Abstract. Recently, division property based cube attack has achieved new progress and some cryptanalytic results against well-known stream ciphers. At EUROCRYPT 2020, Hao et al. proposed a new modeling method for three-subset division property without unknown subset. With this method, the exact expression of the superpoly in cube attack can be recovered.

In this paper, we propose a method to search good cubes for both distinguishing attacks and key recovery attacks in the division property based cube attack scenario. Our cube searching procedure is based on the algorithm of degree evaluation of the superpoly and the algorithm of superpoly recovery. In the process of cube searching, we mainly use the embedded property to narrow down the searching space. As a result, we find some new cube testers of dimension 126 on 775-round ACORN.

We also find a new key recovery attack on 775-round ACORN with a 126-dimensional cube, whose corresponding superpoly is a 2-degree polynomial with respect to key bits.

Keywords: division property based cube attack · cube searching · degree evaluation · superpoly recovery · embedded property · ACORN.

1 Introduction

In symmetric-key cryptography, integral cryptanalysis \cite{11} is one of general cryptanalytic techniques. The basic idea of integral attack is to traverse some active plaintext bits and check whether the summation of the corresponding ciphertext bits have zero-sum property.

Division property \cite{15}, proposed at EUROCRYPT 2015, is a generalization of the integral property. With division property, attackers can evaluate more accurate integral characteristics. The division property for a multiset of texts $X \subseteq \mathbb{F}_2^n$ is defined by dividing a set of $u$’s into two subsets: the \textit{0-subset} of vectors $u \in \mathbb{F}_2^n$ satisfy $\bigoplus_{x \in X} x^u = 0$, and the \textit{unknown subset} satisfy the value of $\bigoplus_{x \in X} x^u$ is unknown. Moreover, the bit-based division property was introduced...
in [18], and three propagation rules for basic operations, \textbf{and}, \textbf{xor}, and \textbf{copy} are shown. While arbitrary block ciphers can be evaluated by using the bit-based division property, it requires much time and memory complexity [18]. In [24], Xiang \textit{et al.} used the mixed integer linear programming (MILP) to model the propagation of the bit-based division property, and the propagation can be evaluated efficiently with the MILP solvers (e.g., Gurobi [5]).

Although (conventional) bit-based division property can find more accurate integral distinguishers, some practically verified integral distinguishers (e.g., [21]) cannot be proved with it. To find the exact integral characteristics, Todo and Morii [18] proposed the three-subset division property, and the set of vector \( u \) is divided into three subsets rather than two ones: the \( 0 \)-subset, the unknown subset, and the \( 1 \)-subset satisfying \( \oplus_{x \in X} x^u = 1 \). With the three-subset division property, the 15-round integral distinguisher of Simon32 was proved [18].

Cube attack, proposed by Dinur and Shamir [2] at EUROCRYPT 2009, can be seen as a type of higher-order differential (integral) attacks [12]. Given a cipher \( f \) with public variables \( v \in \mathbb{F}_{2^m}^n \) and secret variables \( x \in \mathbb{F}_{2^n}^n \), the cipher can be viewed as a polynomial \( f(x,v) \). Denote a set of indices \( I = \{i_1, i_2, \ldots, i_{|I|}\} \subset \{0,1,\ldots,m-1\} \) by cube indices. Such an \( I \) determines a specific structure called cube \( C_I \), which contains \( 2^{|I|} \) values where the variables in \( \{v_{i_1}, v_{i_2}, \ldots, v_{i_{|I|}}\} \) take all possible combinations of values and the remaining variables (key and non-cube IV variables) are fixed to static values. Then the sum of \( f \) over all values of the cube \( C_I \) is

\[
\bigoplus_{C_I} f(x,v) = \bigoplus_{C_I} (t_I \cdot p(x,v) + q(x,v)) = p(x,v),
\]

where \( t_I = v_{i_1} \cdots v_{i_{|I|}}, p(x,v) \) is independent of \( \{v_{i_1}, v_{i_2}, \ldots, v_{i_{|I|}}\} \), and \( q(x,v) \) misses at least one variable from \( \{v_{i_1}, v_{i_2}, \ldots, v_{i_{|I|}}\} \). Then, \( p(x,v) \) is called the \textbf{superpoly} of the cube \( C_I \). The cube attack consists of two phases. In offline phase, attackers select some cubes, and recover their corresponding superpolys. In online phase, attackers compute the value of the superpoly by summing the output bit \( f(x,v) \) over the cube. If the expression of superpoly \( p(x,v) \) is simple, then we get some simple equations from these superpolys, and we can immediately recover partial key information by solving the system of equations.

In [1] the notion of cube tester was proposed. The main idea of cube tester is similar to cube attack, however, it aims to find some superpolys which have the distinguishable properties (e.g., the superpoly is equal to a constant, which is most commonly used).

For cube attack, recovering the superpoly plays an important role. Traditional approaches [2, 3] treat the cipher as a black-box polynomial, and attackers can test the low-degree property of the superpoly by executing the linearity or quadraticity tests. Then the ANF of the superpoly can be experimentally recovered by interpolation. However, the most time-consuming part is to calculate the cubesums, if the size of the cube is large (e.g., exceeds 40), the computation is practically infeasible.

Breakthroughs have been made by Todo \textit{et al.} at CRYPTO 2017 [16] where they proposed the \textbf{division property based cube attack} to analyze the ANF of
the superpoly. Based on the propagation of the (conventional) bit-based division property of stream ciphers, they gave a proposition to decide which key bits do not exist in the superpoly. By using high-dimensional cubes, they proposed the theoretical cube attacks on 832-round Trivium/183-round Grain128a/704-round ACORN/872-round Kreyvium [17]. Later at CRYPTO 2018, Wang et al. [20, 19] proposed some new techniques (flag technique, degree evaluation, and term enumeration) to improve the division property based cube attack, and new theoretical key recovery attacks were proposed.

Since the theory of conventional division property cannot guarantee that the superpoly is non-constant, the key recovery attack may be degenerated to a distinguisher. As reported in [26, 22], the key recovery attack on 839-round Trivium [20] is in fact a zero-sum distinguisher. Recently, several methods have been proposed to model for the three-subset version. In [9], a variant of the three-subset division property was proposed. Using MILP to model propagation rules, it improves some integral distinguishers at the cost of some accuracy loss. In [22], Wang et al. proposed a method to accurately model the propagation for the three-subset division property. By combining the MILP with the original breadth-first search algorithm [18], they could recover some superpolies for 832- and 839-round Trivium. However, as pointed in [8], this method is not always efficient, it requires an assumption that almost all elements in 1-subset can be pruned.

