ABSTRACT
A random beacon provides a continuous public source of randomness and its applications range from public lotteries to zero-knowledge proofs. Existing random beacon protocols sacrifice either the fault tolerance or the communication complexity for security, or ease of reconfigurability. This work overcomes the challenges with the existing works through a novel communication efficient combination of state machine replication and (Publicly) Verifiable Secret Sharing (PVSS/VSS).

For a system with \( n \) nodes in the synchronous communication model and a security parameter \( \kappa \), we first design an optimally resilient Byzantine fault-tolerant state machine replication protocol with \( O(\kappa n^2) \) bits communication per consensus decision \( \text{without} \) using threshold signatures. Next, we design GRandPiper (Good Pipelined Random beacon), a random beacon protocol with bias-resistance and unpredictability, that uses PVSS and has a communication complexity of \( O(\kappa n) \) \( \text{always} \) for a static adversary. However, GRandPiper allows an adaptive adversary to predict beacon values up to \( f + 1 \) epochs into the future. Therefore, we design BRandPiper (Better RandPiper), that uses VSS and has a communication complexity of \( O(\kappa f n^2) \), where \( f \) is the actual number of faults, while offering a strong unpredictability with an advantage of only a single round even for an adaptive adversary. We also provide reconfiguration mechanisms to restore the resilience of the beacon protocols while still maintaining quadratic communication complexity per epoch. We implement BRandPiper and compare it against the state-of-the-art practically deployed beacon protocol, Drand, and show that we are always better than or equal to it in performance.

1 INTRODUCTION
Public digital randomness is essential across a large spectrum of security applications ranging from e-voting to blockchains. Its practical relevance is further evident from NIST’s Randomness Beacons project [21] and from the recent emergence of Drand Organization [25]. In addition, several other proposals [16, 20, 24, 29, 30, 43, 44, 47] and implementations [18, 28, 39] offer random beacons protocols [40].

A random beacon protocol emits a new random value at intermittent intervals such that the emitted values are bias-resistant, i.e., no entity can influence a future random beacon value, and unpredictable, i.e., no entity can predict future beacon value. Clearly, we cannot trust a single node to offer such a service — the node can easily affect both bias-resistance and unpredictability of the beacon. A series of recent works have instead relied on distributing the trust across multiple nodes such that even if a subset of nodes gets compromised, the beacon is still secure [16, 30, 44, 47].

In a system consisting of \( n \) nodes, tolerating \( t \) Byzantine faults, with security parameter \( \kappa \), an ideal distributed randomness beacon protocol, in addition to being bias-resistant and unpredictable, should have the following properties: (i) optimal resilience, (ii) low communication overhead, (iii) reconfiguration friendliness (allowing efficient addition and removal of nodes), and (iv) use efficient cryptographic schemes as opposed to computationally expensive schemes such as Proof-of-Work (PoW) or Verifiable Delay Functions (VDFs). Existing works trade one or the other of the above features expected from a random beacon. For instance, HydRand [44] sacrifices optimal resilience \( (t < n/3) \) for better communication complexity \( O(\kappa n^2) \) in the best case and \( O(\kappa n^3) \) in the worst case) with minimal setup assumptions. Cachin et al. [16] provide a protocol with communication complexity of \( O(\kappa n^2) \), but it requires
a threshold (cryptographic) setup and hence cannot support a re-
configuration of the system without changing the threshold setup
through proactive secret (re-)sharing techniques. Several other so-
lutions [24, 43] use computationally expensive mechanisms such as
VDFs\(^1\) [12] where nodes compute VDF function constantly to
ensure security of the beacon.

In this work\(^2\), we ask whether we can design an optimally re-
silient random beacon protocol that achieves good commu-
nication complexity while using efficient cryptographic schemes and
a re-usable setup, i.e., avoiding setups such as those of threshold
signatures where the entire setup needs to be re-generated when
a participating node is replaced. To answer this question, we first
design an optimally resilient Byzantine fault-tolerant (BFT) state
machine replication (SMR) protocol with \(O(\kappa n^2)\) communication
complexity per consensus decision while requiring a structured
reference string (SRS) [34] setup that allows any bounded reconfig-
uration. Next, we present two random beacon protocols GRandPiper
(Good Pipelined Random beacon) and BRandPiper (Better Pipelined
Random beacon) using our BFT SMR protocol as a building block
and provide similar guarantees. GRandPiper is communication ef-
ficient (\(O(\kappa n^2)\) in the best and worst case) but allows an adaptive
adversary to predict \(t + 1\) epochs into the future. BRandPiper offers
stronger unpredictability guarantees, but has a communication com-
plexity of \(O(f n^2)\) where \(f\) is the actual number of faults. Finally,
we present a communication efficient reconfiguration protocol to
add nodes to the system while maintaining quadratic communica-
tion complexity per round.

1.1 Efficient State Machine Replication
Without Threshold Signatures

There has been a long sequence of work in improving commu-
nication complexity of consensus protocols [1, 4, 14, 26, 33, 35, 49].
In the synchronous SMR setting, the optimal communication com-
plexity per consensus decision of an SMR protocol is \(O(\kappa n^2)\) bits [1,
3, 35, 46]. However, all of these solutions use threshold signatures.
Our first result improves upon the communication complexity in
the absence of threshold signatures. Specifically, we show the fol-
lowing:

**Theorem 1.1.** Assuming public-key infrastructure and a universal
structured reference string setup under \(q\)-SDH assumption, there exists
a state machine replication protocol with amortized \(O(\kappa n^2)\)
communication complexity per consensus decision tolerating
\(t < n/2\) Byzantine faults.

To be precise, the protocol incurs \(O(\kappa n^2)\) communication com-
plexity under \(q\)-strong Diffie-Hellman (SDH) assumption [13] (Can
be generated using distributed protocols) or \(O(\kappa n^2 \log n)\) without
it. Getting rid of threshold signatures allows for efficient reconfig-
uration of the participating nodes and does not require generating
threshold keys each time a new node joins the system. It is in this
sense that our system is reconfiguration-friendly. Thus, an efficient
BFT protocol in this setting is also of independent interest. We re-
duce communication by making use of efficient erasure coding [41]
and cryptographic accumulators [8] to efficiently broadcast large
messages at the expense of increase in latency of SMR protocol.
As we will see, the increase in latency does not affect our random
beacon protocols adversely.

1.2 RandPiper – Random Beacon Protocols

RandPiper is a suite of random beacon protocols that use our SMR
protocol as a building block. We present two protocols: GRand-
Piper (Good Pipelined Random beacon) and BRandPiper (Better Pipelined
Random beacon) which differ in unpredictability and
communication complexity. In both protocols, we use secret shar-
ing schemes to privately commit random numbers ahead of time.
This ensures bias-resistance as the random number once shared
cannot be changed. For unpredictability, we ensure that the beacon
outputs are generated using inputs from \(t + 1\) nodes (where \(t\) is the
threshold of Byzantine nodes) at least one of which is truly random,
and therefore the output is truly random.

**GRandPiper.** In GRandPiper, we explore how to build a commu-
nication optimal random beacon protocol with bias-resistance and
strong unpredictability, i.e., allowing a static adversary to predict
up to a security parameter number of epochs into the future. In
particular, we show the following:

**Theorem 1.2 (Informal).** Assuming public-key infrastructure
and a universal structured reference string setup under \(q\)-SDH as-
sumption, there exists a reconfiguration friendly, bias-resistant, and
\(O(\min(\kappa, t))\)-absolute unpredictable (see Definition 2.2) random bea-
con protocol tolerating \(t < n/2\) Byzantine faults with \(O(\kappa n^2)\)
communication per beacon output.

Our GRandPiper protocol outputs a random beacon with \(O(\kappa n^2)\) communication complexity per beacon output, where \(\kappa\) is the secu-

\(^{1}\)VDFs require computing operations such as squarings, which are energy intensive.
\(^{2}\)An adaptive adversary may also break the security of PVSS used in GRandPiper, as we
do not know of any adaptively secure PVSS.
and learning their committed secrets. At this point, continuing to use the PVSS scheme to improve the unpredictability leads to a loss of quadratic communication complexity. Hence, we look in a different direction to improve unpredictability.

**BRandPiper.** In BRandPiper, we explore how to achieve the best possible unpredictability while having the best possible communication complexity and also supporting reconfiguration. In particular, we show the following result:

**Theorem 1.3 (Informal).** Assuming public-key infrastructure and a universal structured reference string setup under q-SDH assumption, there exists a reconfiguration-friendly, bias-resistant and 1-absolute unpredictable (see Definition 2.2) adaptively secure random beacon protocol tolerating $t < n/2$ Byzantine faults with $O(\kappa f n^2)$ communication, where $f \leq t$ is the actual number of faults.

Our second protocol BRandPiper outputs a random beacon with $O(\kappa f n^2)$ communication per output, and guarantees bias-resistance and strong unpredictability against an adaptive adversary. Here, $f$ is the actual number of faults; when $f = O(1)$, the protocol enjoys $O(\kappa n^2)$ communication complexity. BRandPiper uses random inputs from $> t$ nodes in every epoch, ensuring strong unpredictability of only 1 epoch into the future.

As a building block, we first construct an improved VSS (iVSS) protocol by modifying the state-of-the-art VSS scheme eVSS [32]. Compared to eVSS, which requires $O(\kappa n + \kappa f + \kappa f n)$ information on the bulletin board (broadcast channel), iVSS posts only $O(\kappa n)$ bits of information on the bulletin board which in effect improves the amortized communication complexity of the VSS scheme to $O(\kappa f n^2)$ where $f$ is the actual number of faults. This may be of independent interest in applications requiring batch VSS.

At a high level, we use round-robin leaders and iVSS in point-to-point channels to secret share $n$ random numbers in every epoch. Since we are producing $n$ shares every epoch, we can now consume $n$ shares in every epoch. Thus, in every epoch, using the homomorphic properties of VSS secret shares, we reconstruct a homomorphic sum of $n$ shares in every epoch, thus eliminating the $t + 1$ epoch advantage held by the adaptive adversary and reducing it to just 1 epoch. We carefully design the protocol so that we have a communication complexity of $O(\kappa f n^2)$. Our key insight in BRandPiper is that a leader can efficiently secret share $n$ shares at once instead of one. These shares are buffered by all nodes, and it ensures that there are always sufficient shares available for reconstruction in the next epochs so far as leaders are chosen in a round-robin manner. The buffering helps prevent a Byzantine node from biasing by refusing to share new blocks, when the outputs are unfavorable. Without our techniques, while assuming threshold signatures, existing VSS protocols have an optimistic communication complexity of $O(\kappa n^3)$ [32] and worst case communication complexity of $O(\kappa n^4)$ to perform one secret sharing. The difference in the order arises from opening $f$ shares for every node that complains against the leader. BRandPiper shows how to perform $O(n)$ VSS with a communication complexity of $O(\kappa f n^3)$ which is quadratic when $f = O(1)$.

**1.3 Efficient Reconfiguration**

While prior works [16, 44] provide a random beacon protocol with $O(\kappa n^2)$ communication without threshold signatures and claim to be reconfiguration-friendly, they do not provide any reconfiguration mechanisms. In this work, we provide reconfiguration protocols to restore the resilience of our beacon protocol when some Byzantine nodes have been removed from the system. Since we do not rely on threshold signatures, new nodes can join the system without generating new keys for all nodes. Moreover, the reconfiguration protocol is executed while still maintaining quadratic communication complexity per round.

Clock synchronization for the new joining nodes during reconfiguration while keeping low communication overhead is challenging.

$k$ is the security parameter denoting maximum of sizes of signatures, hashes, and other components used in the protocol. Res. refers to the number of Byzantine faults tolerated in the system. Unpred. refers to the unpredictability of the random beacon, in terms of the number of future rounds an adaptive rushing adversary can predict. A rushing adversary can always obtain outputs before correct nodes, and hence, the minimum is 1. Adp. Adv refers to Adaptive Adversary whether the adversary can pick its $t$ corruptions at any point in the protocol. Reusable Setup refers to a setup that can be reused when a node is replaced in the system. $c$ probabilistically $O(\kappa n^2)$ when $O(n)$ consecutive leaders are bad. $f$ is the average (constant) size of the groups of server nodes. $\dagger$ In expectation it is 2 rounds, the probability of an adversary predicting $e$ epochs into the future is $2^{-e}$, with a security parameter $\kappa$ it is $\min(\kappa, t) + 1$ epochs. $\uparrow$ In the optimistic case, when the leader is honest and $f = O(1)$ nodes are Byzantine.
Prior protocols [1] incur $O(kn^3)$ communication without threshold signatures, and moreover, the execution cannot be split across rounds to reduce per round complexity. We introduce a new clock synchronization primitive that synchronizes new nodes when a majority of honest nodes are already synchronized while maintaining quadratic communication per round. The protocol utilizes homomorphic addition property of VSS secret shares that yields constant-sized secrets when the secret is open. The homomorphic secret can be broadcast among all nodes to synchronize all the nodes with only $O(kn^2)$ communication.

