \beta \in S_j \) for some \( j \in [4] \) broadcasts different GC\(_j\), invoke \( S_{\text{god3PC}} \) and send the output \( y \) to all received from \( S_{\text{god3PC}} \) on behalf of honest parties in \( P^3 \) to complete the simulation. If there is no conflict in the garbling phase, then the GC (described in Fig. ??) will be the output of honest parties.

**Masked input bit and Key Transfer Phase.**
For $i \in \{3, 4\}$ and $j \in S_i \setminus S_2$, do as per the protocol: broadcast $\lambda^\alpha_w$ for each input wire $w$ belonging to $P^*_2$ where $g \in [2]$ and $\lambda^\alpha_w$ for each output wire $w$ on behalf of $P_i$ where $l \in S_i$. Broadcast $\lambda^\beta_w$ on behalf of honest $P_i$ for input wire $w$ belonging to honest $P^*_g$, where $g' \in \{3, 4\} \setminus \{i\}$ and $g' \notin S_i$. Also, receive on behalf of the honest $P_i$, $\lambda^\alpha_w$ (for each input wire $w$) where $\alpha \notin S_i$ and $\lambda^\beta_w$ (for each output wire $w$) from $P^*_g$, $g \in [2]$ where $l \in S_g$. If for any $\alpha, l$, the received $\lambda^\alpha_w/\lambda^\beta_w$ from $P^*_g$, does not correspond to the one generated using $s_\alpha$, then invoke $S_{\text{god3PC}}$ with $\mathcal{P}^3 = \mathcal{P} \setminus \{P^*_g, P_\beta\}$, where $\beta \in S_\gamma$ is the index of the party in conflict with $P^*_g$ and send the output $y$ received from $S_{\text{god3PC}}$ on behalf of honest parties in $\mathcal{P}^3$ to complete the simulation.

For each wire $w$ corresponding to input $x_w = x^{ij}$ held by $P^*_\alpha$, $\alpha \in [2] \cap \mathcal{X}_{ij}$, compute the masked input $b_w = x_w \oplus \lambda_w$ as per the protocol and broadcast $b_w$ on behalf of $P_i$, $l \in \{3, 4\} \cap \mathcal{X}_{ij}$. Also receive $b_w$ from $P^*_\alpha$ on behalf of honest parties. If the received $b_w$ for any $w$ from $P^*_\alpha$ does not match with the one originally broadcast by $P_i$, then invoke $S_{\text{god3PC}}$ with $\mathcal{P}^3 = \mathcal{P} \setminus \{P^*_\alpha, P_1\}$ and send the output $y$ received from $S_{\text{god3PC}}$ on behalf of honest parties in $\mathcal{P}^3$ to complete the simulation.

For each wire $w$ holding the input share $x_w = x^{ij}$ belonging to only honest parties, broadcast random $b_w$ on behalf of the honest parties.

For every input wire $w$, where $\{k^g_{w,0}, k^g_{w,1}\}_g \in [4]$ denote the super-key derived from seeds $\{s_g\}_g \in [4]$, each $P_i$, $l \in \{3, 4\}$ computes commitments on these as per the protocol steps and broadcasts $\{c^l_{w,b}\}_{b \in \{0,1\}, j \in S_i}$ on behalf of $P_i$. Also receive on behalf of the honest parties, $\{c^l_{w,b}\}_{b \in \{0,1\}}$ sent by $P^*_\alpha$, $\alpha \in [2] \cap S_\gamma$. If the commitment received for any $w$ from $P^*_\alpha$ does not match with the one originally created on behalf of $P_i$, then invoke $S_{\text{god3PC}}$ with $\mathcal{P}^3 = \mathcal{P} \setminus \{P^*_\alpha, P_1\}$ and send the output $y$ received from $S_{\text{god3PC}}$ on behalf of honest parties in $\mathcal{P}^3$ to complete the simulation.

**Evaluation and Output Phase.**

Compute $Y$ such that for all output wires $w$, each key in $Y$ maps to $(y_w \oplus \lambda_w)$. Broadcast $Y$ on behalf of $P_5$.