Very recently, at EUROCRYPT 2020, Hao et al. [8] proposed a new modeling method for the three-subset division property without unknown subset. They introduced a modified three-subset division property that is equivalent with the three-subset division property without unknown subset. This modified version is defined by using the multiset of the 1-subset, and it is suited to modeling with MILP or SAT/SMT solvers. By counting all feasible solutions that are enumerated, this new method can recover the superpoly efficiently. As a result, the exact expression of superpolies on 842-round Trivium/190-round Grain-128AEAD/774-round ACORN/892-round Kreyvium can be determined [7].

Our Contributions. In this paper, we propose a method to search good cubes for distinguishing attacks and key recovery attacks in the division property based cube attack. Our cube searching procedure is based on the algorithm of degree evaluation of the superpoly [20] and the algorithm of superpoly recovery [8]. In the process of cube searching, we mainly use the embedded property to narrow down the searching space. Using this method, we give some new cryptanalytic results on ACORN cipher [23].

Our cube searching procedure consists of two phases. In the first phase, we search a set of good cube testers in the conventional division property based cube attack. We first demonstrate that the embedded property [14] proposed at ASIACRYPT 2017 can also be applied to the search of cube testers. Based on the embedded property for cube tester, we propose several algorithms to search good cube testers efficiently.
Since the conventional division property based cube attack can not guarantee that the superpoly is non-constant, the key recovery attack may be degenerated to a distinguisher. In the second phase, we use the modified three-subset division property based cube attack to improve the cube testers, and to search cubes for key recovery attack. In the process of cube searching, we try to maximize the number of attacked rounds under the condition that the estimated degree of the superpoly is relatively low. Meanwhile, we keep the cube dimension as small as possible.

We apply our cube searching method to ACORN. As a result, we find some new cube testers for 775-round ACORN with a complexity of $2^{126}$. We also find a key recovery attack on 775-round ACORN with a 126-dimensional cube, whose corresponding superpoly is a 2-degree polynomial with respect to key bits. Our results for ACORN are summarized in Table 1, and the comparisons with previous attacks are also included.

Table 1. Summary of the distinguishing attacks and key recovery attacks on ACORN.

† This attack has been proved to be a constant-sum distinguisher by Hao et al. [7] using the modified three-subset division property based cube attack.

Organization. The rest of the paper is organized as follows. In Section 2 we introduce some basic definitions and theories. In Section 3, we propose several algorithms to search good cube testers and suitable cubes for key recovery attacks in the division property based cube attack. Then we use these algorithms to analyze the security of ACORN in Section 4. Section 5 concludes the paper.
2 Preliminaries

2.1 Boolean Function and Algebraic Degree

Let $\mathbb{F}_2$ denote the binary field and $\mathbb{F}_n^2$ denote the $n$-dimensional vector space over $\mathbb{F}_2$. A Boolean function $f$ is a mapping from $\mathbb{F}_n^2$ to $\mathbb{F}_2$. In general, Algebraic Normal Form (ANF) is used to represent a Boolean function. An $n$-variable Boolean function $f$ can be uniquely represented as

$$f(x_1, x_2, \cdots, x_n) = \bigoplus_{u=(u_1, \cdots, u_n) \in \mathbb{F}_n^2} a^f_u \prod_{i=1}^{n} x_i^{u_i}, \quad a^f_u \in \mathbb{F}_2,$$

where $a^f_u$ is a constant depending on $f$ and $u$. The algebraic degree of $f$ is defined as $\deg(f) = \max\{ \text{wt}(u) \mid a^f_u \neq 0 \}$, where $\text{wt}(u)$ is the Hamming weight of $u$.

2.2 Cube Attack and Cube Tester

Cube attack, proposed by Dinur and Shamir [2] at EUROCRYPT 2009, can be seen as a type of higher-order differential (integral) attacks [12]. Given a cipher $f$ with public variables $v \in \mathbb{F}_m^2$ and secret variables $x \in \mathbb{F}_n^2$, the cipher can be viewed as a polynomial $f(x, v)$. Denote a set of indices $I = \{i_1, i_2, \ldots, i_{|I|}\} \subset \{0, 1, \ldots, m-1\}$ by cube indices. Such an $I$ determines a specific structure called cube $C_I$, which contains $2^{|I|}$ values where the variables in $\{v_{i_1}, v_{i_2}, \ldots, v_{i_{|I|}}\}$ take all possible combinations of values and the remaining variables (key and non-cube IV variables) are fixed to static values. Then the sum of $f$ over all values of the cube $C_I$ is

$$\bigoplus_{C_I} f(x, v) = \bigoplus_{C_I} (t_I \cdot p(x, v) + q(x, v)) = p(x, v),$$

where $t_I = v_{i_1} \cdots v_{i_{|I|}}$, $p(x, v)$ is independent of $\{v_{i_1}, v_{i_2}, \ldots, v_{i_{|I|}}\}$, and $q(x, v)$ misses at least one variable from $\{v_{i_1}, v_{i_2}, \ldots, v_{i_{|I|}}\}$. Then, $p(x, v)$ is called the superpoly of the cube $C_I$. The cube attack consists of two phases. In offline phase, attackers select some cubes, and recover their corresponding superpolys. In online phase, attackers compute the value of the superpoly by summing the output bit $f(x, v)$ over the cube. If the expression of superpoly $p(x, v)$ is simple, then we get some simple equations from these superpolys, and we can immediately recover partial key information by solving the system of equations.

In [1] the notion of cube tester was proposed. The main idea of cube tester is similar to cube attack, however, it aims to find some superpolys which have the distinguishable properties (e.g., the superpoly is equal to a constant, which is most commonly used).

2.3 Conventional Division Property and its MILP Representation

The (conventional) division property, proposed at EUROCRYPT 2015 [15], is a generalization of the integral property for the detection of better integral
characteristics for word-oriented cryptographic primitives. Moreover, the bit-based version was proposed in [18] to describe the propagation of integral characteristics for bit-oriented ciphers. The bit-based division property is defined as follows.

**Definition 1 ((Bit-Based) Division Property [18]).** Let $X$ be a multiset whose elements take a value of $\mathbb{F}_2^n$. Let $K$ be a set whose elements take an $n$-dimensional bit vector. When the multiset $X$ has the division property $D_{\oplus}^n K$, it fulfills the following conditions:

$$
\bigoplus_{x \in X} x^u = \begin{cases} 
\text{unknown} & \text{if there exist } k \in K \text{ s.t. } u \succeq k, \\
0 & \text{otherwise},
\end{cases}
$$

where $u \succeq k$ if $u_i \geq k_i$ for all $i$, and $x^u = \prod_{i=1}^n x_i^{u_i}$.