**Implementation and Evaluation.** We implement our protocol and demonstrate the practicality of our random beacon. We show that our BRandPiper protocol is as good as the state of art practically deployed system: Drand in terms of beacons per minute. Concretely, we show that choosing a $\Delta$ value for BRandPiper such that it always succeeds, we are always better than Drand if we assume a similar low $\Delta$ value for Drand. Giving a benefit of doubt to Drand, by choosing slightly relaxed value of 99.9th percentile value of $\Delta$, we show that our protocol is still as practical as Drand.

**Summary of contributions.** To summarize, we make the following contributions in this work:

1. In Section 3, we present a communication efficient BFT SMR protocol with quadratic communication per consensus decision.
2. We then present two random beacon protocols. Section 4.1 presents GRandPiper, a simple beacon protocol using PVSS with $O(kn^2)$ communication. We then present BRandPiper, a protocol with better unpredictability in Section 4.2.
3. In Section 5, we evaluate our BRandPiper protocol.
4. We present mechanisms for synchronizing a new node in Appendix C and reconfiguration in Appendix D.

**Related Work.** We present detailed related works in Appendix A.

**Limitations.** Our protocol depends on the synchrony assumption, i.e., messages sent between any two honest nodes in the system are always delivered within a public value $\Delta$.

## 2 MODEL AND DEFINITIONS

We consider a system $\mathcal{P} := \{p_1, \ldots, p_n\}$ consisting of $n$ nodes out of which at most $t = \lfloor n - 1/2 \rfloor$ nodes can be Byzantine which we term as a $t$-bounded adversary. The Byzantine nodes may behave arbitrarily. When we assume an adaptive adversary $\mathcal{A}$, the nodes can be corrupted to behave arbitrarily at any time during execution. When we assume a static adversary $\mathcal{A}$, the nodes to be corrupted must be chosen by the adversary before the start of the protocol execution. We also use the term $t$-bounded adversary. A node that is not faulty throughout the execution is considered to be honest and executes the protocol as specified.

We assume the network between nodes consists of point-to-point secure (authenticated and confidential) synchronous communication channels. Messages between nodes may take at most $\Delta$ time before they arrive, where $\Delta$ is a known maximum network delay. To provide safety under adversarial conditions, we assume that the adversary is capable of delaying the message for an arbitrary time upper bounded by $\Delta$. In addition, we assume all honest nodes have clocks moving at the same speed. They also start executing the protocol within $\Delta$ time from each other. This can be easily achieved by using the clock synchronization protocol [1] once at the beginning of the protocol.

We make use of digital signatures and a public-key infrastructure (PKI) to prevent spoofing and replays and to validate messages. Message $x$ sent by a node $p$ is digitally signed by $p$’s private key and is denoted by $\langle x \rangle_p$. In addition, we use $H(x)$ to denote the invocation of the random oracle $H$ on input $x$.

### 2.1 Definitions

We consider a state machine replication protocol defined as follows:

**Definition 2.1** (Byzantine Fault-tolerant State Machine Replication [45]). A Byzantine fault-tolerant state machine replication protocol commits client requests as a linearizable log to provide a consistent view of the log akin to a single non-faulty server, providing the following two guarantees: (i) Safety. Honest nodes do not commit different values at the same log position. (ii) Liveness. Each client request is eventually committed by all honest nodes.

We define $d$-absolute unpredictability as follows:

**Definition 2.2** ($d$-absolute unpredictability). Consider an epoch based protocol. Let the fastest honest node be at epoch $e$. The protocol is said to be unpredictable with absolute bound $d$ for $d \geq 1$, if the probability of an adversary $\mathcal{A}$ predicting the honest output for any epoch $e' \geq e + d$ is $\text{neg}(\cdot)$.

We define the security requirements for a random beacon protocol $\mathcal{RB}$ as follows:

**Definition 2.3** (Secure random beacon protocol). An epoch based protocol $\mathcal{RB}$ is said to be a $d$-secure random beacon protocol if it satisfies the following conditions:

1. **Bias-resistance.** Let $O$ be the output of the beacon for some epoch $e$. No adversary $\mathcal{A}$ can bias $O$ with probability greater than $\text{neg}(c) + \text{neg}(\cdot)$.

2. **Unpredictability.** The protocol is $d$-absolute unpredictable.

3. **Guaranteed Output Delivery.** For every epoch $e \geq 1$, the protocol outputs a value.

### 2.2 Primitives

In this section, we present several primitives used in our protocols.

**Linear erasure and error correcting codes.** We use standard $(t + 1, n)$ Reed-Solomon (RS) codes [41]. This code encodes $t + 1$ data symbols into code words of $n$ symbols and can decode the $t + 1$ elements of code words to recover the original data.

- **ENC.** Given inputs $m_1, \ldots, m_{t+1}$, an encoding function $\text{ENC}(s_1, \ldots, s_n) = \text{ENC}(m_1, \ldots, m_{t+1})$, where $(s_1, \ldots, s_n)$ are code words of length $n$. A combination of any $t + 1$ elements of $n$ code words uniquely determines the input message and the remaining of the code word.

- **DEC.** $\text{DEC}(m_1, \ldots, m_{t+1}) = \text{DEC}(s_1, \ldots, s_n)$, and is capable of tolerating up to $c$ errors and $d$ erasures in code words $(s_1, \ldots, s_n)$, if and only if $t \geq 2c + d$.

**Cryptographic accumulators.** A cryptographic accumulator scheme constructs an accumulation value for a set of values and produces a witness for each value in the set. Given the accumulation value and a witness, any node can verify if a value is indeed in the
set. Formally, given a parameter $k$, and a set $D$ of $n$ values $d_1, \ldots, d_n$, an accumulator has the following components:

- $\text{Gen}(k, n)$: This algorithm takes a parameter $k$ represented in unary form $1^k$ and an accumulation threshold $n$ (an upper bound on the number of values that can be accumulated securely), returns an accumulator key $a_k$. The accumulator key $a_k$ is part of the $q$-SDH setup and therefore is public to all nodes.
- $\text{Eval}(a_k, D)$: This algorithm takes an accumulator key $a_k$ and a set $D$ of values to be accumulated, returns an accumulation value $z$ for the value set $D$.
- $\text{CreateWit}(a_k, z, d_i, D)$: This algorithm takes an accumulator key $a_k$, an accumulation value $z$ for $D$ and a value $d_i$, returns $\perp$ if $d_i \in D$, and a witness $\psi_{ij}$ if $d_i \in D$.
- $\text{Verify}(a_k, z, \psi_{ij}, d_i)$: This algorithm takes an accumulator key $a_k$, an accumulation value $z$ for $D$, a witness $\psi_{ij}$ and a value $d_i$, returns true if $\psi_{ij}$ is the witness for $d_i \in D$, and false otherwise.

In this paper, we use collision free bilinear accumulators from [37] as cryptographic accumulators.

**Verifiable Secret Sharing and Commitments.** We assume the existence of a secure Verifiable secret sharing scheme VSS with commitments, satisfying the security properties in Definition 2.4. We use the interfaces to a secure VSS scheme VSS as described in Table 2 (Appendix B).

**Definition 2.4 (VSS Security [6]).** A VSS protocol consists of two phases: sharing and reconstruction. We call an $n$-node VSS protocol, with $t$-bounded adversary $\mathcal{A}$ and security parameter $\kappa$, an $(n-t)$-VSS protocol if it satisfies the following conditions:

1. **Secrecy.** If the dealer $L$ is honest, then the probability of $\mathcal{A}$ learning any information about the dealer’s secret $s$ in the sharing phase is $\text{negl}(\kappa)$.

2. **Correctness.** If $L$ is honest, then the honest nodes output the secret $s$ at the end of the reconstruction phase with a high probability of $1 - \text{negl}(\kappa)$.

3. **Commitment.** If $L$ is Byzantine, then at the end of the sharing phase there exists a value $s^*$ in the input space including $\perp$, such that at the end of the reconstruction phase all honest nodes output $s^*$ with high probability $1 - \text{negl}(\kappa)$.

In our work, we implicitly assume that the VSS scheme used is $(n/2 + 1)$-secure.

**Publicly Verifiable Secret Sharing — PVSS.** PVSS schemes consist of communication such as broadcasts, posts on the bulletin board, as well as computational components such as share generation, encryption, etc. We separate the two components and present interfaces to computational algorithms that we will use in our protocols. We use the interfaces to a secure PVSS scheme PVSS as described in Table 3 (Appendix B).

We assume the existence of a secure PVSS algorithm PVSS as defined in Definition 2.5.

**Definition 2.5 (PVSS Security [6, 17]).** Let $L \in \mathcal{P}$ be the dealer with secret $s$ and $k$ be the security parameter. A PVSS scheme PVSS is a secure VSS scheme (see Definition 2.4) and must provide the following guarantees:

4. **Public Verifiability.** If the check in share verification algorithm (PVSS.ShVerf, see Table 3) returns 1, i.e., succeeds, then with high probability $1 - \text{negl}(\kappa)$, the encryptions are valid shares of some secret.

**Normalizing the length of cryptographic building blocks.** Let $\lambda$ denote the security parameter, $\kappa_d = \kappa_d(\lambda)$ denote the hash size, $\kappa_a = \kappa_a(\lambda)$ denote the size of the accumulation value and witness of the accumulator and $\kappa_s = \kappa_s(\lambda)$ denote the size of secret share along with the associated proofs (both for PVSS and VSS). Further, let $\kappa = \max(\kappa_h, \kappa_a, \kappa_s)$; we assume $\kappa = \Theta(\kappa_d) = \Theta(\kappa_a) = \Theta(\kappa_s)$. Throughout the paper, we will use the same parameter $\kappa$ to denote the hash size, signature size, accumulator size and secret share size for convenience.

**3 BFT SMR Protocol**

In this section, we present a simple BFT SMR protocol as a basic building block for the random beacon protocols discussed in following sections. Our SMR protocol achieves $O(\kappa n^2)$ bits communication complexity with a universal structured reference string (SRS) setup under the $q$-SDH assumption, or $O(\kappa n^2 \log n)$ bits communication complexity without the $q$-SDH setup assumption. In particular, we do not use threshold signatures, and thus avoid any distributed key generation during the setup or proactive secret sharing during reconfiguration. We note that prior synchronous BFT SMR protocols [3, 19, 46] with honest majority incur $O(\kappa n^3)$ communication per consensus decision without threshold signatures.

**Epochs.** Our protocol progresses through a series of numbered epochs with each epoch coordinated by a distinct leader. Epochs are numbered by integers starting with one. Each epoch lasts for $11\Delta$ time. The leaders for each epoch are rotated irrespective of the progress made in each epoch. For simplicity, we use round-robin leader election in this section and the leader of epoch $e$, represented as $L_e$, is determined by $e \bmod n$. Later in the beacon protocols, we introduce different leader election rules.

**Blocks and block format.** An epoch leader’s proposal is represented as a block. Each block references its predecessor except for the genesis block which has no predecessor. We call a block’s position in the chain as its height. A block $B_h$ at height $h$ has the format, $B_h := (b_h, H(B_{h-1}))$ where $b_h$ denotes the proposed payload at height $h$, $B_{h-1}$ is the block at height $h - 1$ and $H(B_{h-1})$ is the hash digest of $B_{h-1}$. The predecessor for the genesis block is $\perp$. A block $B_h$ is said to be valid if (1) its predecessor block is valid, or if $h = 1$, predecessor is $\perp$, and (2) the payload in the block meets the application-level validity conditions. A block $B_h$ extends a block $B_j$ ($h \geq j$) if $B_j$ is an ancestor of $B_h$. Note that a block’s height $h$ and its epoch $e$ need not necessarily be the same.

**Certified blocks, and locked blocks.** A block certificate on a block $B_h$ consists of $t + 1$ distinct signatures in an epoch $e$ and is represented by $C_e(B_h)$. Block certificates are ranked by epochs, i.e., blocks certified in a higher epoch has a higher rank. During the protocol execution, each node keeps track of all certified blocks and keeps updating the highest ranked certified block to its knowledge. Nodes will lock on highest ranked certified blocks and do not vote for blocks that do not extend the locked blocks to ensure safety of a commit.

**Equivocation.** Two or more messages of the same type but with different payload sent by an epoch leader are considered an equivocation. In this protocol, the leader of an epoch $e$ sends propose
We first describe a simple function that is used by an honest node to forward a long message received from the epoch leader.

**Deliver function.** The Deliver() function (refer Figure 2) implements efficient broadcast of long messages using erasure coding techniques and cryptographic accumulators. The input parameters to the function are message type mtype, long message b, accumulation value z_e corresponding to object b and epoch e in which the Deliver function is invoked. The input message type mtype corresponds to message type containing large message b sent by leader L_e of epoch e. In order to facilitate efficient leader equivocation checks, the input message type mtype, hash of object b, accumulation value z_e and epoch e are signed by leader L_e.