Figure 22: Simulator $S^{ij}_{\text{god5PC}}$ for god5PC with actively corrupt $P^*_1, P^*_2$

The hybrid arguments are as follows:

**Security against corrupt $P^*_1, P^*_2$:** We now argue that $\text{IDEAL}_{F_{\text{god5PC}}}, S^{ij}_{\text{god5PC}} \approx \text{REAL}_{\text{god5PC}}, A$ when an adversary $A$ corrupts $P_1, P_2$. The views are shown to be indistinguishable via a series of intermediate hybrids.

- **HYB0**: Same as $\text{REAL}_{\text{god5PC}}, A$.

- **HYB1**: Same as HYB0 except that when the execution does not result in $P^*_1, P^*_2$ getting access to the opening of the commitment $c_{ij}, i \in \{3, 4, 5\}, j \in \{6\}$ in the inputGOD, the commitment is replaced with the commitment of a dummy value.

- **HYB2**: Same as HYB1 except that $P_0$ raises a conflict to identify a 3PC instance if any decioment for $\{k^g_{w,0}, k^g_{w,1}\}_g \in [4]$ corresponding to a committed share not held by $P_5$ opens to a value other than what was originally committed and held by $P^*_i$, $i \in [2]$.

- **HYB3**: Same as HYB2 except that $Y$ is computed as $Y = \{k^g_{w,y_w \oplus \lambda_w}\}_g \in [4]$ for each output wire $w$ instead of running the Evaluation Phase of garbling.

- **HYB4**: Same as HYB3 except that in case of a 3PC instance elected, run $S_{\text{god3PC}}$ in place of the 3PC protocol algorithm.

Note that $\text{HYB}_4 = \text{IDEAL}_{F_{\text{god5PC}}}, S^{ij}_{\text{god5PC}}$. Next, we show that each pair of hybrids is computationally indistinguishable as follows:

- **HYB0 $\approx$ HYB1**: The only difference between the hybrids is that in HYB1, when the execution does not result in $P^*_1, P^*_2$ getting access to the opening of commitments $c_{ij}, i \in \{3, 12\}, j \in \{6\}$ in the inputGOD, the commitment is replaced with the commitment of a dummy value. The indistinguishability follows from the hiding property of the commitment scheme.

- **HYB1 $\approx$ HYB2**: The only difference between the hybrids is that in HYB1, $P_3$ raises a conflict if the decioment for $\{k^g_{w,0}, k^g_{w,1}\}_g \in [4]$ corresponding to a committed share not held by $P_5$ and sent by $P^*_i$, $i \in [2]$ is invalid
(the decommitment is ⊥) whereas in HYB₂, P₅ raises a conflict to identify the 3PC instance if the decommitment corresponding a committed share opens to a value other than what was originally committed and held by P₅*. Since the commitment scheme Com is binding for any pp, P₅* could have successfully decommitted to a value than what was originally committed with negligible probability. Hence, the hybrids are indistinguishable.

HYB₂ ≈ HYB₃: The only difference between the hybrids is that, in HYB₃, Y is computed as $Y = \{k^g_{w,y_w⊕λ_w}\}_{g∈[4]}$ instead of running the Evaluation Phase of the garbling. The indistinguishability follows from the correctness of the garbling scheme since Y computed using the Evaluation Phase of garbling would also result in $Y = \{k^g_{w,y_w⊕λ_w}\}_{g∈[4]}$.

HYB₃ ≈ HYB₄: The only difference between the hybrids is that, in HYB₃, a real-world 3PC is run in case of conflict whereas $S_{god3PC}$ is run in HYB₄. Since, IDEAL$_{god}$-$S_{god3PC}$ ≈ REAL$_{god3PC}$, indistinguishability follows.

Security against corrupt $P₁^*, P₅^*$: We now argue that IDEAL$_{god}$-$S_{god3PC}^{15}$ ≈ REAL$_{god3PC}$ when an adversary A corrupts $P₁, P₅$. The views are shown to be indistinguishable via a series of intermediate hybrids.