In [15, 18], the propagation rules are provided when the bitwise operations COPY, XOR, AND are applied to the elements in $X$. To evaluate the propagation of bit-based division property, attackers determine indices $I = \{i_1, i_2, \ldots, i_l\}$ and prepare $2^{|I|}$ chosen plaintexts (IVs for stream ciphers) where variables indexed by $I$ are taking all possible combinations of values. If the division property of the corresponding ciphertexts (keystream for stream ciphers) does not contain a unit vector $e_i$ whose only $i$-th element is 1, the $i$-th bit of the $r$-round ciphertexts is balanced.

**Represent the Propagation of Division Property using MILP.** At ASIACRYPT 2016, Xiang et al. [24] first introduced a new concept division trail to describe the propagation of the division property, and showed that the basic propagation rules of the division property can be translated as some variables and constraints of an MILP model. With this method, all possible division trails can be covered with an MILP model $M$ and the division property of some output bit can be known according to the solutions of $M$.

**Definition 2 (Division Trail [24]).** Let us consider the propagation of the division property $\{k\} \stackrel{\oplus}{\rightarrow} K_0 \rightarrow K_1 \rightarrow K_2 \rightarrow \cdots \rightarrow K_r$. Moreover, for any vector $k^{*}_{i+1} \in K_{i+1}$, there must exist a vector $k^*_i \in K_i$ such that $k^*_i$ can propagate to $k^{*}_{i+1}$ by division property propagation rules. Furthermore, for $(k_0, k_1, \ldots, k_r) \in (K_0 \times K_1 \times \cdots \times K_r)$, if $k_i$ can propagate to $k_{i+1}$ for all $i \in \{0, 1, \ldots, r-1\}$, we call $(k_0 \rightarrow k_1 \rightarrow \cdots \rightarrow k_r)$ an $r$-round division trail.

Let $E_k$ be the $r$-round iterated cipher. If there is a division trail $k_0 \not\rightarrow E_k k_r = e_j (j = 1, \ldots, n)$, the summation of $j$-th bit is unknown; otherwise, if there is no division trail s.t. $k_0 \not\rightarrow E_k k_r = e_j$, we know the $j$-th bit of the ciphertext is balanced.
2.4 Division Property and Cube Attack

In cube attack, we want to recover the superpoly \( p(x, v) \). Let \( x_0, x_1, \ldots, x_{n-1} \) be all key bits. If the initialization is not enough for thorough diffusion, the superpoly may only be related to a part of key bits \( J \subseteq \{0, 1, \ldots, n-1\} \). At CRYPTO 2017, Todo et al. [16] proposed an algorithm for determining such a set \( J \) by using the bit-based division property. This algorithm is based on the following proposition.

**Proposition 1 (Key bits that are not involved in the superpoly [16]).**

Let \( f(x, v) \) be a polynomial, where \( x \) and \( v \) denote the secret and public variables, respectively. For a set of indices \( I = \{i_1, i_2, \ldots, i_{|I|}\} \subset \{0, 1, \ldots, m-1\} \), let \( C_I \) be a set of \( 2^{|I|} \) values where the variables in \( \{v_{i_1}, v_{i_2}, \ldots, v_{i_{|I|}}\} \) are taking all possible combinations of values. Let \( k_I \) be an \( m \)-dimensional bit vector such that \( v_{k_I} = t_I = v_{i_1}v_{i_2}\ldots v_{i_{|I|}} \), i.e. \( k_i = 1 \) if \( i \in I \) and \( k_i = 0 \) otherwise. Assuming there is no division trail such that \( (e_{\lambda}, k_I) \mapsto 1 \), \( x_\lambda \) is not involved in the superpoly of the cube \( C_I \).

According to this proposition, one can check that whether there is a division trail \( (e_{\lambda}, k_I) \mapsto 1 \) for \( \lambda = 0, 1, \ldots, n-1 \) via the MILP modeling method. If the division trail \( (e_{\lambda}, k_I) \mapsto 1 \) exists, then \( \lambda \in J \); otherwise, \( \lambda \notin J \). With the knowledge of \( J \), one can recover the superpoly by computing its truth table in offline phase.

Later at CRYPTO 2018, Wang et al. [20, 19] proposed some techniques to improve the division property based cube attack. The main contribution of [19] can be summarized as follows.

**Flag Technique.** In previous MILP modeling of the bitwise operations COPY, XOR, AND, each intermediate state bit \( b \) is assigned a binary value \( b.val \) to represent its bit-based division property value. In [19], Wang et al. added a ‘flag’ value for each state bit. The flag value \( b.F \) can be \( 0_c, 1_c \) or \( \delta \) to indicate whether the state bit is constant 0, constant 1 or variable. This change mainly affects the MILP model for AND. If the flag value \( b.F \) of state bit \( b \) is \( 0_c \), then we add a constraint \( b.val = 0 \), thus may improve the accuracy of MILP model description of the division property propagation. With flag technique, the new MILP model for COPY, XOR, AND are called copyf, xorf, andf. We refer to [19] for more details.

**Degree Evaluation and Term Enumeration.** To recover the superpoly more efficiently, Wang et al. [19] proposed another two algorithms to compute the algebraic degree and enumerate all possible terms of the superpoly, respectively. The two algorithms are based on the following proposition, which is actually a generalization of Proposition 1.

**Proposition 2 (Degree evaluation and term enumeration of the superpoly [19]).** Let \( f(x, v) \) be a polynomial, where \( x \) and \( v \) denote the secret and public variables, respectively. For a set of indices \( I = \{i_1, i_2, \ldots, i_{|I|}\} \subset \{0, 1, \ldots, m-1\} \), define \( C_I \) be a set of \( 2^{|I|} \) values where the variables in \( \{v_{i_1}, v_{i_2}, \ldots, v_{i_{|I|}}\} \) are taking all possible combinations of values. Let \( k_I \) be an \( m \)-dimensional bit vector such that \( v_{k_I} = t_I = v_{i_1}v_{i_2}\ldots v_{i_{|I|}} \), i.e. \( k_i = 1 \) if \( i \in I \) and \( k_i = 0 \) otherwise. Assuming there is no division trail such that \( (e_{\lambda}, k_I) \mapsto 1 \), \( x_\lambda \) is not involved in the superpoly of the cube \( C_I \).
\{0, 1, \ldots, m - 1 \}$, let $C_I$ be a set of $2^{|I|}$ values where the variables in $\{v_{i_1}, v_{i_2}, \ldots, v_{i_{|I|}}\}$ are taking all possible combinations of values. Let $k_I$ be an $m$-dimensional bit vector such that $v^{k_i} = t_I = v_{i_1}v_{i_2}\ldots v_{i_{|I|}}$. Let $F_A$ be an $n$-dimensional bit vector. Assuming there is no division trail such that $(k_A||k_I) \rightarrow \leftarrow 1$, the term $x^{k_A}$ is not involved in the superpoly of the cube $C_I$.