When the function is invoked using the above input parameters, the message b is partitioned into t + 1 data symbols. The t + 1 data symbols are then encoded into n code words (s_1, ..., s_n) using ENC function (defined in Section 2). Then, the cryptographic witness w_j is computed for each code words (s_1, ..., s_n) using CreateWit (defined in Section 2). Then, the code word and witness pair (s_j, w_j) is sent to the node p_j ∈ P along with the accumulation value z_e, message type mtype, and L_e’s signature on the message.

When a node p_j receives the first valid code word s_j for an accumulation value z_e such that the witness w_j verifies the code word s_j (using Verify function defined in Section 2), it forwards the code word and witness pair (s_j, w_j) to all nodes. Note that node p_j forwards only the first code word and witness pair (s_j, w_j). Thus, it is required that all honest nodes forward the code word and witness pair (s_j, w_j) for long message b; otherwise all honest nodes may not receive t + 1 code words for b. When a node p_j receives t + 1 valid code words corresponding to the first accumulation value z_e, it receives, it reconstructs the object b. Note that node p_j reconstructs object b for the first valid share even though it detects equivocation in an epoch.

The Deliver function contains two communication steps and hence requires 2Δ time to ensure all honest nodes can receive at least t + 1 code words sufficient to reconstruct the original input b. Invoking Deliver on a long message of size t incurs O(n(t + (κ + w)n^2)) bits where κ is the size of accumulator and w is the size of the accumulator witness. The witness size is O(κ) and O(κ log n) when bilinear accumulators and Merkle trees are respectively used as witnesses. Thus, the total communication complexity to broadcast a single message of size t is O(n(t + κn^2)) bits, or O(n(t + κn^2 log n) bits without the q-SDH assumption.

**BFT SMR Protocol.** Our BFT SMR protocol is described in Figure 1. Consider an epoch e and its epoch leader L_e. To ensure an honest leader can always make progress, leader L_e first collects the highest ranked certificate C_{e'}(B_{e'}) from all honest nodes. In each epoch, at a high level, there are two “rounds” of communication from the epoch leader. The first round involves leader making a proposal and the second round involves sending certificates to aid in committing the proposal.

**Efficient propagation of proposal.** In the first round, the leader proposes a block B_h to every node (step 2) by extending the highest ranked certificate C_{e'}(B_{e'}). The proposal for B_h, conceptually, has the form (propose, B_h, C_{e'}(B_{e'}), z_{pe}, e)_{L_e} where z_{pe} is the accumulation value for the pair (B_h, C_{e'}(B_{e'})). In order to facilitate efficient equivocation checks, the leader signs the following tuple (propose, H(B_h, C_{e'}(B_{e'})), z_{pe}, e) and sends B_h and C_{e'}(B_{e'}) separately. The size of this signed message is O(κ) bits. In case of equivocation, all-to-all broadcast of this signed message incur only O(κn^2) in communication.

If the received proposal is valid and it extends the highest ranked certificate known to a node p_i, node p_i forwards the proposal. Forwards the received proposal is required to ensure all honest nodes receive a common proposal; otherwise only a subset of the nodes may receive the proposal if the leader is Byzantine. Observe that the size of the proposal is linear as it contains certificate C_{e'}(B_{e'}) (which is linear in the absence of threshold signatures). A naïve approach of forwarding the entire proposal incurs O(κn^2) when all nodes broadcast their proposal. In order to save communication, nodes forward the proposal by invoking Deliver function. For linear sized proposal, invoking Deliver incurs O(κn^2) bits (or O(κn^2 log n) bits under q-SDH assumption) in communication.

Observe that the Deliver primitive requires 2Δ time. In particular, we need to ensure all honest nodes forward their code word and witness pair for the proposal. Thus, our protocol waits for 2Δ time (i.e., vote-timer_e) before voting to check for equivocation. Hence, if no equivocation is detected at the end of 2Δ wait, all honest nodes forwarded their code word and witness pair for the proposal and all honest nodes can reconstruct the proposal. At the end of 2Δ wait, if there is no equivocation detected, nodes vote for the proposed block B_h (step 3).

**Ensuring the receipt of a certificate efficiently.** Observe that a vote message is O(κ) sized and hence, it can be broadcast using all-to-all communication with communication complexity of O(κn^2). However, if every node that commits needs to ensure that all honest nodes receive a certificate for the block being committed, this can result in O(κn^2) complexity again. This is because, all-to-all broadcast of linear sized certificate incurs O(κn^2). One might try to invoke Deliver to propagate the certificate. However, this does not save communication. This is because, in general, there can be exponentially many combinations of t + 1 signatures forming a certificate depending on the set of signers, and each node may invoke Deliver on a different combination.

This issue can be addressed if we ensure that there is a single certificate for a block. Hence, we use the leader to collect signatures and form a single certificate (step 3). The leader forwards this certificate via (vote-cert, C_{e'}(B_{e'}), z_{pe}, e)_{L_e} to all nodes (step 4) where z_{pe} is the accumulation value of C_{e'}(B_{e'}). Similar to the proposal, the hash of the certificate is signed to allow for efficient equivocation checks. It is important to note that two different certificates for the same value is still considered an equivocation in this step.

To ensure that every honest node receives this certificate, we again resort to the Deliver primitive which yields a communication complexity of O(κn^2) when all honest nodes are invoking it using the same certificate. Again, to tolerate malicious behaviors such
Let $e$ be the current epoch and $L_e$ be the leader of epoch $e$. For each epoch $e$, node $p_j$ performs the following operations:

1. **Epoch advancement.** When epoch-timer$_{e-1}$ reaches 0, enter epoch $e$. Upon entering epoch $e$, send the highest ranked certificate $C_{e'}(B_j)$ to $L_e$. Set epoch-timer$_e$ to 11Δ and start counting down.

2. **Propose.** $L_e$ waits for 2Δ time after entering epoch $e$ and broadcasts $(\text{propos}, B_h, C_{e'}(B_j), z_{pe}, e) \!\!_L_e$ where $B_h$ extends $B_j$. $C_{e'}(B_j)$ is the highest ranked certificate known to $L_e$.

3. **Vote.** If epoch-timer$_e \geq 7Δ$ and node $p_j$ receives the first proposal $p_e = (\text{propos}, B_h, C_{e'}(B_j), z_{pe}, e) \!\!_J_e$ where $B_h$ extends a highest ranked certificate, invoke Deliver$(\text{propos}, p_e, z_{pe}, e)$. Set vote-timer$_e$ to 2Δ and start counting down. When vote-timer$_e$ reaches 0, send $(\text{vote}, H(B_h), e) \!\!_J_e$ to $L_e$.

4. **Vote cert.** Upon receiving $t + 1$ votes for $B_{h1}$, $L_e$ broadcasts $(\text{vote-cert}, C_{e'}(B_{h1}), z_{de}, e) \!\!_L_e$.

5. **Commit.** If epoch-timer$_e \geq 3Δ$ and node $p_j$ receives the first vote $v_e = (\text{vote-cert}, C_{e'}(B_{h1}), z_{de}, e) \!\!_J_e$, invoke Deliver$(\text{vote-cert}, v_e, z_{de}, e)$. Set commit-timer$_e$ to 2Δ and start counting down. When commit-timer$_e$ reaches 0, if no equivocation for epoch-$e$ has been detected, commit $B_{h1}$ and all its ancestors.

6. **(Non-blocking) Equivocation.** Broadcast equivocating hashes signed by $L_e$ and stop performing epoch-$e$ operations.

### Figure 1: BFT SMR Protocol with $O(kn^2)$ bits communication per epoch and optimal resilience

**Deliver$(\text{mtype}, b, z_{e}, e)$:**

1. Partition input $b$ into $t + 1$ data symbols. Encode the $t + 1$ data symbols into $n$ code words $(s_1, \ldots, s_n)$ using ENC function. Compute witness $w_j \forall j \in (s_1, \ldots, s_n)$ using CreateWit function. Send $(\text{codeword}, \text{mtype}, s_j, w_j, z_e, r_j)$ to node $j$ where $j \in [n]$.

2. If node $p_j$ receives the first valid code word $(\text{codeword}, \text{mtype}, s_j, w_j, z_e, e)$, for the accumulator $z_e$, forward the code word to all the nodes.

3. Upon receiving $t + 1$ valid code words for the accumulator $z_e$, decode $b$ using DEC function.

**Figure 2: Deliver function**

as sending multiple different certificates for the same block (due to which none of them may be delivered), we treat the vote-cert message similar to the proposal and perform equivocation checks. Thus, nodes commit only if they observe no equivocation $2\Delta$ time after they invoke Deliver (step 5).

**Epoch timers.** Observe that we set the epoch timer epoch-timer$_e$ for each epoch $e$ to be $11\Delta$. This is the maximum time required for an epoch when the leader is honest and all messages take $\Delta$ time. Similarly, in different steps, we make appropriate checks w.r.t. epoch-timer$_e$ to ensure that the protocol is making sufficient progress within the epoch.

**Latency.** We note that all honest nodes commit in the same epoch when the epoch leader is honest. However, when the epoch leader is Byzantine, only some honest nodes may commit in that epoch. Due to the round-robin leader selection, there will be at least one honest leader every $t + 1$ epochs and all honest nodes commit common blocks up to the honest epoch. Thus, our protocol has a worst-case commit latency of $t + 1$ epochs.

Due to space constraints, we present complete proofs in Appendix B.1.

## 4 RANDOM BEACON PROTOCOLS

In this section, we present two random beacon protocols while tolerating $f < t < n/2$ Byzantine faults. The first protocol GRandPiper outputs a random beacon with $O(kn^2)$ communication complexity always, per beacon output, where $k$ is the security parameter, guarantees bias-resistance, and $O(\min(k, t))$-absolute unpredictability against a static adversary, but $t + 1$-absolute unpredictability against an adaptive adversary. The second protocol BRandPiper outputs a random beacon with $O(kf n^2)$ communication complexity per output after amortization where $f$ is the security parameter, and guarantees bias-resistance and 1-absolute unpredictability. When the actual number of faults $f = O(1)$, the communication complexity is quadratic.

A key aspect of both of our protocols is their reconfiguration-friendliness. A protocol is said to be reconfiguration-friendly if it changes reconfiguring parameters such as the scheme and nodes, without stopping the old instance, and starting a new one. Such reconfiguration is possible if the setup used for the protocol does not bind to the system, as such a binding will force a new setup to change any parameter in the system. This is true, for instance, when using threshold signatures in a protocol which is used by many existing permissioned systems [7, 14, 15, 27]. Neither of our protocols use setups for threshold signatures, but a setup based on the $q$-SDH assumption. This allows for easy reconfiguration.\(^4\)

### 4.1 RandPiper – GRandPiper Protocol

![Figure 3: Overview of RandPiper – GRandPiper. In each even, a PVSS sharing of some random value is secret shared. At the same time, a reconstruction protocol is used to reconstruct the random value committed by the leader of this epoch, the last time it was a leader. $O_e$ is generated using the random value $\mathcal{R}_e$, shared in epoch $e$, reconstructed in epoch $e' > e + t$, and outputs $(O_{e'-1}, \ldots, O_{e'-1})$ from previous epochs by using them as inputs to the random oracle $H$.](image)

\(^4\)We can use Merkle trees instead of $q$-SDH at the expense of $O(\log n)$ multiplicative communication complexity.
We use the SMR protocol (refer Figure 1) described in Section 3 as a building block. At a high-level, consider using the SMR protocol such that the leader outputs a number chosen uniformly at random in each epoch. The random beacon output can be a function of the outputs of the last \( t + 1 \) epochs, allowing for the presence of at least one honest input (chosen uniformly at random) which is potentially sufficient to obtain a random output. This argument holds only if each leader chooses their input in the SMR protocol independently of other inputs. Otherwise, if a Byzantine leader can choose an input after knowing the outputs of the previous \( t \) instances then it can bias the output. A separate concern with using the SMR protocol as is, is that in an epoch with a Byzantine leader, honest nodes may not all output the same value or output at all.

To fix both of these concerns, we require each node to send a commitment of a random value more than \( t \) epochs before it will be reconstructed and used in the beacon protocol. To ensure the secrecy of this value (for unpredictability and bias-resistance), the values are shared with the nodes using a publicly verifiable secret sharing (PVSS) scheme (refer to Appendix B for detailed PVSS interface). Committing a secretly chosen value ahead of time helps us solve both of our previous concerns. First, if the same leader is not chosen twice in any span of \( t + 1 \) epochs, it ensures that the \( t + 1 \) values that will be used to construct the beacon protocol are chosen independently of one another. Thus, when nodes reconstruct a value in an epoch, it corresponds to a value committed more than \( t \) epochs before. Moreover, the nodes can reconstruct this value independent of the participation of the leader in this epoch. Second, waiting for \( t + 1 \) epochs before opening allows for the value to be committed by the SMR protocol. Thus, all honest nodes will open the same value in an epoch.