- HYB₀: Same as REAL$_{god3PC}$.
- HYB₁: Same as HYB₀ except that when the execution does not result in $P₁^*, P₅^*$ getting access to the opening of the commitment $c_{ij}, i ∈ \{2, 3, 4\}, j ∈ [6]$ in inputGOD₁, the commitment is replaced with the commitment of a dummy value.
- HYB₂: Same as HYB₁ except that the commitment to seed $s₂$ in seedGOD₂ is replaced with the commitment on dummy value.
- HYB₃: Same as HYB₂ except that some of the commitments of input keys sent by $P₂, P₃, P₄$ wrt seed $s₂$, which will not be opened are replaced with commitments of dummy values. These commitments correspond to the labels that do not correspond to any input share.
- HYB₄: Same as HYB₃ except that the GC is created as simulated one with the knowledge of $s₂$ and output $y$ along with the share $λ²_{w_i}$ for each output wire $w$ set to the value $λ²_{w_i} = y ⊕ (⊕_{i∈[4]} i ≠ 2 λ¹_{w_i})$.
- HYB₅: Same as HYB₄ except that a 3PC instance is chosen as per the protocol if the received $Y$ does not correspond to the $Y$ originally created by the simulated GC. Note that HYB₅ = IDEAL$_{god}$-$S_{god3PC}^{15}$. 
- HYB₆: Same as HYB₅ except that in case of a 3PC instance elected, run $S_{god3PC}$ in place of the 3PC protocol algorithm.

Next, we show that each pair of hybrids are computationally indistinguishable as follows:

HYB₀ ≈ HYB₁: The only difference between the hybrids is that, in HYB₁, when the execution does not result in $P₁^*, P₅^*$ getting access to the opening of commitments $c_{ij}, i ∈ \{2, 3, 4\}, j ∈ [6]$ in inputGOD₁, the commitment is replaced with the commitment of a dummy value. The indistinguishability follows from the hiding property of the commitment scheme.

HYB₁ ≈ HYB₂: The only difference between the hybrids is that, in HYB₂, the commitment to the seed $s₂$ is replaced with the commitment on a dummy value. The indistinguishability follows from the hiding property of the commitment scheme.

HYB₂ ≈ HYB₃: The only difference between the hybrids is that, in HYB₃, the commitments of input wire labels wrt seed $s₂$, which will not be opened are replaced with commitments on dummy values. The indistinguishability follows from the hiding property of the commitment scheme.
Simulation of \( S_{\text{godGOD}} \) for \( P_1^*, P_5^* \) are corrupt

Input and Seed Distribution Phase.
- Simulation of \( S_{\text{inputGOD}}\), \( i \in [5] \) instances for input \( x_i \). Invoke \( F_{\text{god}} \) with \((\text{Input}, x_1)\), \((\text{Input}, x_5)\) on behalf of \( P_1^*, P_5^* \) to obtain \( y_5 \).
- For simulation of seedGOD, receive \((pp^1, c_1)\) from \( P_1^* \) on behalf of all honest parties. Receive \( o_1 \) on behalf of \( P_3 \) and \( P_4 \) from \( P_1^* \). If there exists a valid opening \( o_1 \) received on behalf of at least one of \( P_3, P_4 \), use the corresponding valid opening to obtain \( s_1 \). Else assume a default value for \( s_1 \).
- For simulation of seedGOD, \( g \in \{3, 4\} \), sample random \( s_g \) and compute \( (c_g, o_g) \leftarrow \text{Com}(pp^g, s_g) \). Broadcast \((pp^g, c_g)\) on behalf of \( P_g \) and send \( o_g \) on behalf of \( P_g \) to \( P_1^* \). For seedGOD, broadcast random commitment \((pp^2, c_2)\) on behalf of \( P_2 \).