The complexity of the superpoly recovery can be reduced from $2^{|I|+|J|}$ to $2^{|I|} \times (1 + \sum_{l=1}^d |J_l|)$, where $I$ is the cube indices, $J$ is the involved key bits in the superpoly, $d$ is the algebraic degree of the superpoly, and $J_l$ is all possible terms of degree $t$. In the rest of this paper, we denote the algorithm of the degree evaluation of the superpoly [19] by Algorithm $\mathcal{A}$.

2.5 Three-Subset Division Property and its Propagation Rules

Although (conventional) bit-based division property can find more accurate integral distinguishers, some practically verified integral distinguishers (e.g., [21]) cannot be proved with it. To find the exact integral characteristics, Todo and Morii [18] proposed the three-subset division property.

**Definition 3 (Three-Subset Division Property [18]).** Let $X$ be a multiset whose elements take a value of $\mathbb{F}_2^d$. Let $K, L$ be the set whose elements take an $n$-dimensional bit vector. When the multiset $X$ has the three-subset division property $D^n_{K,L}$, it fulfills the following conditions:

$$
\bigoplus_{x \in X} x^u = \begin{cases} 
\text{unknown} & \text{if there are } k \in K \text{ s.t. } u \succeq k, \\
1 & \text{else if there is } l \in L \text{ s.t. } u = l, \\
0 & \text{otherwise.}
\end{cases}
$$

where $u \succeq k$ if $u_i \geq k_i$ for all $i$, and $x^u = \prod_{i=1}^n x_i^{u_i}$.

**Propagation Rules for Three-Subset Division Property.** In [18], the propagation rules of the three-subset division property for the bitwise operations COPY, AND, XOR are given.

**Rule 1 (copy).** Let $F$ be a copy function, where the input $x \in \mathbb{F}_2^n$ and the output is calculated as $(x[1], x[1], x[2], x[3], \ldots, x[n])$. Let $X$ and $Y$ be the input and output multisets, respectively. Assuming that $X$ has $D^{n+1}_{K,L}$, $Y$ has $D^{n+1}_{K',L'}$, where $K'$ and $L'$ are computed as

$$
K' \leftarrow \begin{cases} 
(0, 0, k[2], \ldots, k[n]), & \text{if } k[1] = 0, \\
(1, 0, k[2], \ldots, k[n]), (0, 1, k[2], \ldots, k[n]), & \text{if } k[1] = 1.
\end{cases}
$$

$$
L' \leftarrow \begin{cases} 
(0, 0, l[2], \ldots, l[n]), & \text{if } l[1] = 0, \\
(1, 0, l[2], \ldots, l[n]), (0, 1, l[2], \ldots, l[n]), (1, 1, l[2], \ldots, l[n]), & \text{if } l[1] = 1.
\end{cases}
$$

from all $k \in K$ and all $l \in L$, respectively. Here, $K' \leftarrow k$ (resp. $L' \leftarrow l$) denotes that $k$ (resp. $l$) is inserted into $K'$ (resp. $L'$).
Rule 2 (and). Let $F$ be a function compressed by an AND, where the input $x \in \mathbb{F}_2^n$ and the output is calculated as $(x[1] \land x[2], x[3], \ldots, x[n])$. Let $X$ and $Y$ be the input and output multisets, respectively. Assuming that $X$ has $D_{X,Y}^1$, $Y$ has $D_{Y,K}^{1+2}$, where $K'$ is computed from all $k \in \mathbb{K}$ as
\[
K' \leftarrow \left(\left\lfloor \frac{k[1] + k[2]}{2} \right\rfloor, k[3], k[4], \ldots, k[n]\right).
\]
Moreover, $L'$ is computed from all $l \in \mathbb{L}$ s.t. $(l[1], l[2]) = (0,0)$ or $(1,1)$ as
\[
L' \leftarrow \left(\left\lfloor \frac{l[1] + l[2]}{2} \right\rfloor, l[3], l[4], \ldots, l[n]\right).
\]

Rule 3 (xor). Let $F$ be a function compressed by an XOR, where the input $x \in \mathbb{F}_2^n$ and the output is calculated as $(x[1] \oplus x[2], x[3], \ldots, x[n])$. Let $X$ and $Y$ be the input and output multisets, respectively. Assuming that $X$ has $D_{X,Y}^1$, $Y$ has $D_{Y,K}^{1+2}$, where $K'$ is computed from all $k \in \mathbb{K}$ s.t. $(k[1], k[2]) = (0,0), (1,0), \text{or} (0,1)$ as
\[
K' \leftarrow \left(\left\lfloor \frac{k[1] + k[2]}{2} \right\rfloor, k[3], k[4], \ldots, k[n]\right).
\]
Moreover, $L'$ is computed from all $l \in \mathbb{L}$ s.t. $(l[1], l[2]) = (0,0), (1,0), \text{or} (0,1)$ as
\[
L' \leftarrow \left(\left\lfloor \frac{l[1] + l[2]}{2} \right\rfloor, l[3], l[4], \ldots, l[n]\right).
\]
Here, $\not\in l$ denotes that $l$ is inserted if it is not included in $L'$. If $l$ is already included in $L'$, $l$ is removed from $L'$. We call this property the cancellation property.

Another important rule is that bitvectors in $L$ influence $K$. Assuming that a state has $D_{X,Y}^1$, the secret key is XORed with the first bit in the state. Then, for all $l \in \mathbb{L}$ satisfying $l[1] = 0$, a new bitvector $(1, l[2], \ldots, l[n])$ is generated and stored into $K$. We call this property the unknown-producing property.

2.6 Three-Subset Division Property and Cube Attack

In [16], the authors assume $a^i_u = 1$ when the division property $D_{u}^{1+2}$ can propagate to $D_1^1$. When these assumptions do not hold, the superpoly can be much simpler than estimated, and in the extreme case, the superpoly becomes a constant function. Then, the key recovery attack degenerates into the distinguishing attack. In [22], the authors proposed proposition 4 to remove these assumptions by using three-subset division property. A simplified version is shown below.

Lemma 1 (Simple case of [22]). Let $f(x)$ be a polynomial from $\mathbb{F}_2^n$ to $\mathbb{F}_2$ and $a^i_u \in \mathbb{F}_2^n$ ($u \in \mathbb{F}_2^n$) be the ANF coefficients. Let $l$ be an $n$-dimensional bitvector. Then, assuming that the initial division property $D_{\phi,1}^{1+2}$ propagates to $D_{\phi,1}^1$ after evaluating the function $f$, $a^1_u = 1$.