A graphical description of this approach is presented in Figure 3. In epoch \( e \), a leader \( L_e \) inputs PVSS shares corresponding to a random value \( R_e \) to the SMR protocol. Conceptually, when the block is committed, this value is added to a queue \( Q(L_e) \) corresponding to this leader. When the same node is chosen the next time as a leader, say in epoch \( e' \), the committed shares of \( R_e \) is dequeued and reconstructed by all honest nodes to obtain \( R_e \). The output \( O_e \) of epoch \( e' \) can be computed as \( H(R_e, O_{e-1}, \ldots, O_{e-t}) \). To allow for unpredictability in leader selection while disallowing repetition within \( t + 1 \) epochs, the leader for the next epoch \( e' + 1 \) is chosen based on \( O_e \) and by removing the leaders \( L_{e'}, \ldots, L_{e-t} \).

A remaining concern is when no values are added to the chain at epoch \( e \). Observe that the reconstruction in epoch \( e \) is not affected, since nodes reconstruct values previously committed. However, nodes may not have shares in epoch \( e' > e + t \) where \( e' \) is the first epoch where \( L_e \) is chosen as the leader again. To fix this concern, we ensure that such a malicious leader who does not commit in epoch \( e \) can be removed by all nodes by \( e + t < e' \). Subsequently, we can ensure that \( L_e \) is never chosen as the leader again. To allow for reconstruction the first time a node is chosen as the leader, we ensure a setup where each node has an agreed upon share buffered for every other node.

### 4.1.1 Protocol details

We now explain the protocol in detail (described in Figure 4). We use a Publicly Verifiable Secret Sharing (PVSS) scheme PVSS with threshold \( t \) to generate encrypted shares and an associated proof that guarantees that any \( > t \) nodes will reconstruct a unique secret.

**Setup.** We establish PVSS parameters \( PVSS.pp \), and public keys \( PVSS.pk_i \) for every node \( p_i \in P \). We also buffer shares for one random value for every node \( p_i \), i.e., fill \( Q(p_i) \) for \( p_i \in P \). We start with epoch \( e = 1 \) and use seed random values for \( R_e \) and \( \{O_e-1, \ldots, O_e-1\} \). We also assign \( L_{Last} \leftarrow \{p_n, \ldots, p_{n-t}\} \) and set \( \mathcal{P}_f \leftarrow 0 \) arbitrarily.

**Leader selection.** The leader for epoch \( e \) is chosen based on the following rule:

**Definition 4.1** (Leader selection rule). Let \( e \) be the current epoch, \( L_{Last} := \{L_e-1, \ldots, L_e-1\} \) be the leaders of the last \( t \) epochs, \( \mathcal{P}_r \) be the set of nodes that are removed (due to misbehavior), and \( L_e = (P \setminus L_{Last}) \setminus \mathcal{P}_r := \{l_0, \ldots, l_{w-1}\} \), be a set of candidate leaders for epoch \( e \) ordered canonically, with \( 0 < w < n - t \) and \( L_e \subseteq P \). Then the leader \( L_e \) of epoch \( e \), is derived from output \( O_{e-1} \), as

\[
L_e \leftarrow L_{e-1} \mod w
\]

**Blocks.** The leader of an epoch chooses \( R \) uniformly at random from the input space of the PVSS algorithm (which could be a cyclic additive/multiplicative group, or pairing groups). The leader uses the PVSS.ShGen algorithm to generate share PVSS.si for node \( p_i \) which are encrypted using PVSS.pk, and all shares for the nodes are stored in PVSS.\( \bar{E} \). The PVSS.ShGen algorithm also outputs the proof PVSS.\( \pi \) that any \( > t \) shares will reconstruct a unique secret, which implies that the degree of the polynomial cannot be more than \( t \). Finally, the block in our SMR protocol consists of the outputs of the PVSS.ShGen algorithm, i.e., \( b_i := (PVSS.\bar{E}, PVSS.\pi) \rightarrow PVSS.ShGen(R_i) \). An honest node acknowledges \( b_i \) if \( b_i \) meets the validity condition PVSS.ShVrfy algorithm. Note that despite the blocks being \( O(\kappa n) \) sized, due to our usage of Deliver primitive, we retain a communication complexity of \( O(\kappa n^2) \) per epoch.

**Commit, reconstruct, and output beacon value.** In each epoch, nodes commit the shares sent by the leader. They also reconstruct the last sharing sent by the leader at the start of the epoch. Note that each node can separately maintain the last time a node was elected as the leader, and thus, be able to appropriately invoke Dequeue(\( Q(L_e) \)). Moreover, since a leader does not repeat in any consecutive \( t + 1 \) epochs, and we ensure that the set of leaders are consistently known to all honest nodes (as will be shown in the next subsection), the value being reconstructed is agreed upon by all the honest nodes. When the nodes reconstruct \( R_e \), they already have access to \( \{O_{e-1}, \ldots, O_1\} \). Hence, they can compute a consistent output \( O_e \). Observe that since all nodes enter epoch \( e \) within a delay of \( \Delta \), they also output the beacon value within \( \Delta \) time of each other.

**Remove misbehaving leaders.** Finally, at the end of an epoch \( e \), if no block was committed in epoch \( e - t \) by \( L_{e-1} \), \( L_{e-1} \) is removed from all future proposals. Since this operation is performed after \( t + 1 \) epochs, all nodes will perform this action consistently.

Due to space constraints, we analyze security in Appendix B.2.

### 4.2 RandPiper – BRandPiper Protocol

In this section, we present a random beacon protocol using \( O(\kappa n^2) \) bits of communication complexity where \( f \leq t \) is the actual number of faults and with \( 1 \)-absolute unpredictability. Thus, in the optimistic
case when \( f = O(1) \), our communication complexity is quadratic.
In order to achieve 1-absolute unpredictability, we need to ensure that we reconstruct inputs from \( > t \) nodes in every epoch. If we use PVSS schemes, we need to add \( O(t) \) shares in every epoch, so that we can consume \( > t \) combined shares in every round. A PVSS sharing for one secret is of size \( O(n) \), and therefore performing \( O(nt) \) sharings trivially results in a communication complexity of \( O(n^2) \). Therefore, we will use VSS schemes (refer to Appendix B for detailed VSS interface) in an attempt to improve the communication complexity for a 1-absolute unpredictable random beacon protocol.

4.2.1 Improved VSS. We will first describe an improved VSS (iVSS) scheme that achieves better communication complexity to share \( n \) secrets in the optimistic case which will then be used in our random beacon protocol.

Efficient VSS (eVSS).  eVSS [32] (refer Figure 5) presents the state-of-the-art VSS scheme for synchronous network setting. The protocol is described assuming the presence of a bulletin board (or broadcast channels) [6, 17, 20, 32] where there exists a public bulletin board, in which messages posted by any node are available instantly, and the bulletin board provides a consistent view to all the nodes. We can realize such message delivery guarantees by invoking Byzantine Broadcast (BB) protocols.

In this protocol, a dealer \( L \) creates a commitment VSS.C to a random polynomial whose constant term is the secret, and posts the commitment on the bulletin board (Step 1), while \textit{privately} sending individual shares VSS.sj along with witnesses VSS.pi to every node \( p_j \in \mathcal{P} \) (Step 2). Nodes post complaints on the bulletin board in the form of blame message if they do not receive valid shares (Step 3) in a timely manner. The dealer then opens the secret shares on the bulletin board corresponding to the blamed node (Step 4). If there are \( > t \) complaints, the nodes abort (Step 5). Otherwise, the honest nodes commit their shares (Step 5), with the guarantee that all honest nodes will be able to reconstruct the shared secret.

Note that \( f \leq t \) Byzantine nodes can always blame regardless of the dealer being honest or not. This forces an honest dealer to post \( O(fn) \) shares on the bulletin board when secret sharing \( O(n) \) secrets. In general, the amount of information posted on the bulletin board is \( O(kn + kf + fn) \) corresponding to \( O(n) \) commitments, \( f \) blame messages and \( O(fn) \) opened secret shares. A naïve approach of using BB protocols (extension protocols [36] for larger inputs) to instantiate the bulletin board involves following steps:

1. \textit{Commitments and sharing.} Dealer \( L \) invokes BB to broadcast \( n \) commitments Step 1, while privately sharing individual shares Step 2.
2. \textit{Blame.} Nodes invoke \( n \) parallel instances of BB to broadcast blame messages Step 3.
3. \textit{Open shares.} Dealer \( L \) invokes an instance of BB with secret shares corresponding to the blames received.

We note that state-of-the-art honest majority BB protocols, without threshold signatures, incur \( O(kn^2) \) bits communication cost to achieve consensus on a single decision [1, 23, 33]. Thus, invoking \( n \) parallel instances of BB trivially incurs \( O(kn^2) \) communication cost. In addition, running BB on inputs of size \( O(fn) \) incurs \( O(kf n^2) \) without threshold signatures and extension techniques. Thus, the total communication complexity is \( O(kn^2) \) bits.

Improved eVSS (iVSS). In order to reduce the large communication overhead, we first present an improved VSS scheme, that reduces (i) the number of posts to the bulletin board, and (ii) the amount of information posted on the bulletin board.

In iVSS (refer Figure 6), the dealer posts commitments on the bulletin board, privately sends the secret shares and corresponding witnesses similar to eVSS. However, unlike eVSS, nodes send the blame messages to all nodes. In addition, nodes forward the received blame messages to the dealer to request for missing shares. The dealer \textit{privately} sends missing shares to the nodes that forwarded the blame message instead of posting on the bulletin board. If an honest node receives missing shares for all blame messages it forwarded, it sends an ack to the dealer. The dealer collects \( t+1 \) ack messages and posts the ack certificate on the bulletin board. An honest node commits the proposed commitment if it observes an ack certificate on the bulletin board.

The honest nodes then forward the missing shares if the dealer sent the missing shares. A key correctness argument for our scheme is the following: if an honest node \( p_j \in \mathcal{P} \) does not receive commitments and secret shares, it must have sent blame messages to all honest nodes. If some honest node \( p_j \in \mathcal{P} \) sends an ack message, it must have received missing shares corresponding to the blame messages it received and forwarded (which includes share for \( p_j \)). Thus, all the honest nodes shares to reconstruct the proposed secrets.

We note that both eVSS and iVSS schemes guarantee secrecy (see Definition 2.4) only when the dealer is honest. If \( t \) Byzantine nodes send a blame message, then an honest but curious node can...
Let VSS be the VSS scheme being used. Let VSS.pp be the public VSS parameters. Let L be a dealer with secret s. Assuming the existence of a bulletin board, each node $p_i \in P$ does the following:

1. **Post commitment.** If $p_i$ is $L$, then generate shares for every node by running $(VSS.\tilde{S}, VSS.\tilde{W}, VSS.C) \leftarrow VSS.ShGen(s)$, and post the commitment $VSS.C$ to the secret on the bulletin board.

2. **Send shares.** If $p_i$ is $L$, then send shares $VSS.s_j \in VSS.\tilde{S}$ and witness $VSS.\pi_j \in VSS.\tilde{W}$ over the confidential channel to all nodes $p_j \in P$.

3. **Send blames.** Post complaints (blame, $L_i$) on the bulletin board, if no valid share is received privately or if $VSS.ShVrfy(VSS.s_i, VSS.\pi_i, VSS.C) = 0$.

4. **Open shares.** For all blamess (blame, $L_i$), if $p_i \neq L$, post their shares $VSS.s_j$ and witnesses $VSS.\pi_j$ on the bulletin board.

5. **Decide.** If the published share and witness satisfies $VSS.ShVrfy(VSS.s_k, VSS.\pi_k, VSS.C) = 1$ for every blame, and there are only up to $f \leq t$ blames on the bulletin board, then commit $VSS.s_j$. Otherwise, abort, i.e., output $\perp$.

Figure 5: eVSS [32] protocol description. This scheme is to secret share one secret.

Let VSS be the VSS scheme being used. Let VSS.pp be the public VSS parameters. Let L be a dealer with $n$ secrets $S = \{s_1, \ldots, s_n\}$ it wishes to secret share with nodes $P$. Assuming the existence of a bulletin board, each node $p_i \in P$ does the following:

1. **Post commitment.** If $p_i$ is $L$, run $(VSS.\tilde{S}_i, VSS.\tilde{W}_i, VSS.C_i) \leftarrow VSS.ShGen(s_i)$ for all $s_i \in S$. Build the commitment vector $VSS.\tilde{C} = \{VSS.C_1, \ldots, VSS.C_n\}$ which contain commitments $VSS.C_i$ for $s_i$. Post $VSS.\tilde{C}$ on the bulletin board.