Garbling Phase.
- For simulation of Round 1 of Garble4, on behalf of honest \( P_1, l \in \{2, 3, 4\} \), all the seeds are known. Additionally, \( s_2 \) is not known to \( P_1^* \), so the randomness and \( GC^2 \) generated using \( s_2 \) is unknown to \( P_1^* \). Use the \( y \) obtained from the \( F_{\text{god}} \) to compute \( \lambda_w^l = y \oplus \lambda_w^l \oplus \lambda_w^3 \) for each output wire \( w \). Participate in the distributed garbling as before but constructing a simulated \( GC \) with the help of \( s_2 \) and with the knowledge of \( y \) such that each ciphertext encrypts the same output key that represents the masked output which corresponds to the evaluation performed using the extracted inputs of the adversary and the inputs of the honest parties. Simulate each instance of \( \Pi_{\text{AOTGOD}} \) by acting as honest party. If a \( \Pi_{\text{AOTGOD}} \) instance returns \( P^3 \) (due to inconsistent messages from \( P_1^* \)), invoke \( S_{\text{god3PC}} \) and send the output \( y \) received from \( S_{\text{god3PC}} \) on behalf of honest parties in \( P^3 \) to complete the simulation.
- For simulation of Round 2 of Garble4, compute the simulated garble circuit using \( s_2 \) on behalf of \( P_1, l \in \{2, 3, 4\} \). If a \( \Pi_{\text{AOTGOD}} \) instance returns \( P^3 \) (due to inconsistent messages from \( P_1^* \)) or \( P^3 = P \backslash \{P_1^*, P_3\} \) is identified when \( (P_1^*, P_3) \) with \( 1, \beta \in S_1 \) for some \( j \in [4] \) broadcasts different \( GC^3 \), invoke \( S_{\text{god3PC}} \) and send the output \( y \) received from \( S_{\text{god3PC}} \) on behalf of honest parties in \( P^3 \) to complete the simulation. If there is no conflict in the garbling phase, then the \( GC \) (described in Fig. 2?) will be the output of honest parties.

Masked input bit and Key Transfer Phase.
- For \( i \in \{2, 3, 4\} \) and \( j \in S_1 \), do as per the protocol: broadcast \( \lambda_w^l \) for each input wire \( w \) belonging to \( P_5^* \). For \( j \notin S_1 \), broadcast \( \lambda_w^l \) for each input wire \( w \) belonging to \( P_1^* \) and \( \lambda_w^l \) for each output wire \( w \) on behalf of \( P_i \) where \( \lambda \in S_1 \). Broadcast \( \lambda_w^l \) on behalf of honest \( P_1 \) for input wire \( w \) belonging to honest \( P_g \) where \( g \in \{2, 3, 4\} \backslash \{i\} \) and \( \beta \notin S_1 \). Also, receive on behalf of the honest \( P_1, \lambda_w^l \) (for each input wire \( w \)) where \( \beta \notin S_1 \) and \( \lambda_w^l \) (for each output wire \( w \)) from \( P_1^* \) where \( \lambda \in S_1 \). If for any \( \alpha, \lambda \), the received \( \lambda_w^l / \lambda_w^l \) from \( P_1^* \), does not correspond to the one generated on behalf of the honest parties, then invoke \( S_{\text{god3PC}} \) with \( P^3 = P \backslash \{P_5^*, P_3\} \), with \( \beta \in S_1 \) and the output \( y \) received from \( S_{\text{god3PC}} \) on behalf of honest parties in \( P^3 \) to complete the simulation.
- For each wire \( w \) corresponding to input \( x_w = x^{ij} \) held by \( P_1^* \) and two honest garblers, set the masked input \( b_w = x_w \oplus \lambda_w \) as per the protocol and broadcast \( b_w \) on behalf of \( P_1, l \in \{2, 3, 4\} \backslash \{X_{ij}\} \). Also receive \( b_w \) from \( P_1^* \) on behalf of honest parties. Also, for \( x_w \) held by only honest parties, broadcast a random \( b_w \) on behalf of all honest parties. If the \( b_w \) received for any \( w \) from \( P_1^* \) does not match with the one created on behalf of honest \( P_1 \), then invoke \( S_{\text{god3PC}} \) with \( P^3 = P \backslash \{P_1, P_3\} \) and send the output \( y \) received from \( S_{\text{god3PC}} \) on behalf of honest parties in \( P^3 \) to complete the simulation.
- For every input wire \( w \), where \( \{k_w^0, k_w^g\}_{g \in [4]} \) denote the super-keys derived from seeds \( \{s_g\}_{g \in [4]} \) on behalf of each \( P_i, l \in \{3, 4\} \) compute commitments on these as per the protocol steps for all seeds except \( s_2 \). For commitments in \( \{c_{w,0}^l, c_{w,1}^l\} \) obtained using \( s_2 \) that correspond to input keys, generate commitments to the shares as per NICOM. Commit to dummy values for all other keys that are not input keys. Broadcast \( \{c_{w,b}^l\}_{b \in \{0, 1\}, i \in S_1} \) on behalf of \( P_\alpha, \alpha \in \{2, 3, 4\} \). Also receive \( \{c_{w,b}^l\}_{b \in \{0, 1\}} \) sent by \( P_1^* \) on behalf of honest parties. If the commitment received for any \( w \) from \( P_1^* \) does not match with the one originally created on behalf of honest \( P_3 \), where \( \beta \in S_1 \), then invoke \( S_{\text{god3PC}} \) with \( P^3 = P \backslash \{P_1^*, P_5\} \) and send the output \( y \) received from \( S_{\text{god3PC}} \) on behalf of honest parties in \( P^3 \) to complete the simulation.