When the function $f$ is not key-dependent, the propagation for $K$ and that for $L$ are perfectly independent. In other words, we no longer consider the propagation for $K$ because the initial division property is empty $\phi$. 

9
2.7 Three-Subset Division Property w/o Unknown Subset

In [22], Wang et al. proposed a method to accurately model the propagation for the three-subset division property. However, as pointed in [8], this method is not always efficient, it requires an assumption that almost all elements in 1-subset can be pruned. To address this problem, Hao et al. [8] proposed a new modeling method for the three-subset division property without unknown subset. They introduced a modified three-subset division property that is equivalent with the three-subset division property without unknown subset.

**Definition 4 (Modified Three-Subset Division Property [8]).** Let \(X\) be a multiset whose elements take a value of \(\mathbb{F}_2^n\). Let \(\bar{L}\) be also a multiset whose elements take a value of \(\mathbb{F}_2^n\). When the multiset \(X\) has the modified three-subset division property \(T_1^n\), it fulfills the following conditions:

\[
\bigoplus_{x \in X} x^u = \begin{cases} 
1 & \text{if there are odd-number of } u \text{'s in } \bar{L}, \\
0 & \text{otherwise.}
\end{cases}
\]

where \(x^u = \prod_{i=1}^{n} x_i^{u_i}\).

Instead of considering the cancellation property, they count the number of appearances in each bitvector in the multiset \(\bar{L}\) and check its parity. Since we do not need to consider the cancellation property, the modeling for \(\text{xor}\) is simplified as follows:

**Rule 3’ (xor).** Let \(F\) be a function compressed by an XOR, where the input \(x \in \mathbb{F}_2^n\) and the output is calculated as \((x[1] \oplus x[2], x[3], \ldots, x[n])\). Let \(X\) and \(Y\) be the input and output multisets, respectively. Assuming that \(X\) has \(T_1^{n-1}\), \(Y\) has \(T_1^{n-1}\), where \(\bar{L}'\) is computed from all \(l \in L\) s.t. \((l[1], l[2]) = (0, 0), (1, 0), \) or \((0, 1)\) as

\[
\bar{L}' \leftarrow (l[1] + l[2], l[3], l[4], \ldots, l[n]).
\]

Here, \(\bar{L}\) and \(\bar{L}'\) are multisets, and \(\bar{L}' \leftarrow l\) allows the same \(l\) is stored into \(\bar{L}'\) several times.

The modified three-subset division property implies that we do not need to consider the cancellation property in every round. We just enumerate the number of three-subset division trails \(l \xrightarrow{f} e_i\). When the number of trails is odd, the algebraic normal form of \(f\) contains \(x^l\). Otherwise, it does not contain \(x^l\).

Based on this modified three-subset division property and the new propagation rules, Hao et al. [8] proposed its MILP models and Algorithm 2 to recover the superpoly. We denote the new MILP models for COPY, XOR, AND by \(\text{copyt, xort, andt}\). We refer to [8] for more details. In the rest of this paper, we denote the algorithm of superpoly recovery [8] by Algorithm B.
3 Searching Cubes in Division Property Based Cube Attack

In this section, we propose a method to search good cubes for an iterated cipher in the division property based cube attack. Our cube searching procedure consists of two phases. In the first phase, we use conventional division property based cube attack to search a set of good cube testers. In the second phase, we use the modified three-subset division property based cube attack to improve the cube testers, and to search cubes for key recovery attack.

3.1 Phase 1: Searching Cube Testers using Conventional Division Property

For conventional bit-based division property, there is an embedded property [14] reflecting the features of its propagation. The embedded property says that, for different initial division properties \( k_0 \) and \( k_1 \) s.t. \( k_0 \succeq k_1 \), there is no need to test \( k_1 \), if the output multi-set under \( k_0 \) does not have integral property, likewise, it is not necessary to test \( k_0 \), if the output multi-set under \( k_1 \) has integral property.

In the following, we will show that, the embedded property can apply to the search of cube testers as well. We first introduce the following lemma which was proposed in [19].

Lemma 2 ([19]). If \( k \succeq k' \) and there is division trail \( k \xrightarrow{f} l \), then there is also division trail \( k' \xrightarrow{f} l' \) s.t. \( l \succeq l' \).

Based on this lemma, we propose the following proposition.

Proposition 3. Let \( f(x, v) \) be a polynomial, where \( x \) and \( v \) denote the secret and public variables, respectively. For a set of indices \( I = \{i_1, i_2, \ldots, i_{|I|}\} \subset \{0, 1, \ldots, m-1\} \), let \( k_I \) be an \( m \)-dimensional bit vector such that \( v^{k_{I}} = t_I = v_{i_1}v_{i_2}\ldots v_{i_{|I|}} \). Let \( k_{A} \) be an \( n \)-dimensional bit vector. For a given set of indices \( I_S \subseteq I \), if there is no division trail such that \( (k_{A}||k_{I_S}) \xrightarrow{f} 1 \) for any \( k_{A} \in \mathbb{F}_2^{n} \), then there is also no division trail such that \( (k_{A}||k_{I}) \xrightarrow{f} 1 \) for any \( k_{A} \in \mathbb{F}_2^{n} \).

Proof. From Lemma 2, if \( k \succeq k' \) and there is division trail \( k \xrightarrow{f} 1 \), then there is also division trail \( k' \xrightarrow{f} 1 \). Suppose there is a division trail such that \( (k'_{A}||k_{I}) \xrightarrow{f} 1 \) for a fixed \( k'_{A} \in \mathbb{F}_2^{n} \), then there is also a division trail such that \( (k'_{A}||k_{I_S}) \xrightarrow{f} 1 \) (since \( (k'_{A}||k_{I}) \succeq (k'_{A}||k_{I_S}) \)), which leads to a contradiction. \( \Box \)

Denote the superpoly of cube \( I \) by \( p_{S}(I) \). From the above Proposition and Proposition 2 in Section 2, we know that,

Proposition 4 (Embedded Property for Cube Tester). For an \( r \)-round iterated cipher, if \( I_S \) is a subset of cube \( I \), and there is no monomials in \( p_{S}(I_S) \) (i.e., \( \deg(p_{S}(I_S)) = 0 \)), then there is also no monomials in \( p_{S}(I) \) (i.e., \( \deg(p_{S}(I)) = 0 \)). Likewise, if \( \deg(p_{S}(I)) \neq 0 \), then \( \deg(p_{S}(I_S)) \neq 0 \).
Proposition 4 is useful to search cube testers efficiently in the conventional division property based cube attack.