2. **Send shares.** If $p_i$ is $L$, collect shares and witnesses $(VSS.s_j, VSS.\pi_j)$ for every node $p_j \in P$, and secret $s_i \in S$, and build $VSS.\tilde{S}_j, VSS.\tilde{W}_j$. Send $(VSS.\tilde{S}_j, VSS.\tilde{W}_j)$ to node $p_j \in P$.

If $p_i \in P$ is not the dealer, then wait to obtain $(VSS.\tilde{S}_j, VSS.\tilde{W}_j)$ from the dealer $L$, and ensure that $VSS.ShVrfy(VSS.s_j, VSS.\pi_j, VSS.\tilde{C}_j) = 1$ holds for every $VSS.s_j \in VSS.\tilde{S}_j$, and $VSS.\pi_j \in VSS.\tilde{W}_j$.

3. **Send blames.** If invalid/no shares are received from the dealer $L$, then send (blame, $L_i$) to all the nodes. Collect similar blames from other nodes.

4. **Private open.** Send all the collected blames to the dealer $L$. If $p_i$ is the leader, then for every blame (blame, $L_i$)$_k$ received from node $p_j$, send $(VSS.\tilde{S}_j, VSS.\tilde{W}_j)$ to node $p_j$.

If $p_i$ is not $L$, then ensure that $VSS.ShVrfy(VSS.s_j, VSS.\pi_j, VSS.\tilde{C}_j) = 1$ for every (blame, $L_i$)$_j$, $VSS.s_j \in VSS.\tilde{S}_j$, and $VSS.\pi_j \in VSS.\tilde{W}_j$.

5. **Ack and decide.** If $p_i$ received $t \leq t$ blames and the leader responded with valid shares $(VSS.s_j, VSS.\tilde{W}_j)$ for every (blame, $L_i$)$_j$ it forwarded, then send an ack message to the dealer $L$.

If $p_i$ is $L$, then post ack certificate (denoted by $\mathcal{AC}(VSS.\tilde{C})$) on the bulletin board.

If there is an ack certificate $\mathcal{AC}(VSS.\tilde{C})$ on the bulletin board, commit $VSS.\tilde{C}$, and send $(VSS.\tilde{S}_j, VSS.\tilde{W}_j)$, if received from $L$.

6. **Reconstruction.** Each node $p_i \in P$ does the following:

(a) If there is a share $VSS.s_j, VSS.\pi_j$ send the share and witness to all the nodes.

On receiving a share and witness $(VSS.s_j, VSS.\pi_j)$ from $p_j$, ensure that $VSS.ShVrfy(VSS.s_j, VSS.\pi_j, VSS.C) = 1$.

(b) On receiving $t+1$ valid shares in $VSS.\tilde{S}$, reconstruct the secret $s$ using $s \leftarrow VSS.Recon(VSS.\tilde{S})$. Send $s$ to all the nodes.

(c) On receiving an opened secret $s$, ensure that $VSS.ComVrfy(VSS.C, s) = 1$ and output $s$.

Figure 6: iVSS - Improved eVSS protocol description

violate secrecy, however this was also possible in the bulletin board based protocol and can be easily solved by assuming an additional honest node, i.e., $n > 2t + 1$.

4.2.2 Random Beacon for BRandPiper. In this section, we instantiate bulletin boards using our SMR protocol (Section 3) and present a random beacon protocol, we call BRandPiper, using the iVSS scheme. If we use our SMR protocol with rotating leaders, we can commit blocks of size $O(kn)$ within $t+1$ epochs while incurring $O(kn^2)$ bits of communication per epoch. To obtain 1-absolute unpredictability, we need to reconstruct at least $t+1$ secrets from distinct nodes in each epoch. For simplicity, we reconstruct one secret from all nodes that have not been removed. Using the round-robin leader selection rule, every node can share secrets at least once every $n$ epochs. If in every epoch, the leader proposes commitments to $n$ secrets using SMR protocol, we can use these secrets for the next $n$ epochs in the reconstruction. Our beacon output step can take advantage of the homomorphic properties of the underlying VSS scheme VSS to combine secret shares for multiple secrets from different nodes into an $O(\kappa)$-sized share which can be efficiently broadcast to all nodes. Honest nodes collect $t+1$ homomorphic shares to reconstruct the common randomness $R_c$. Such reconstructed randomness is guaranteed to be unbiased since an adversary cannot know the secrets of honest nodes until reconstructed, and an adversary cannot prevent reconstruction. For the same reason, our BRandPiper protocol ensures 1-absolute unpredictability, even for a rushing adaptive adversary.

**Protocol Details.** **Leader selection.** We employ a round robin leader selection policy. If an epoch leader $p_i$ fails to commit within $t+1$ epochs, it is added to the set of removed nodes $\mathcal{P}_r$ and is prevented from being a future leader. The remaining nodes $\mathcal{P} \setminus \mathcal{P}_r$ propose in a round robin manner.

**Setup.** During the setup phase, all the nodes are provided with VSS parameters VSS.pp required for using the VSS scheme VSS. Each node maintains $n$ queues $Q(p_i)$, for $p_i \in \mathcal{P}$. Each queue $Q(p_i)$ holds tuples with each tuple containing a secret share, its witness and commitment proposed by node $p_i$ when node $p_i$ was an epoch leader. During the setup phase, each queue $Q(p_i)$ is filled with $m = n + t$ tuples containing secret shares, witnesses and commitments for $m$ secrets. This ensures that all honest nodes have common secret shares in $Q(p_i)$ and can perform Dequeue($Q(p_i)$).
up to epoch $n + t$ even if $p_n$ does not propose in epoch $n$. This is because honest nodes perform Dequeue($Q(p_n)$) (explained later) in each epoch unless node $p_n$ has been removed. If node $p_n$ does not propose in epoch $n$, it is removed only in epoch $n + t$.

Buffer $t + 1$ shares

\[ Q(3) \]

Figure 7: An example illustration of BRandPiper for $n = 5$ and $t = 2$ in epoch $e = 5$. The region marked in red are the shares that will be homomorphically combined in every epoch for reconstruction. In general, in every epoch, shares from the left-most column will be used for reconstruction. The region marked in yellow is the addition of $n$ new shares by the leader $L_e = p_5$.

Example. Consider an example scenario as shown in Figure 7. In epoch 5, $p_5$ proposes and adds $n$ VSS shares to the system which will be committed within $t + 1 = 3$ epochs. If $p_5$ is Byzantine, by the end of epoch 8, all the nodes will remove $p_5$ from future proposals, thus guaranteeing outputs for every epoch. Until epoch 8 observe that we have shares for $p_5$.

Block validation protocol. BRandPiper uses a block validation protocol to generate valid blocks for use in the SMR. A valid block in BRandPiper is a vector of VSS commitments $\overline{VSS.C}$ along with acks from $t + 1$ nodes. The block validation protocol is essentially an instance of VSS where the leader ends up with $t + 1$ votes for a VSS commitment vector $\overline{VSS.C}$. The commitment and ack certificate is then input to the SMR protocol to ensure that all honest nodes agree on a single commitment vector. During the SMR protocol, the honest nodes vote only if a valid block is produced via the block validation protocol. The block validation protocol guarantees that if a block is certified, then all the honest nodes have sharings for all the secrets committed in $\overline{VSS.C}$. When these commitments are via VSS, all the honest nodes use the secret shares in the commitments in different epochs to generate the common randomness.

The block validation protocol (refer Figure 8) is executed in parallel with SMR protocol. The leader $L_e$ of epoch $e$ executes the block validation protocol while in epoch $e - 1$ to generate an ack certificate for commitments to be proposed in epoch $e$. The protocol consists of the following steps:

Distribute. Leader $L_e$ creates $n$ commitments $\overline{VSS.C}$ corresponding to $n$ secrets $\{s_1, \ldots, s_n\}$ it wishes to share using VSS.ShGen algorithm for secrets $\{s_i\}_{1 \leq i \leq n}$, along with shares $\overline{VSS.S_j} := \{VSS.s_{1,j}, \ldots, VSS.s_{n,j}\}$ and witnesses $\overline{VSS.W_j} := \{VSS.pi_{1,j}, \ldots, VSS.pi_{n,j}\}$, for all $p_j \in P$. We define a block containing $n$ commitments $\overline{VSS.C}$ as $SB := \langle \text{Commitment}, \overline{VSS.C}, e, z_{se}\rangle_{L_e}$. The leader $L_e$ sends VSS.$\overline{S_j}$, VSS.$\overline{W_j}$, and SB to node $p_j$, for all $p_j \in P$. Similar to the SMR protocol, the leader signs the tuple $(\text{Commitment}, H(\overline{VSS.C}), e, z_{se})$ and sends VSS.$\overline{C}$ separately to facilitate efficient equivocation checks. It is important to note that commitment VSS.$\overline{C}$, shares VSS.$\overline{S_j}$, and witness VSS.$\overline{W_j}$ are $O(n)$-sized and the shares VSS.$s_{i,j}$ are only sent to node $p_j$. Sending only the required shares to designated nodes reduces communication complexity.

Blame/Forward. If a node $p_i$ receives a valid secret share VSS.$\overline{S_j}$, witness VSS.$\overline{W_j}$, and sharing block $SB := \langle \text{Commitment}, \overline{VSS.C}, e, z_{se}\rangle_{L_e}$ within $3A$ time in epoch $e - 1$, it then calls the functionality Deliver($\text{Commitment}, SB, z_{se}, e$). The valid share must satisfy VSS.ShVrfy($\overline{VSS.s_{i,j}}, \overline{VSS.pi_{j}}, VSS.\overline{C}_j = 1, \forall j \in [n]$. Otherwise, node $p_i$ broadcasts (blame, $e$) to all nodes.

Request open. Node $p_i$ waits for $6A$ time in epoch $e - 1$ to collect any blames sent by other nodes. If no blames or equivocation by $L_e$ has been detected within that time, $p_i$ sends $(\text{ack}, H(SB), e)$ to $L_e$. If up to $t$ blames are received, $p_i$ forwards the blames to $L_e$.

Private open. If $L_e$ receives any blames from node $p_i$, it sends valid VSS.$\overline{S_j}$, witness VSS.$\overline{W_j}$ for every blame $(\text{blame}, e)_j$ received from node $p_i$.

Ack. If node $p_i$ forwarded any blames and received valid secret shares VSS.$\overline{S_j}$ and witness VSS.$\overline{W_j}$ for every blame $(\text{blame}, e)_j$ it forwarded and detects no equivocation, node $p_i$ sends a signed ack $(\text{ack}, H(SB), e)_j$ to $L_e$. In addition, node $p_i$ forwards secret shares VSS.$\overline{S_j}$ and witness VSS.$\overline{W_j}$ for every blame $(\text{blame}, e)_j$ it received. Thus, if an honest node sends an ack for the sharing block SB, then all honest nodes have their respective secret shares corresponding to sharing block SB (more details in Lemma B.17).

Equivocation. At any time in epoch $e - 1$, if a node $p_i$ detects an equivocation, it broadcasts equivocating hashes signed by $L_e$ and stops participating in epoch $e - 1$ block validation protocol.

Beacon protocol. We now present the beacon protocol (refer Figure 9) in BRandPiper. It consists of the following rules for an epoch $e$. Here, an epoch corresponds to an epoch in SMR protocol.

Generate Blocks. The leader $L_e$ of an epoch $e$ chooses $n$ secrets uniformly at random and invokes the block validation protocol while in epoch $e - 1$ to obtain an ack certificate (denoted by $\overline{AC_e}(SB)$) to generate a valid block SB corresponding to the $n$ secrets. In epoch $e$, the leader proposes block $B_h$ with $b_h := (H(SB), \overline{AC_e}(SB))$ where $\overline{AC_e}(SB)$ is an ack certificate for commitment SB using the SMR protocol obtained from the block validation protocol. We redefine valid blocks for the SMR protocol with an additional constraint to contain an ack certificate created in epoch $e - 1$ and all honest nodes vote in the SMR protocol as long as the proposed block meets this additional constraint. As mentioned before, an ack certificate for a sharing block SB implies all honest nodes have secret shares required to reconstruct the secrets corresponding to commitments in SB. Thus, it is safe for honest nodes to vote in the SMR protocol although they sent blame during the block validation phase.