Evaluation and Output Phase.
- Receive \( Y \) from \( P_5^* \) on behalf of \( P_g, g \in \{2, 3, 4\} \). If received \( Y \) for some output wire \( w \) and index \( j \in S_1 \) does not match with the output super-key created in the generation of simulated \( GC \), invoke \( S_{\text{god3PC}} \) with \( P^3 \) with \( P^3 = P \backslash \{P_1^*, P_5\} \) and send the output \( y \) received from \( S_{\text{god3PC}} \) on behalf of honest parties in \( P^3 \) to complete the simulation.

Figure 23: Simulator \( S_{\text{god5PC}} \) for god5PC with actively corrupt \( P_1^*, P_5^* \)
HYB\textsubscript{3} ≈ HYB\textsubscript{4}: The only difference between the hybrids is that in HYB\textsubscript{4}, GC is constructed as a simulated one using the seed s\textsubscript{2} and the knowledge of output y instead of a real GC. More concretely, in HYB\textsubscript{3}, Rounds 1, 2 are run as per Garble\textsubscript{E}, which gives GC. In HYB\textsubscript{4}, it is generated as a simulated circuit and additionally, for each output wire w, \lambda\textsubscript{w} is set to \lambda\textsubscript{w} = y \oplus (\oplus_{i \in [4], i \neq 2} \lambda\textsubscript{i}). Indistinguishability follows from reduction to the security of distributed garbling which in turn relies on the the double-keyed PRF F.

HYB\textsubscript{4} ≈ HYB\textsubscript{5}: The only difference between the hybrids is that, in HYB\textsubscript{4}, a 3PC instance is identified if \kappa\textsubscript{w,b} of the received Y for some output wire w and index \textsubscript{g} = \lambda\textsubscript{w} \oplus (\oplus_{i \in [4], i \neq 2} \lambda\textsubscript{i}) or the three keys \kappa\textsubscript{w,b}, \kappa\textsubscript{w,b}, j \in S\textsubscript{g} in Y do not map to the same b\textsubscript{w} whereas in HYB\textsubscript{5}, a 3PC committee is identified if the received Y does not match the one created using simulated GC. By security of the garbling scheme, P\textsubscript{b} could have forged such a Y only with negligibility probability.

HYB\textsubscript{5} ≈ HYB\textsubscript{6}: The only difference between the hybrids is that, in HYB\textsubscript{5}, a real-world 3PC is run in case of conflict whereas S\textsubscript{god3PC} is run in HYB\textsubscript{6}. Since, IDEAL\textsubscript{god-S\textsubscript{god3PC}} ≈ REAL\textsubscript{god3PC, A} [BJPR18], indistinguishability follows.