In the following, we propose Algorithm 1, 2, and 3 to efficiently reduce the complexity of searching. Algorithm 1 is used to determine the maximum number of distinguishable rounds \( r_m \) for a given cube indices \( I \). Algorithm 1 can be seen as a subfunction of Algorithm 2. In Algorithm 2, we determine the maximum number of distinguishable rounds for a specific cipher, and restrict the search scope. In Algorithm 3, we use the output of Algorithm 2 as input, and returns a set of constant-sum cube testers.

**Algorithm 1** Determining the Maximum Number of Distinguishable Rounds for a Given Cube

```plaintext
1: procedure DetermineMaximumRoundsForCube
   (Given iterated cipher \( f \) with \( R \) initialization rounds, cube indices \( I \), return the maximum number of distinguishable rounds \( r_m \) for cube \( I \).)
2: \( r_h = R, \ r_l = 0, \ r_m = 0, \ r = 0, \ flag = 0; \)
3: while \( r_h - r_l > 1 \) do
4: \( r = \lfloor (r_h + r_l )/2 \rfloor \)
5: use Algorithm A to evaluate the degree \( d \) of the superpoly of cube \( I \) for \( f \) reduced to \( r \) rounds;
6: if \( d = 0 \) then
7: \( r_l = r, \ flag = 0; \)
8: else
9: \( r_h = r, \ flag = 1; \)
10: end if
11: end while
12: if \( flag = 0 \) then
13: \( r_m = r; \)
14: else
15: \( r_m = r - 1; \)
16: end if
17: return \( r_m; \)
18: end procedure
```

The basic idea of Algorithm 1 is binary search, which can reduce the complexity of searching. In Algorithm 1, we set two variables \( r_h \) and \( r_l \) to indicate the upper bound and lower bound of the maximum number of distinguishable rounds \( r_m \) for a specific cipher. For a cipher \( f \) with \( R \) initialization rounds, we first use Algorithm A to evaluate the degree \( d \) of the superpoly of cube \( I \) for \( f \) reduced to \( \lfloor (r_h + r_l )/2 \rfloor = \lfloor R/2 \rfloor \) rounds. If \( d = 0 \), then \( r_m \) is at least \( \lceil R/2 \rceil \), so we set \( r_l = r \). Otherwise, we set \( r_h = r \). We iteratively repeat this process, so the distance between \( r_h \) and \( r_l \) can be reduced quickly. In the end, we can determine the value of \( r_m \) with at most \( \lceil \log_2 R \rceil \) iterations.

In Algorithm 2, we first check all cubes of dimension \( m - 1 \), where \( m \) is the number of public variables. For each \((m - 1)\)-dimensional cube \( I \), we use
Algorithm 2 Determining the Maximum Number of Distinguishable Rounds & Restricting the Search Scope

1: procedure DETERMINE_MAX_ROUNDS_AND_RESTRICSCOPE (Given iterated cipher $f$ with $m$ public variables $(v_0, \ldots, v_{m-1})$, return the maximum number of distinguishable rounds $r_{\text{max}}$ of cube testers, and the index set $S$.)
2: $r_{\text{max}} = 0, \ S = \emptyset$
3: for $i = 0; i < m$ do
4: \hspace{0.5cm} let cube indices $I_i = \{0, 1, \ldots, m - 1\} \setminus \{i\}$
5: \hspace{0.5cm} use Algorithm 1 to compute the maximum number of distinguishable rounds $r_i$ for cube $I_i$, and store $(I_i, r_i)$
6: \hspace{0.5cm} if $r_{\text{max}} < r_i$ then
7: \hspace{1cm} $r_{\text{max}} = r_i$
8: \hspace{0.5cm} end if
9: end for
10: for $i = 0; i < m$ do
11: \hspace{0.5cm} if $r_i = r_{\text{max}}$ then
12: \hspace{1cm} $S = S \cup \{i\}$
13: \hspace{0.5cm} end if
14: end for
15: return $r_{\text{max}}, S$
16: end procedure

Algorithm 1 to compute its maximum number of distinguishable rounds as cube testers. Among all $m$ cubes, we select those cubes which can lead to the longest ($r_{\text{max}}$-round) cube tester, and store their missing index $i$ of public variables in $S$. We claim that the elements in the complementary set $\bar{S} = \{0, 1, \ldots, m - 1\} \setminus S$ of $S$ are ‘necessary’ bit indices to obtain an $r_{\text{max}}$-round cube tester. By Proposition 4, if any index which belongs to $S$ is not in cube indices $I$, then this cube will not lead to an $r_{\text{max}}$-round cube tester. In the following, we call $S$ the necessary set, whose elements must be in the cube indices, while $\bar{S}$ is called the sufficient set, and the elements in $S$ are called sufficient indices.

In Algorithm 3, we first test whether the cube $I = \{0, 1, \ldots, m - 1\} \setminus S$ will lead to the $r_{\text{max}}$-round cube tester. If not, we gradually increase the dimension of cubes by reducing the value of $t$ where we pick $t$ indices from $S$, and check whether the cube tester exists or not. After $t$ is fixed (Line 15 in Algorithm 3), there exists at least one cube which will lead to the $r_{\text{max}}$-round cube tester, so Algorithm 3 returns a set of constant-sum cube testers.

3.2 Phase 2: Searching Cubes using Modified Three-Subset Division Property

In phase 2, we propose Algorithm 4 to search more cubes for improved distinguishers and key recovery attack. Given $r$-round cipher $f$ with public variables $(v_0, \ldots, v_{m-1})$ and secret variables $(x_0, \ldots, x_{n-1})$. Algorithm 4 returns a set $\mathcal{D}$ containing the cubes for improved distinguishers, and a set $\mathcal{K}$ containing the cubes for key recovery attack. Moreover, the maximum number of
Algorithm 3 Searching Constant-Sum Cube Testers

1: procedure SEARCHCONSTANTSUMCUBETESTERS (Given iterated cipher $f$ with $m$
public variables $(v_0, \ldots, v_{m-1})$, the maximum number of distinguishable rounds $r_{max}$ of cube testers, and the sufficient set $S$, return a set $Res$ containing the constant-sum cube testers.)