Update. At the end of epoch $e$, node $p_i$ updates $Q(L_{e-1})$ as follows. If $L_{e-1}$ proposed a valid block $B_i$ in epoch $e$ and $B_i$ has been committed by epoch $e$, node $p_i$ replaces the contents of $Q(L_{e-1})$ with $n$ tuples with each tuple containing secret shares, witnesses

\footnote{For the first epoch, an ack certificate can be created during the setup phase.}
At the end of epoch e - 1, Node \( p_i \) performs following operations while in epoch e - 1:

1. Distribute. \( L_e \) waits for \( \Delta \) time after entering epoch e - 1 and then does the following:
   - Let \( \{s_1, \ldots, s_n\} \) be \( n \) random numbers chosen uniformly from the input space of VSS.
   - Build \( SB = \langle \text{Commitment}, VSS.C, e, z_e \rangle_L_e \), the sharing block which consists of commitments \( VSS.C = \{VSS.C_1, \ldots, VSS.C_n\} \) to the \( n \) random numbers generated by running \( VSS.S_i, VSS.W_i, VSS.C_i \) for \( i = 1, \ldots, n \), where \( VSS.S_i = \{VSS.s_{1,i}, \ldots, VSS.s_{l,n}\} \) and \( VSS.W_i = \{VSS.w_{1,i}, \ldots, VSS.w_{l,n}\} \).
   - Build the share vector \( VSS.S_j = \{VSS.s_1, VSS.S_{1,j}, \ldots, VSS.s_n, VSS.S_{n,j}\} \) and the witness vector \( VSS.W_j = \{VSS.w_1, VSS.W_{1,j}, \ldots, VSS.w_n, VSS.W_{n,j}\} \) for node \( p_j \) using \( j^{th} \) share and witness from \( VSS.S_i \) and \( VSS.W_i \) for random number \( s_i \).
   - Send \( VSS.S_j, VSS.W_j \) to every node \( p_j \in \mathcal{P} \).

2. Blame/Forward. If epoch-time \( e_{e-1} \) \( \geq 8\Delta \) and node \( p_i \) receives valid share vector \( VSS.S_j \), witness vector \( VSS.W_j \) and commitment \( SB = \langle \text{Commitment}, VSS.C, e, z_e \rangle_L_e \), then invoke Deliver \( \langle \text{Commitment}, SB, z_e, e \rangle \). If no shares has been received within \( 3\Delta \) time while in epoch e - 1, broadcast a blame (blame, \( e_j \)) to all nodes.

3. Request open. Wait until epoch-time \( e_{e-1} \) \( \geq 5\Delta \). Collect all blames received so far. If up to \( t \) blames are received so far, forward the blames to \( L_e \). If no blames or equivocation by \( L_e \) has been detected, send \( \langle \text{ack}, H(SB), e_j \rangle \) to \( L_e \).

4. Private open. \( L_e \) sends valid share \( VSS.S_j \) and witness \( VSS.W_j \) to node \( p_i \) for every blame (blame, \( e_j \)) received from node \( p_i \).

5. Ack. Upon receiving valid share \( VSS.S_j \) and witness \( VSS.W_j \) for every (blame, \( e_j \)), it forwarded and detects no equivocation, send \( \langle \text{ack}, H(SB), e_j \rangle \) to \( L_e \).

6. (Non-blocking) Equivocation. Broadcast equivocating hashes signed by \( L_e \) and stop performing any operations.

![Figure 8: Block validation protocol.](image)

And commitments shared in epoch \( e - t \). If no epoch \( e - t \) block was committed, it removes \( L_{e-t} \) from future proposals, i.e., \( \mathcal{P}_0 \leftarrow \mathcal{P}_0 \setminus \{L_{e-t}\} \). It is important to note that the SMR protocol guarantees all honest nodes commit proposed blocks in \( t + 1 \) epochs. Thus, all honest nodes either update \( Q(L_{e-t}) \) or remove \( L_{e-t} \) in epoch e.

5 PERFORMANCE EVALUATION

In this section, we evaluate the performance of RandPiper, and compare it with the performance of related works.

**Implementation.** We implement BRandPiper protocol in Rust [11, Performance Evaluation], due to its strong support for correctness in concurrency, and compile-time memory safety guarantees. Our implementation is lock-free and uses message passing to ensure efficiency. We provide the setup parameters for every node in the config files. Our code is event driven, and reacts to various timeouts and messages from the network. We use ED25519 for digital signatures. We use the BLS12-381 [9] curve and use implementations of SCRAPE (17) over this curve as the PVSS scheme, Pedersen-based eVSS and Polycommit [32] over this curve as the VSS and bilinear accumulator scheme.

**Optimizations.** We perform some system-level optimizations. In particular, we do the following: (1) We generate random shares before the propose step (this can be done using extra cores, an external node supplying the shares) and use it during the propose
step, so that the share generation does not block the critical path.

(2) We take advantage of the Tokio library [48] and futures in Rust to run concurrently without spawning threads. (3) We implement both the accumulator libraries: the bilinear accumulator and the Merkle tree accumulator. We observe that the computational performance of the Merkle tree accumulator is much better in practice in general.

**Setup.** All our experiments were conducted on t2.micro AWS instances from Ohio region, which have 1 GB RAM, 8 GB hard disk, 1 vCPU running at up to 3.3 GHz. The advertised bandwidth for these instances is 60–80 MBit/s.

**Baselines.** We compared the performance of our implementation with two baselines which are the current state-of-the-art public implementations: Drand [25] and HydRand [42, 44]. We chose Drand because it is a practically deployed system implementing Cachin et al. [16] and evaluating our performance against it justifies our practicality. We chose HydRand as our second baseline because, it is theoretically related to our work: HydRand requires 2/3 honest majority as compared to the optimal 1/2 honest majority necessary for us. Note that the basic HydRand protocol and implementation [42] only offers bias-resistance but no unpredictability: an adversary may correctly predict a random beacon in \( t + 1 \) epochs in advance.

**Micro-Benchmarks.** We measure the efficiency of the primitives used in our protocol. Concretely, we measure the run times for (1) accumulator share generation, verification and reconstruction for the bilinear accumulator as well as the Merkle tree accumulator, (2) PVSS share generation, verification, and reconstruction, (3) eVSS share generation, verification, and reconstruction, and (4) the size of the various messages used in the protocol. The details are provided in [11]. We observe that the Merkle tree accumulator for our small scales has smaller message sizes and very efficient run times. We also observe that eVSS operations in general perform much better than its PVSS counterparts.

We build communication-efficient random beacon protocols with comparable or better performance than the state-of-the-art solutions. Thus, the key metric we compare is the number of beacon values that can be produced in a minute. In addition, compared to Drand, we have the advantage of reconfigurability and weaker network assumptions, and compared to HydRand, we can tolerate more faults. The methodology is to run protocols at appropriate values of \( \Delta \), which in turn depends on the computation and communication costs. We provide additional micro benchmarks in the full online version [10].

**BRandPiper.** Our beacon produces a value every \( 11\Delta \). We measure the smallest value of \( \Delta \) for which our beacon produces outputs without any of the \( n \) correct nodes blaming/reporting malicious behavior in the logs. Using this, we measure the metric: number of beacons produced per minute for BRandPiper protocol, and present them in Figure 10. We run our beacon for 100 rounds, thereby giving a strong confidence that the \( \Delta \) used is viable, provided the network conditions stay the same.

**Drand.** For Drand, we measure the parameter **time discrepancy**, which is a value output by Drand by every node. It reports the time (in ms) between obtaining the beacon value and the time at which the epoch started. This time accounts for the synchronization losses, network delays as well as the computations. The beacon continues to produce values every **period** seconds. However, the time discrepancy parameter defines the lowest period we can set to ensure continuous beacon output. We give the benefit of the doubt to Drand here as there is no guarantee that setting such low values for \( \Delta \) does not overwhelm the system. We allow the beacon to run for 100 epochs, and measure the 99.9\textsuperscript{th} percentile of the time discrepancies observed in the logs of all the nodes over all the epochs, and present their growth in Figure 10. For 100 percentile, we observe that we are always better than Drand. In our experiments, when \( n = 65 \), we observed that the DKG initialization in Drand results in all the nodes aborting, even after setting large values for period.

**HydRand.** We use the public implementation [42]. It consists of three rounds: propose, acknowledge and vote, timeouts for which can be configured. We find the smallest such configuration that allows the system to work and report the numbers in Figure 10. HydRand on its own offers \( t + 1 \)-absolute unpredictability where \( t < n/3 \) along with the bias-resistance property. However, Drand and BRandPiper are both 1-absolute unpredictable, and in that sense, HydRand is not unpredictable.

From Figure 10, we can clearly see that the Merkle tree based BRandPiper is quantitatively as practical as the state-of-the-art practical random beacon protocol: Drand. Drand uses a leader to coordinate the DKG and reconfiguration protocols. There is no description on how to recover if the leader was Byzantine. Additionally, in Drand, the synchronization for the reconfigured instance is via the coordinator (the leader). It is not clear how the protocol will recover if the leader becomes Byzantine. Therefore, qualitatively, we use much clearer and formal network assumptions and allow efficient and secure reconfiguration, including synchronization for the incoming nodes, without pausing the protocol, unlike Drand, and therefore can conclude that BRandPiper protocol is not just theoretically interesting, but also practical.

**ACKNOWLEDGEMENTS**

We would like to thank our shepherd Alin Tomescu, Sourav Das and the anonymous reviewers for their insightful feedback to improve this draft. This work has been partially supported by research gift grants from VMware Research and Novi, the Army Research Laboratory (ARL) under grant W911NF-20-2-0026, the National Institute of Food and Agriculture (NIFA) under grant 2021-67021-34251, and the National Science Foundation (NSF) under grant CNS-1846316.
REFERENCES

A RELATED WORK

A.1 Related Works in the BFT SMR Literature

There has been a long line of work in improving the latency and communication complexity of consensus protocols [1, 4, 5, 14, 26, 33, 35, 46, 49]. The state-of-the-art BFT SMR protocols [1, 3, 5, 46] incur quadratic communication per consensus decision while using
threshold signatures. Without threshold signatures, they incur cubic communication per consensus decision. Our BFT SMR protocol makes progress in the setting where threshold signatures are not desirable. Our protocol incurs $O(kn^2)$ communication complexity under the $q$-SDH assumption or $O(kn^3 \log n)$ without it at the expense of increased latency.

### A.2 Related Works in the Random Beacons

#### Literature

In this section, we explore random beacon protocols, sometimes also referred to as coin tossing protocols, in the synchronous setting. Some works were originally designed for the asynchronous settings, but in this section, we evaluate them in the synchronous setting.

Cachin et al. [16] use a threshold shared secret $x_i$ of the secret $x \in \mathbb{Z}_p$, where $q$ is the order of a group $G$. To generate beacons, they create shares $g^x v_i$ of the beacon $g^x$, for some generator $g \in G$. The beacon value $c$ is some agreed upon coin value, say for instance, a counter. When $t > r$ such shares are obtained, all the honest nodes obtain the same beacon value $g^c x$. Drand [25] uses a similar approach by replacing the threshold secret with a threshold BLS key and using signatures on the common coin $c$ (say, a counter). This incurs a communication complexity of $O(kn^2)$ always, but comes with the drawback that it does not support reconfiguration, i.e., if a single node is replaced or joins the system, the threshold shares are updated with group leaders in a tree structure during the setup. This incurs a communication complexity of $O(kn^3)$ always, but has the drawback that it does not support reconfiguration, i.e., if a single node is replaced or joins the system, the threshold shares need to be resharable between the new participants.

Homomorphic Encryption Random Beacon (HERB) [20] uses homomorphic threshold ElGamal encryption scheme to generate random numbers. The system tolerates $n > 3t$ faults. Each node in the system encrypts a random share and posts it on the bulletin board. The protocol uses $t + 1$ such encryptions to produce the final beacon output. The work requires the use of a Byzantine Agreement protocol whose inputs are $O(kn)$ sized, and therefore trivially has a communication complexity of $O(kn^3)$ in the best and worst cases. It also uses a variant of the threshold setup, thereby not permitting a re-usable setup.

RandChain [29] builds a DRB - Decentralized Random Beacon that assumes sequential Proof-of-Work (Seq-PoW), and VDFs along with Nakamoto consensus for consistency. Constructions using these assumptions are not energy-efficient. In PoW, an adversary with more hash power can neglect unfavorable random numbers by forking, and to avoid this requires the total honest hash power to be greater than $1/2$. The work uses existing Byzantine Agreement techniques which make the protocol have a communication complexity of $O(kn^2)$ in the best case, while inheriting the $O(kn^3)$ communication complexity from BA [22] in the worst case.

Drake et al. [24] proposed a minimal bias-resistant VDF-based random beacon scheme, that assumes the existence of a VDF [12] and that the adversary has an advantage $A_{\text{max}}$ in terms of speed over the honest nodes, in computing the VDF. The VDF is used to determine the beacon output for a round, and sufficiently old beacon outputs are used to select leaders for the Ethereum Proof-of-Stake protocol. The system tolerates $n > 3t$ faults, and is designed for partial synchrony.