\section{3PC with GOD}

In this section, we include the robust 3PC instantiation of [BJPR18] in Fig 24 for completeness. For every case of conflict when a 3PC committee is chosen, the routine god3PC invokes the protocol in Fig 24 to compute the output robustly while ensuring consistency of inputs committed in inputGOD routine. In the protocol g3PC, that is assumed to run between the 3 parties P\textsubscript{1}, P\textsubscript{2}, P\textsubscript{3}, P\textsubscript{1}, P\textsubscript{2} act as garblers and P\textsubscript{3} is the evaluator. Yao’s garbled circuit [Yao82] with security defined as per [BHR12] is used for garbling. The property of soft decoding used in this protocol allows decoding of the garbled circuit output without the use of decoding information [MRZ15]. This can be trivially achieved by appending the truth value to each output key.

**Transition from 5PC to 3PC** For better understanding, we describe how the transition from 5PC to 3PC takes place with a diagram when a conflict is identified and a 3PC instance is chosen. In such a case, input consistency must be maintained for 1) an \textsubscript{xij} that is held by the two garblers. 2) an \textsubscript{xij} that is held by one garbler, say P\textsubscript{1}, and evaluator P\textsubscript{b}. The case when all the three parties hold \textsubscript{xij} is subsumed in one of the above cases. The most critical case when \textsubscript{xij} is with only one of \{P\textsubscript{1}, P\textsubscript{3}, P\textsubscript{b}\} which is further categorized into two cases depending on whether 3) the input share is held either by the garbler or 4) the input share is held by the evaluator. For the purpose of our explanation, we consider the case when a corrupt P\textsubscript{b} does not broadcast Y and the garblers choose P\textsubscript{1}, P\textsubscript{2}, P\textsubscript{3} to run the robust 3PC of [BJPR18]. Hence, we have \alpha = 1, \beta = 2, \gamma = 3. We specifically consider the input shares of input x\textsubscript{1} of P\textsubscript{1} to describe the first 3 cases. We use the share of x\textsubscript{3} to describe case 4). For input x\textsubscript{1}, P\textsubscript{1} holds all the shares (dealer), while P\textsubscript{2} holds (x\textsubscript{14}, x\textsubscript{15}, x\textsubscript{16}) and P\textsubscript{3} holds (x\textsubscript{12}, x\textsubscript{13}, x\textsubscript{16}). For input x\textsubscript{3}, P\textsubscript{3} holds all the shares (dealer) while P\textsubscript{1} holds (x\textsubscript{34}, x\textsubscript{35}, x\textsubscript{36}) and P\textsubscript{2} holds (x\textsubscript{32}, x\textsubscript{33}, x\textsubscript{36}).

In the Fig 25, p\textsubscript{ij} denotes the permutation bit for input x\textsubscript{ij} and thus the commitments on both input keys for wire belonging to x\textsubscript{ij} are sent in permuted order as per p\textsubscript{ij}; m\textsubscript{ij} denotes the XOR of x\textsubscript{ij} and p\textsubscript{ij}. Recall that as per inputGOD\textsubscript{1}, (c\textsubscript{ij}, o\textsubscript{ij}) denotes the commitment-opening pair for share x\textsubscript{ij} \oplus r\textsubscript{ij} while (c\textsubscript{ij}, o\textsubscript{ij}) denotes the commitment-opening pair for share r\textsubscript{ij} and all the commitments are broadcast, while the openings are sent privately. During the transition from 5PC to 3PC, for the shares of the form say x\textsubscript{11} that are held by only one party, P\textsubscript{1} in the 3PC (the other two share holders are eliminated), the opening o\textsubscript{11} (for share x\textsubscript{11} \oplus r\textsubscript{11}) is distributed to say P\textsubscript{2} while the opening o\textsubscript{11} (for share r\textsubscript{11}) is distributed to P\textsubscript{3}. Similar steps are done for the lone input share x\textsubscript{31} held by P\textsubscript{3} and all others held by only one party in 3PC. Inside the 3PC instance, in case 1) x\textsubscript{14} is held by both garblers and not by the evaluator P\textsubscript{3}. The garblers broadcast m\textsubscript{14} and send the opening O[m\textsubscript{14}] corresponding to the key K[x\textsubscript{14}]. If the copies of m\textsubscript{14} match, then P\textsubscript{3} uses a valid opening O[m\textsubscript{14}] (one of the two sent by the garblers) to get the key K[x\textsubscript{14}]. Else, the conflict resolution steps in [BJPR18] are followed. In case 2), x\textsubscript{12} is held by garbler P\textsubscript{1} and evaluator P\textsubscript{3}. The garbler P\textsubscript{1} sends O[x\textsubscript{12}].
Inputs: Party $P_α$ has $x_α$ for $α ∈ [3]$.