2: $Res = \emptyset$, $flag = 0$;

3: $t = |S|$;

4: while $flag = 0$ do

5: for every $t$-tuple $(i_0, i_1, \ldots, i_{t-1})$ of $S$ do

6: let cube indices $I = \{0, 1, \ldots, m - 1\} \setminus \{i_0, i_1, \ldots, i_{t-1}\}$;

7: use Algorithm $A$ to evaluate the degree $d$ of the superpoly of cube $I$ for $f$ reduced to $r_{max}$ rounds;

8: if $d = 0$ then

9: $flag = 1$;

10: break;

11: end if

12: end for

13: $t = t - 1$;

14: end while

15: $t = t + 1$;

16: for every $t$-tuple $(i_0, i_1, \ldots, i_{t-1})$ of $S$ do

17: let cube indices $I = \{0, 1, \ldots, m - 1\} \setminus \{i_0, i_1, \ldots, i_{t-1}\}$;

18: use Algorithm $A$ to evaluate the degree $d$ of the superpoly of cube $I$ for $f$ reduced to $r_{max}$ rounds;

19: if $d = 0$ then

20: $Res = Res \cup \{I\}$;

21: end if

22: end for

23: return $Res$;

24: end procedure
0 < d < δ, so the running time for Algorithm B will not be too long. If Algorithm B returns a constant superpoly, then we obtain a new distinguisher, and we add I to set D; otherwise, we obtain a new key recovery attack if |I| ≤ m − 2, and we add I to set K.

At the beginning of Algorithm 4, we make use of the set Res containing the constant-sum cube testers, which is returned by Algorithm 3. For cube c ∈ Res, |c| represents the minimal dimension of cube where the cube will lead to r_{max}-round cube tester. Therefore, for r-round cipher f, if r ≤ r_{max}, we first test cubes of dimension |c|. As we are going to find cubes for improved distinguishers and key recovery, we will test cubes of smaller dimension after that. However, if r > r_{max}, we do not know which dimension would be enough for r-round cube tester, therefore we start with dimension m − 1.

In Algorithm 4, we still use the embedded property to restrict our search scope. The sufficient set S returned by Algorithm 2 is a set of good missing indices of cube indices. Let S′ ⊆ S, for different cubes with the same dimension, the cube indices I = {0, 1, . . . , m − 1} \ S′ is more likely to reach more rounds for distinguishing attacks. Therefore testing these cubes would be our priority.

For cubes with dimension m − t, we first test cube indices I = {0, 1, . . . , m − 1} \ {i_0, i_1, . . . , i_{t−1}} which satisfy \{i_0, i_1, . . . , i_{t−1}\} ⊆ S. For a cube I, if the estimated degree d of superpoly is less than δ, then by running Algorithm B we obtain a cube for new distinguisher or key recovery attack. However, if all cubes are turned to be distinguishers, then we need to test cubes randomly, since other cubes might still have non-constant superpolys. We introduce parameter trial and we will test cubes randomly trial times for cubes with dimension m − t. After that, we will test cubes of dimension m − t − 1. On the other hand, for cube indices I = {0, 1, . . . , m − 1} \ {i_0, i_1, . . . , i_{t−1}} which satisfy \{i_0, i_1, . . . , i_{t−1}\} ⊆ S, if the estimated degree d of superpolies of all these cubes satisfy that d ≥ δ, then we will not test cubes of dimension less than m − t, since superpolies of small cubes are more likely to have higher degrees, and we can not run Algorithm B efficiently.

It should be pointed out that, Algorithm 4 is only a general solution for searching good cubes. Sometimes, we will not run Algorithm 4 strictly. In the application to ACORN, we only test a part of all tested cubes to save time, and we will not test more cubes after we find a key recovery attack.
Algorithm 4 Searching Cubes for Improved Distinguishers and Key Recovery Attack

1: procedure SearchCubesForDistinguisherAndKeyRecovery(Given $r$-round cipher $f$ with public variables $(v_0, \ldots, v_{m-1})$ and secret variables $(x_0, \ldots, x_{n-1})$, the number of distinguishable rounds $r_{\text{max}}$, the sufficient set $S$, and the set $Res$ containing the constant-sum cube testers, return a set $D$ containing the cubes for improved distinguishers, and a set $K$ containing the cubes for key recovery attack.)

2: $D = K = \emptyset$, $flag = 1$, $\delta = 4$, $trial = 10$; ▷ the parameter $\delta, trial$ can be set to other suitable values.

3: let $|c|$ be the dimension of cube $c \in Res$;
4: let $t = m - |c|$ if $r \leq r_{\text{max}}$, and $t = 1$ otherwise;
5: while $flag = 1$ and $t \leq |S|$ do

6: flag = 0;
7: for every $t$-tuple $(i_0, i_1, \ldots, i_{t-1})$ of $S$ do
8: let cube indices $I = \{0, 1, \ldots, m - 1\} \setminus \{i_0, i_1, \ldots, i_{t-1}\}$;
9: use Algorithm A to evaluate the degree $d$ of the superpoly of cube $I$;
10: if $d < \delta$ then
11: flag = 1;
12: use Algorithm B to recover the superpoly $p(x)$ of cube $I$ if $d > 0$;
13: if $d = 0$ or $p(x) = 0$ or $p(x) = 1$ then
14: $D = D \cup \{I\}$;
15: else if $t \geq 2$ then
16: $K = K \cup \{I\}$;
17: end if
18: end if
19: end for
20: if $flag = 1$ and $K = \emptyset$ and $t \geq 2$ then
21: for $i = 0; i < trial$ do
22: randomly pick $t$-tuple $(i_0, i_1, \ldots, i_{t-1})$ of $\{0, 1, \ldots, m - 1\}$;
23: let cube indices $I = \{0, 1, \ldots, m - 1\} \setminus \{i_0, i_1, \ldots, i_{t-1}\}$;
24: use Algorithm A to evaluate the degree $d$ of the superpoly of cube $I$;
25: if $d < \delta$ then
26: use Algorithm B to recover the superpoly $p(x)$ of cube $I$ if $d > 0$;
27: if $d = 0$ or $p(x) = 0$ or $p(x) = 1$ then
28: $D = D \cup \{I\}$;
29: else
30: $K = K \cup \{I\}$;
31: break;
32: end if
33: end if
34: end for
35: end if
36: $t = t + 1$;
37: end while
38: return $D, K$;
39: end procedure
4 Applications to ACORN

In this section, we apply our cube searching methods to ACORN. As a result, we find some new cube testers of dimension 126 on 775-round ACORN. We also find a new key recovery attack on 775-round ACORN with a 126-dimensional cube, whose corresponding superpoly is a 2-degree polynomial with respect to key bits.

4.1 A Brief Description of ACORN

ACORN [23] is an authenticated encryption stream cipher, and it has been selected as one of the 6 algorithms in the final portfolio of the CAESAR competition. ACORN has a 128-bit key and a 128-bit initialization vector. As an authenticated encryption scheme, ACORN has 4 procedures: initialization, processing the associated data, encryption, and finalization. In this paper, we only focus on the process of initialization, because the number of rounds we can attack is smaller than the 1792 initialization rounds. For more details about ACORN, we refer to [23].