RandRunner [43] builds a random beacon protocol using VDFs. Therefore, it has a setup that can be re-used. It uses trapdoor Verifiable Delay Functions - VDFs with strong uniqueness properties that produces unique values efficiently for the node that has the trapdoor, but takes time $T$ to produce an output for the nodes that do not have the trapdoor. This allows the beacon to output bias-resistant outputs in every round. It is not immediately unpredictable as an adaptive adversary can corrupt the next $t < n/2$ leaders to know the outputs for the next $t$ epochs. RandRunner uses reliable broadcasts which results in communication complexity of $O(kn^2)$ for every round.

RandShare [47] is a strawman protocol for where the beacon output is generated using $n$ independent Byzantine Agreement instances are run in a system tolerating $n > 3t$ faults. Running $n$ BA instances incurs a communication complexity of $O(kn^3)$ in the worst case and $O(kn^4)$ in the worst case. RandHerd [47] is an improved version of RandShare, driven by a client seeking a random beacon value. The client splits the system into groups of size $c$ which internally use RandShare, leading to a communication complexity of $O(k c^2 n)$, even in the worst case. However, even though $c$ is a constant, it depends on $n$ as the randomness of the beacon output is determined by $c$. RandHound [47] goes beyond RandHerd by using a stable-leader approach and dividing the system into groups of nodes with group leaders in a tree structure during the setup. This incurs RandHound, a communication complexity of $O(k c^2 \log n)$ when the leader and the group leaders are honest. However, when the leader is bad, it uses a view-change protocol which is analogous to Byzantine Agreement, and incurs a cost of $O(kn^3)$ communication complexity when $t < n/3$ consecutive leaders are Byzantine.

HydRand [44] is a random beacon protocol in the synchrony model which tolerates $t$ faults, with $n > 3t$, with a communication complexity of $O(kn^3)$, and $O(kn^3)$ communication complexity in the worst case. It uses PVSS schemes (in particular SCRAPE [17]) and tolerates an adversary which can predict up to $t + 1$ epochs into the future.

#### Summary of limitations

The state-of-the-art SMR protocols [1, 3, 5, 49] have a lower bound of $O(kn^2)$ on the communication complexity in the best case, which hints that we cannot do better than $O(kn^2)$ without improving SMR first. State-of-the-art random beacon protocols [16, 20, 47] show that we cannot achieve an unpredictability advantage better than 1 epoch, since a rushing adversary can always know one epoch output before the rest of the honest nodes. State-of-the-art Random beacon protocols [16, 20, 47] also show that a random beacon not in lock-step cannot yield giving a time advantage of less than $2\Delta$ to a rushing adversary. Our work aims to bridge these gaps in existing random beacon protocols.

#### Insights from existing works

RandPiPere uses some insights from HydRand [44] and non-trivially improves upon them for optimal fault tolerance ($t < n/2$ unlike $t < n/3$ from HydRand) and better communication complexity (recall that HydRand has a communication complexity of $O(kn^3)$ in the best case and $O(kn^4)$ in the worst case). We first observe that HydRand secret shares one value and uses this shared value the next time the same node becomes a leader again. We observe that this is buffering of shares, and that this buffering can be done for more than one share, i.e., every time a node becomes a leader, we can use the value from the
last $d^{th}$ time it was a leader to buffer $d$ shares. Next, we observe that HydrRand cannot tolerate more than $t > n/3$ because it fails to deliver the PVSS encryptions to all correct nodes, if the leaders fails to send it to them. We solve this concern using extension techniques from recent works [36]. However, these works assume threshold signatures which we avoid in our protocol. Thus, in RandPiper, we achieve an optimal fault tolerance of $t < n/2$ and also improved communication complexity.

**B EXTENDED PRELIMINARIES**

In this section, we provide additional preliminaries used in our paper. The VSS interface is presented in Table 2 and the PVSS interface is presented in Table 3.

**B.1 Safety and Liveness for BFT SMR**

We say a block $B_h$ is committed directly in epoch $e$ if it is committed as a result of its own commit-time, expiring. We say a block $B_h$ is committed indirectly if it is a result of directly committing a proposal $B_t (t > h)$ that extends $B_h$.

**Fact B.1.** If an honest node delivers an object $b$ at time $t$ in epoch $e$ and no honest node has detected an epoch $e$ equivocation by time $t + \Delta$, then all honest nodes will receive object $b$ by time $t + 2\Delta$ in epoch $e$.

Proof. Suppose an honest node $p_i$ delivers an object $b$ at time $t$ in epoch $e$. Node $p_i$ must have sent valid code words and witness (codeword, mtype, sj, wj, ze, e)j computed from object $b$ to every $p_j \in P$ at time $t$. The code words arrive at all honest nodes by time $t + \Delta$. Since no honest node has detected an epoch $e$ equivocation by time $t + \Delta$, it must be that either honest nodes will forward their code words (codeword, mtype, sj, wj, ze, e) when they either delivered object $b$ or received the code word from some other node $p_j$. In any case, all honest nodes will forward their epoch $e$ code word corresponding to object $b$ by time $t + \Delta$. Thus, all honest nodes will have received $t + 1$ valid code words for a common accumulation value ze by time $t + 2\Delta$ sufficient to decode object $b$ by time $t + 2\Delta$. $\square$

**Fact B.2.** If an honest node votes for a block $B_h$ at time $t$ in epoch $e$, then all honest nodes receive $B_h$ by time $t$.

Proof. Suppose an honest node $p_i$ votes for a block $B_h$ at time $t$ in epoch $e$. Node $p_i$ must have received proposal $p_e$ for $B_h$ by time $t - 2\Delta$ and detected no epoch $e$ equivocation by time $t$. This implies no honest node detected an epoch $e$ equivocation by time $t - \Delta$. Node $p_i$ must have invoked Deliver(propose, $p_e$, ze, e) at time $t - 2\Delta$. By Fact B.1, all honest nodes receive $p_e$ by time $t$. Thus, all honest nodes must have received $B_h$ by time $t$. $\square$

**Lemma B.3.** If an honest node directly commits a block $B_h$ in epoch $e$, then (i) no equivocating block certificate exists in epoch $e$, and (ii) all honest nodes receive $C_e (B_h)$ before quitting epoch $e$.

Proof. Suppose an honest node $p_i$ commits a block $B_h$ in epoch $e$ at time $t$. Node $p_i$ must have received a vote-cert for $B_h$ at time $t - 2\Delta$ such that its epoch-timer$e$ $\geq 3\Delta$ and did not detect an equivocation by time $t$. This implies no honest node detected an epoch $e$ equivocation by time $t - \Delta$. In addition, some honest node $p_j$ must have voted for $B_h$ by time $t - 2\Delta$. By Fact B.2, all honest nodes would receive $B_h$ by time $t - 2\Delta$.

For part (i), observe that no honest node received an equivocating proposal by time $t - 2\Delta$; otherwise, all honest nodes would have received a code word for equivocating proposal by time $t - \Delta$ and node $p_i$ would not commit. And, no honest node would vote for an equivocating block after time $t - 2\Delta$ (since they have received $B_h$ by time $t - 2\Delta$). Thus, an equivocating block certificate does not exist in epoch $e$.

For part (ii), observe that node $p_i$ must have invoked the primitive Deliver(vote-cert, ve, ze, e) for ve $= C_e (B_h)$ at time $t - 2\Delta$ and did not detect epoch $e$ equivocation by time $t$. By Fact B.1, all honest nodes receive ve by time $t$. Note that node $p_i$ must have its epoch-timer$e$ $\geq 3\Delta$ at time $t - 2\Delta$. Since, all honest nodes are synchronized within $\Delta$ time, all other honest nodes must have epoch-timer$e$ $\geq 2\Delta$ at time $t - 2\Delta$. Thus, all nodes are still in epoch $e$ at time $t$ and receive $C_e (B_h)$ before quitting epoch $e$. $\square$

**Lemma B.4 (Unique Extensibility).** If an honest node directly commits a block $B_h$ in epoch $e$, then any certified blocks that ranks higher than $C_e (B_h)$ must extend $B_h$.

Proof. The proof is by induction on epochs $e' > e$. For an epoch $e'$, we prove that if a $C_{e'} (B_{h'})$ exists then it must extend $B_h$.

For the base case, where $e' = e + 1$, the proof that $C_{e'} (B_{h'})$ extends $B_h$ follows from Lemma B.3. The only way $C_{e'} (B_{h'})$ for $B_{h'}$ forms is if some honest node votes for $B_{h'}$. However, by Lemma B.3, there does not exist any equivocating block certificate in epoch $e$ and all honest nodes receive and lock on $C_e (B_h)$ before quitting epoch $e$. Thus, a block certificate cannot form for a block that does not extend $B_h$.

Given that the statement is true for all epochs below $e'$, the proof that $C_{e'} (B_{h'})$ extends $B_h$ follows from the induction hypothesis because the only way such a block certificate forms is if some honest node votes for it. An honest node votes in epoch $e'$ only if $B_h$ extends a valid certificate $C_{e'} (B_{h'})$. Due to Lemma B.3 and the induction hypothesis on all block certificates of epoch $e < e' < e'$, $C_{e'} (B_{h'})$ must extend $B_h$. $\square$

**Theorem B.5 (Safety).** Honest nodes do not commit conflicting blocks for any epoch $e$.

Proof. Suppose for the sake of contradiction two distinct blocks $B_h$ and $B_{h'}$ are committed in epoch $e$. Suppose $B_h$ is committed as a result of $B_{h'}$ being directly committed in epoch $e'$ and $B_{h'}$ is committed as a result of $B_{h''}$ being directly committed in epoch $e''$. Without loss of generality, assume $h' < h''$. Note that all directly committed blocks are certified. By Lemma B.4, $B_{h''}$ extends $B_{h'}$. Therefore, $B_h = B_{h'}$. $\square$

**Fact B.6.** Let $B_h$ be a block proposed in epoch $e$. If the leader of an epoch $e$ is honest, then all honest nodes commit $B_h$ and all its ancestors in epoch $e$.

Proof. Suppose leader $L_e$ of an epoch $e$ is honest. Let $t$ be the earliest time when an honest node $p_i$ enters epoch $e$. Due to $\Delta$ delay between honest nodes, all honest nodes enter epoch $e$ by time $t + \Delta$. 

16
Some honest nodes might have received a higher ranked certificate than leader $L_e$ before entering epoch $e$; thus, they send their highest ranked certificate to leader $L_e$.

Leader $L_e$ might have entered epoch $e$ at time $\tau$ while some honest nodes enter epoch $e$ only at time $\tau + \Delta$. The $2\Delta$ wait in the Propose step ensures that the leader can receive highest ranked certificates from all honest nodes. However, leader $L_e$ may enter epoch $e + \Delta$ time after the earliest honest nodes. Due to $2\Delta$ wait after entering epoch $e$, leader $L_e$ receives the highest ranked certificate $C_{e'}(B_1)$ by time $\tau + 3\Delta$ and sends a valid proposal $p_e = (\text{propose}, B_h, e, C_{e'}(B_1), \tau_{pe})_{L_e}$ for a block $B_h$ that extends $C_{e'}(B_1)$ which arrives all honest nodes by time $\tau + 4\Delta$.

Thus, all honest nodes satisfy the constraint epoch-timer$_e \geq 7\Delta$. In addition, $B_h$ extends the highest ranked certificate. So, all honest nodes will invoke Deliver$(\text{propose}, p_e, \tau_{pe}, e)$ and set vote-timer$_e$ to $2\Delta$ which expires by time $\tau + 6\Delta$. All honest nodes send vote for $B_h$ to $L_e$ which arrives $L_e$ by time $\tau + 7\Delta$. Leader $L_e$ forwards $C_{e'}(B_1)$ which arrives all honest nodes by time $\tau + 8\Delta$. Note that all honest nodes satisfy the epoch-timer$_e \geq 3\Delta$ and highest ranked certificate in epoch $e$. Thus, all honest nodes will commit $B_h$ and its ancestors in epoch $e$ before their epoch-timer$_e$ expires.

Theorem B.7 (Liveness). All honest nodes keep committing new blocks.

Proof. For any epoch $e$, if the leader $L_e$ is Byzantine, it may not propose any blocks or propose equivocating blocks. Whenever an honest leader is elected in epoch $e$, by Fact B.6, all honest nodes commit in epoch $e$. Since we assume a round-robin leader rotation policy, there will be an honest leader every $t + 1$ epochs, and thus the protocol has a commit latency of $t + 1$ epochs.

Lemma B.8 (Communication complexity). Let $t$ be the size of block $B_h$, $\kappa$ be the size of accumulator and $w$ be the size of witness. The communication complexity of the protocol is $O(n(t + (\kappa + w)n^2))$ bits per epoch.