Common Inputs: The function $C(x_1, x_2, x_3, x_4)$ that computes $f(x_1, x_2, x_3 ⊕ x_4)$ where inputs, function output are in $\{0, 1\}^ε$ for $ε ∈ \text{poly}(κ)$. $P_3$ is the evaluator and ($P_1, P_2$) are the garblers.

Output: $y = C(x_1, x_2, x_3, x_4) = f(x_1, x_2, x_3 ⊕ x_4)$.

Primitives: A garbling scheme $G = (\text{Gb}, \text{En}, \text{Ev}, \text{De})$ that is correct, private and authentic with the property of soft decoding, a NICOM (Com, Open) and a PRG $G$.

Round 1: $P_1$ chooses random $s ∈_R \{0, 1\}^κ$ for $G$ and sends $s$ to $P_2$. Besides,

- $P_3$ picks $x_31, x_32 ∈ \{0, 1\}^κ$ with $x_3 = x_31 ⊕ x_32$. $P_3$ samples $pp$ for NICOM and generates $(c_{31}, o_{31}) ← \text{Com}(pp, x_{31})$, $(c_{32}, o_{32}) ← \text{Com}(pp, x_{32})$, broadcasts $(pp, c_{31}, c_{32})$ and sends $(x_{31}, o_{31}), (x_{32}, o_{32})$ to $P_1, P_2$ respectively. (This step is not done in our 3PC. as god3PC already does this step to ensure input consistency and privacy).

Round 2: $P_i(i ∈ [2])$ broadcasts $(\text{conflict}, P_3)$ if $\text{Open}(c_{31}, o_{31}) ≠ x_{31}$. Else, it does the following:

- Compute GC $(C, e, d) ← \text{Gb}(1^κ, C)$ with randomness from $G(s)$. Assume $\{K_{α, c}', K_{α, d}'\}_{α ∈ [ε]}, \{K_{α, e}, K_{α, f}\}_{α ∈ [ε]}$. $\{K_{2α + c}, K_{2α + d}\}_{α ∈ [ε]}$ refer to encoding information for the input of $P_1, P_2$ and shares of $P_3$ respectively (w.l.o.g.).

- Compute permutation strings $p_1, p_2 ∈ \{0, 1\}^κ$ for garblers’ input wires, generate commitments on $c$ using randomness from $G(s)$. For $b ∈ \{0, 1\}$, $(α, b) ← \text{Com}(pp, c^b α)$, $(α, b) ← \text{Com}(pp, c^b α)$ for $α ∈ [ε]$, $(c^b α, b) ← \text{Com}(pp, c^b α)$ for $α ∈ [ε]$. Broadcast $B_i = \{C, (c^b α)_{α ∈ [ε]}, b ∈ \{0, 1\}\}$.

- $P_1$ computes $m_{11} = x_1 ⊕ π_1$ and sends to $P_3$: the openings of the commitments corresponding to $(x_1, x_{31}) i.e.$ $\{m_{11}, o_{11} α\}_{α ∈ [ε]}$, $m_{11}$. Similarly, $P_2$ computes $m_{22} = x_2 ⊕ π_2$ and sends to $P_3$: openings of the commitments corresponding to $(x_2, x_{32})$ i.e. $\{m_{22}, o_{22} α\}_{α ∈ [ε]}, m_{22}$.

Every party sets TTP as follows. If exactly one $P_i(i ∈ [2])$ broadcasts $(\text{conflict}, P_3)$ in Round 2, set TTP = $P_{2\setminus i}$. If both raise conflict, set TTP = $P_1$. If $B_1 ≠ B_2$, set TTP = $P_3$.