Denote the internal state (at step \( t \)) of ACORN by \( S_t = (s_t, s_{t+1}, \ldots, s_{t+292}) \), where \( t \in \{0, \ldots, 1791\} \). The initial state \( S_0 = (s_0, s_1, \ldots, s_{292}) \) is set to \((0, \ldots, 0)\). Denote the key and initialization vector by \( K \) and \( IV \) respectively.

\[
\begin{align*}
m_t &= \begin{cases} 
K_t & \text{for } t = 0 \text{ to } 127, \\
IV_{t-128} & \text{for } t = 128 \text{ to } 255, \\
K_0 \oplus 1 & \text{for } t = 256, \\
K_t \mod 128 & \text{for } t = 257 \text{ to } 1791.
\end{cases}
\end{align*}
\]

At each step \( t \), where \( t \in \{0, \ldots, 1791\} \), the state is updated as follows.

1. update using six LFSRs.
   \[
   \begin{align*}
   s_{t+289} &= s_{t+289} \oplus s_{t+235} \oplus s_{t+230}; \\
   s_{t+230} &= s_{t+230} \oplus s_{t+196} \oplus s_{t+193}; \\
   s_{t+193} &= s_{t+193} \oplus s_{t+160} \oplus s_{t+154}; \\
   s_{t+154} &= s_{t+154} \oplus s_{t+111} \oplus s_{t+107}; \\
   s_{t+107} &= s_{t+107} \oplus s_{t+66} \oplus s_{t+61}; \\
   s_{t+61} &= s_{t+61} \oplus s_{t+23} \oplus s_t;
   \end{align*}
   \]

2. generate the keystream bit.
   \[
   \begin{align*}
   k_{s_t} &= s_{t+12} \oplus s_{t+154} \oplus s_{t+235} \oplus s_{t+61} \oplus s_{t+235} \oplus s_{t+235} \oplus s_{t+193} \oplus s_{t+61} \oplus s_{t+193} \oplus s_{t+230} \oplus s_{t+111} \oplus s_{t+230} \oplus s_{t+66} \oplus s_{t+66};
   \end{align*}
   \]

3. generate the nonlinear feedback bit.
   \[
   f_t = s_t \oplus s_{t+107} \oplus 1 \oplus s_{t+244} \oplus s_{t+23} \oplus s_{t+244} \oplus s_{t+160} \oplus s_{t+23} \oplus s_{t+160} \oplus s_{t+196} \oplus k_{s_t};
   \]

4. update with the feedback bit \( f_t \).
   \[
   s_{t+293} = f_t \oplus m_t;
   \]
4.2 ACORN’s MILP Models for Conventional Division Property and Modified Three-Subset Division Property

It should be noticed that, there are some typing errors and inaccurate descriptions of ACORN cipher in the two MILP models given in [19] and [7]. To remove the ambiguity, we give the refined version of the two MILP models in Appendix B and Appendix C.

Our experiments are based on the two MILP models of ACORN, Algorithm A [19], and Algorithm B [7]. We use Gurobi Optimizer [5] with Python/C++ interface to solve the MILP problems.

4.3 Cube Testers of 775-round ACORN

In phase 1, we search cubes using conventional division property based cube attack. We first use Algorithm 2 to find the maximum distinguishable rounds \( r_{\text{max}} \) and the sufficient set \( S \). Our experiments show that \( r_{\text{max}} = 775 \) and \( S = \{1, 2, 11, 18, 26, 27\} \). Then we use Algorithm 3 to find constant-sum cube testers with the smallest dimension (in the conventional division property based cube attack scenario). As a result, only 6 cubes of dimension 127 can lead to the constant-sum cube tester for 775-round ACORN. The cube indices are as follows.

\[
I = \{0, 1, \ldots, 127\} \setminus \{i\}, \quad i \in \{1, 2, 11, 18, 26, 27\}
\]

In phase 2, we use Algorithm 4 to search more cubes for improved distinguishers. We set all the non-cube IV bits to constant 0 when we use Algorithm B to recover the superpoly. As a result, we find 5 cubes with dimension 126, all of which can lead to the constant-sum cube tester for 775-round ACORN. The cube indices are as follows.

\[
I = \{0, 1, \ldots, 127\} \setminus \{i, j\}, \quad \{i, j\} \in \{\{1, 2\}, \{1, 11\}, \{1, 18\}, \{2, 18\}, \{11, 18\}\}
\]

Table 2. 5 constant superpolies against 775-round ACORN.

4.4 A Key Recovery Attack of 775-round ACORN

Using Algorithm 4, we find a cube of dimension 126 which can lead to a key recovery attack for 775-round ACORN. The cube indices is as follows,

\[ I = \{0, 1, \ldots, 127\} \setminus \{1, 26\}. \]

We set all the non-cube IV bits to 0. By running Algorithm A, we know the estimated degree of the superpoly of this cube is 3. Using Algorithm B, we know the superpoly is a summation of 40 monomials as follows.

\[
p(x) = x_{96} + x_{95} + x_{92} + x_{90} + x_{75} + x_{71} + x_{70} + x_{63} + x_{62} + x_{61} + x_{59} + x_{56} + x_{55} + x_{53} + x_{51} + x_{42} + x_{41} + x_{38} + x_{37} + x_{33} + x_{32} + x_{31} + x_{29}x_{71} + x_{28} + x_{27} + x_{26} + x_{25} + x_{17}x_{29} + x_{16} + x_{14} + x_{12}x_{29} + x_{11} + x_{9} + x_{8} + x_{7} + x_{5} + x_{4} + x_{3} + x_{1} + x_{0}.
\]

Since there is a monomial \( x_0 \) that is independent of other monomials, this superpoly is a balanced Boolean function. Therefore, we can recover 1 bit secret information by summing over the cube with a complexity of \( 2^{126} \). After that, the remaining bits can be recovered by exhaustive search with \( 2^{127} \) time complexity.

5 Conclusions

In this paper, we propose a method to search good cubes for both distinguishing attacks and key recovery attacks in the division property based cube attack scenario. Our cube searching procedure combines the conventional division property and the modified three-subset division property. In the process of cube searching, we mainly use the embedded property to narrow down the searching space. As a result, we find some new cube testers of dimension 126 on 775-round ACORN. We also find a new key recovery attack on 775-round ACORN.

Acknowledgements. We would like to thank Yonglin Hao for his suggestions and helping us to run our codes on Linux servers with high performance.