Round 3: If TTP = $∅$, $P_3$ does the following:

- Assign $X_31^α = \text{Open}(pp, m_{11} α, o_{11} α)$ and $X_{31} = \text{Open}(pp, x_{31}, o_{31})$ for $α ∈ [ε]$. Broadcast $(\text{conflict}, P_1)$ if Open results in ⊥.

- Assign $X_32^α = \text{Open}(pp, m_{22} α, o_{22} α)$ and $X_{32} = \text{Open}(pp, x_{32}, o_{32})$ for $α ∈ [ε]$. Broadcast $(\text{conflict}, P_2)$ if Open results in ⊥.

- Else, set $X = X_1 | X_2 | X_{31} | X_{32}$, run $Y ← \text{Ev}(C, X)$ and $y ← \text{De}(Y)$. Broadcast $Y$.

If $P_3$ broadcasts $(\text{conflict}, P_3)$, set TTP = $P_{2\setminus i}$. If TTP = $∅$ and $P_i$ broadcasts $Y$, $P_i(i ∈ [2])$ then do the following: Execute $y ← \text{De}(Y, d)$. If $y = ⊥$, set TTP = $P_1$. If TTP = $∅$ and $P_3$ does not broadcast $Y$, then TTP = $P_3$.

Round 4: If TTP = $∅$: $P_i(i ∈ [2])$ sends $x_i$ and $o_{31}$ (if valid) to TTP. $P_3$ sends $o_{31}, o_{32}$ to TTP.

Round 5: TTP computes $x_{3i} = \text{Open}(c_{3i}, o_{3i})$ using openings sent by $P_1, P_2$ (if available), else uses the openings sent by $P_3$. If valid opening is not received, a default value is used for shares of $x_i$. Compute $y = f(x_1, x_2, x_{3i} ⊕ x_{3i})$ and send to others. Every party computes output as follows. If $y = ⊥$ and received $y'$ from TTP, set $y = y'$.

Figure 24: Protocol 3PC

to $P_3$ who checks if $O[x_{12}]$ is valid. If so, $P_3$ uses opening $O[x_{12}]$ to get the key $K[x_{12}]$. Else, the conflict resolution steps in [BJPR18] are followed. In case 3), $x_{11}$ is held only by garbler $P_1$. However the re-shares $x_{11} ⊕ r_{11}$ and $r_{11}$ are held respectively by $P_2, P_3$ (which are both known to $P_1$ due to inputGOD$)$. Now, $P_1$ sends $m_{11}$ (masked bit wrt share $x_{11} ⊕ r_{11}$) and $O[m_{11}], O[r_{11}]$ to $P_3$, while $P_2$ sends $m_{11}$ and $O[m_{11}]$ to $P_3$. $P_3$ now verifies if: the copies of $m_{11}$ sent by the garblers are the same, the opening $O[r_{11}]$ sent by $P_1$ is valid. If so, $P_3$ obtains the keys $K[x_{11} ⊕ r_{11}]$ and $K[r_{11}]$ from the openings and XORs them to get $K[x_{11}]$. If any of the checks fail, the conflict resolution steps in [BJPR18] are followed. In Case 4), where the evaluator alone holds the share $x_i$ is simpler than case 3). However, the re-shares $x_{3i} ⊕ r_{31}$ and $r_{31}$ are held respectively by $P_1, P_2$ (which are both known to $P_3$ due to inputGOD$$. Now, $P_1$ sends $O[x_{3i} ⊕ r_{31}]$ to $P_3$, while $P_2$ sends $O[r_{31}]$ to $P_3$. $P_3$ now verifies if the openings are valid. If so, $P_3$ obtains the keys $K[x_{3i} ⊕ r_{31}]$ and $K[r_{31}]$ from the openings and XORs them to get $K[x_{3i}]$. Every input share belongs to one of the above described four cases and is handled in a similar way. If all the input keys are obtained, $P_3$ evaluates the Yao’s GC constructed by the garblers as per [BJPR18] and distributes
Case 1: When both garblers hold the input share $x_{14}$

The output to the garblers. Finally, the 3PC communicates the output to all the parties in 5PC. This completes the description.