Proof. At the start of an epoch $e$, each node sends a highest ranked certificate to leader $L_e$. Since, size of each certificate is $O(n\kappa)$, this step incurs $O(n \kappa^2)$ bits communication. A proposal consists of a block of size $f$ and block certificate of size $O(n\kappa)$. Proposing $O(n + f)$-sized object to $n$ nodes incurs $O(n\kappa^2 + nf)$. Delivering $O(n\kappa + f)$-sized object has a cost $O(n(f + (\kappa + w)n^2))$, since each node broadcasts a code word of size $O((n + f)/n)$, a witness of size $w$ and an accumulator of size $\kappa$.

In Vote cert step, the leader broadcasts a certificate for block $B_h$ which incurs $O(n\kappa^2)$ communication. Delivering $O(n\kappa)$-sized $C_{e'}(B_1)$ incurs $O((\kappa + w)n^2)$ bits. Hence, the total cost is $O(n(t + (\kappa + w)n^2))$ bits.

B.2 GRandPiper Security Analysis

Theorem B.9 (Consistent beacon). Let $L = L_e$ denote the leader of epoch $e$. Then the following properties hold:

(i) Block consistency: if an honest node commits a block $B$ proposed in epoch $e' \leq e - t$, then all the honest nodes commit block $B$ by epoch $e$.

</table>
Let $\ell = \ell + 1$. (ii) should hold for the first $t + 1$ leaders because we fill $Q(p_i)$ with $m = 1$ values for all nodes $p_i \in \mathcal{P}$ during the setup phase. Additionally, from Definition 4.1, no leaders repeat in the first $t + 1$ epochs, thereby proving (ii) for the base case. (iii) and (iv) hold since the first $t + 1$ outputs only use the seed values, and pre-agreed upon shares from $Q$ from the setup phase. At epoch $e = t + 1$, from the proof for (iv) for the base cases, we know that all nodes agree on the leaders for epochs $1 \leq e' \leq t + 1$. Therefore, if some honest node commits block $B_1$ from epoch $e = 1$, then all honest nodes will commit $B_1$ by epoch $e + 1$, because at least one leader in some epoch $1 \leq e' \leq t + 1$ must be honest, and from Fact B.6 all honest nodes commit the block proposed in $e'$ and therefore directly or indirectly commit $B_1$. Therefore, by epoch $e = t + 1$ all honest nodes commit $B_1$, thereby proving (iv) for the base cases.

**Induction hypothesis.** The statements hold until epoch $e - 1$.

**Induction step.** Proof for (i). From the induction hypothesis for (iv), we have that all the leaders until epoch $e$ are consistent and at epoch $e = 1$, and from the induction hypothesis for (i) all honest nodes would have committed all the blocks for epoch $e' < e - 1$ by consistent leaders up to epoch $e - 1$. Now, at epoch $e$ all honest nodes need to decide on the block $B$ proposed in epoch $e - t - 1$. In epochs $e - t - 1 \leq e' < e$, there is one epoch $e'$ whose leader $\mathcal{L}_{e'}$ is honest, from Fact B.6, all honest nodes commit $B$ in epoch $e'$, thus proving the hypothesis for (i).

**Proof for (ii).** By the induction hypothesis for (iv), the leader of epoch $e$ and all previous epochs is agreed upon. Let $\mathcal{L}_e$ be the leader for epoch $e$. Then $\mathcal{L}_e$ must have committed a block in some epoch $< e - t$, or during the setup. If $\mathcal{L}_e$ was never the leader, then the hypothesis (ii) is trivially satisfied. Let $e' < e - t$ be the latest epoch in which $\mathcal{L}_e$ was the leader last. If $\mathcal{L}_e$ proposed a block in some epoch $e' < e - f$, then from the proof for (i) for epoch $e$, all nodes agree on the same block for epoch $e'$. If no block proposed in epoch $e'$ is added to the chain by epoch $e' + t < e$, then from our leader selection rule (in Definition 4.1), no honest node will derive $\mathcal{L}_e$ as the leader as $L_e \in \mathcal{P}_r$. Therefore, (ii) also holds for epoch $e$.

**Proof for (iii).** The randomness $\mathcal{R}_e$ depends on choosing a committed value to be reconstructed. The output $O_e$ depends on $\mathcal{R}_e$ and $\{O_{e-1}, \ldots, O_{e-f}\}$. By the induction hypothesis for (iii), all honest nodes agree on $O_{e-1}, \ldots, O_{e-f}$. Moreover, by the induction hypothesis for (iv), they also choose the same leader $\mathcal{L}_e$ for epoch $e$. Thus, if we can prove that all honest nodes agree upon the value from $\mathcal{L}_e$ that is reconstructed in epoch $e$, then agreement on $O_e$ is trivial. From the proof of (i) and (ii), we know that there is a block $b_{\ell}$ that is enqueued in the queue $Q(L_e)$ for $\mathcal{L}_e$, which all honest nodes agree on, and therefore obtain the same $\mathcal{R}_e$ for epoch $e$. Thus, (iii) holds true for epoch $e$.

**Proof for (iv).** The leader derivation depends on the candidate set $\mathcal{L}_e$, outputs of the last $t$ iterations $\{Q_{e-1}, \ldots, Q_{e-t}\}$, and the reconstructed randomness $\mathcal{R}_e$ in epoch $e$. By the induction hypothesis for (iv), and proof of (iii), the output of the last $f$ iterations and that of epoch $e$ is agreed upon. From the proof of (i), (ii), and the induction hypothesis for (iv), all honest nodes have the same $\mathcal{L}_{\text{Last}}$ and $\mathcal{P}_r$. From (iii), all honest nodes derive the same leader for epoch $e + 1$. ⊓⊔

**Theorem B.10 (Secure PVSS).** Assuming a secure PVSS scheme PVSS, the GRandPiper protocol is a secure publicly verifiable secret sharing protocol with the dealer as the leader of an epoch, and the rest of the nodes as the verifiers.

**Proof Sketch.** We already know that our SMR is secure against a $t$-bounded adversary assuming a secure digital signature scheme, $q$-SDH and a random oracle $H$. Given a secure suite of algorithms in PVSS, on a high level we do not reveal any new information.

To formally prove it, consider the view $V_i$ of any honest node $p_i$. It observes $V_i := (\text{PVSS}, \hat{E}, \text{PVSS}.pki, \text{PVSS}.\pi)$. In the underlying PVSS scheme PVSS, the view of a node is also $V_i$. An adversary $\mathcal{A}$ that can successfully violate the secrecy property from GRandPiper can do so by:

1. Breaking the underlying PVSS scheme PVSS. Since PVSS satisfies Definition 2.5, this can occur with negl($\lambda$) probability.
2. Guessing the secret. The probability of an adversary winning this way is negl($\lambda$).

Correctness. Let $\mathcal{L}_e$ be an honest leader for epoch $e$. Then its proposed block that shares $\mathcal{R}_e$ is always committed (from Fact B.6). Thus when the secret is reconstructed in the beacon protocol (Figure 4) all the honest nodes will output $\mathcal{R}_e$ with a high probability of $1 - \text{negl}(\lambda)$ (from the underlying PVSS algorithm).

Commitment. If $\mathcal{L}_e$ is Byzantine, then either all the honest nodes commit to one of the blocks $B_{\ell}$ proposed, or $\bot$ by epoch $e + t + 1$. Therefore, the commitment property is satisfied by our protocol. From the underlying scheme PVSS, there is a negligible probability negl($\lambda$) for two correct nodes $p_i$ and $p_j$ to output different $s_i^f \neq s_j^f$. (Public) Verifiability. This property holds true with high probability from the underlying PVSS scheme PVSS as the views are identical. The probability is over the choice of randomness for the verifier. ⊓⊔

**Concrete instantiations.** Consider instantiating GRandPiper using SCRAPE [17]. We can show a reduction from an adversary breaking the IND1-secrecy [31] property in GRandPiper into an adversary that can break the secrecy property from SCRAPE (which in turn shows a reduction to DDH or DBS assumptions [17, Sec.3, Sec.4]). In the simulation, since the adversary is static, pick random public keys for the $n - t$ honest nodes, and use $\mathcal{A}$ to run an instance of GRandPiper using the input secrets. When $\mathcal{A}$ wins, we can directly break the IND1-Security property.

**Remark.** There are no known adaptively secure PVSS protocols. It is not the case that there are attacks on existing PVSS schemes when assuming an adaptive adversary, it is just that the existing proof techniques fail to show security against adaptive adversaries.

**Lemma B.11 (Rushing Adversary Advantage).** For any epoch $e \geq 1$, a rushing adversary can reconstruct output $O_e$ at most $2\Delta$ time before the honest nodes.

**Proof.** An honest node sends its secret shares in epoch $e$ when its epoch-timer $e - 1$ expires. Let node $p_1$ be the earliest honest node
whose epoch-timer \(\tau - 1\) expires and node \(p_i\) sends its secret share at time \(\tau\). A rushing adversary may instantaneously receive the share and reconstruct the output \(O_e\) at time \(\tau\).

Due to the \(\Delta\) delay among the honest nodes entering epoch \(e\), the other honest nodes may send their secret shares only at time \(\tau + \Delta\) which arrives at all the honest nodes by time \(\tau + 2\Delta\). In the worst case, the honest nodes can reconstruct only at time \(\tau + 2\Delta\). Thus, a rushing adversary can reconstruct output \(O_e\) at most \(2\Delta\) time before honest nodes.

**Lemma B.12 (Guaranteed Beacon Output).** For any epoch \(e \geq 1\), all the honest nodes output a new beacon output \(O_e\).

**Proof.** By Theorem B.9 part (iv), all the honest nodes have consistent leaders. Let node \(p_i\) be the leader of epoch \(e\). The honest nodes output a new beacon output in each epoch \(e\) if \(Q(p_i) \neq \perp\). Suppose for the sake of contradiction \(Q(p_i) = \perp\) in epoch \(e\). Observe that nodes update \(Q(p_i)\) with secret proposed in epoch \(e'\) (with \(e' < e - t\)) when \(p_i\) was an epoch leader in epoch \(e'\) by epoch \(e\) and node \(p_i\) did not propose any secrets in epoch \(e'\). However, if \(p_i\) did not propose in epoch \(e'\), \(p_i\) would have been removed from the candidate leader set for epoch \(e\) and would not be epoch leader for epoch \(e\) and honest nodes would not use \(Q(p_i)\) in epoch \(e\). A contradiction. Thus, all the honest nodes send shares for secret shared in \(Q(p_i)\) and all the honest nodes will receive \(t + 1\) valid shares to reconstruct a common randomness \(R_e\) and output \(O_e\). □

**Lemma B.13 (Bias-Resistance).** For any epoch \(e \geq 1\), the probability that a \(t\) bounded adversary \(A\) can fix any \(c\) bits of the GRandPiper beacon output \(O_e\) is \(\text{negl}(c) + \text{negl}(x)\).

**Proof Sketch.** The output in any epoch \(e\) is \(O_e\) which is the hash \(H(R_e, O_{e-1}, \ldots, O_{e-t})\). Assume that some static adversary \(A\) wants to bias \(c\) bits of \(O_e\). Now there is at least one honest leader in epoch \(e'\) where \(e - t \leq e' \leq e\). WLOG, assume that the leader at epoch \(e' = e - t\) is honest. Then the output of epoch \(e'\) is known only in epoch \(e'\) within \(2\Delta\) time of entering the epoch \(e'\) (from Lemma B.12). Therefore, a rushing adversary \(A\) can know the \(O_e\) at max \(2\Delta\) before an honest node enters epoch \(e'\) (from Lemma B.11). However, the adversary has to choose all \(R_{e'}\) before epoch \(e'\), where \(e - t < e' \leq e\), so that it can bias \(O_e\). All blocks containing \(R_{e'}\) are committed before the epoch \(e'\), since \(R_{e'}\) comes from the blocks previously proposed by the leaders before epoch \(e'\) at the start (or during the setup). Thus all blocks containing \(R_{e'}\) are proposed before observing \(R_{e'}\), which is guaranteed to be secret for a honest node against \(A\) (from the secrecy property of Theorem B.10) except with negligible probability \(\text{negl}(x)\). Thus, an adversary \(A\) can do no better than \(\text{negl}(c) + \text{negl}(x)\) to fix \(c\) bits. □

**Lemma B.14 (GRandPiper unpredictability).** Assuming a secure PVSS scheme PVSS and SMR protocol, the GRandPiper random beacon protocol is an \(O(\min(x, t))\)-absolute unpredictable random beacon protocol against a static adversary.

**Proof Sketch.** Since the leaders are chosen using the beacon outputs, the probability that the adversary’s nodes are chosen in an epoch \(e\) is \(t/n < 1/2\). The probability that \(c\) consecutive leaders are Byzantine is therefore \(\binom{t}{c}/(n - c)^t < 2^{-c}\) for \(3 < c < t\) and is exponentially decreasing in \(c\). The expected value of \(c\) is \([\log 2] = 2\). If \(c = t + 1\), the probability is already \(\text{negl}(x)\) (from the probability of breaking secrecy of secrets shared by honest nodes). Thus, for a given security parameter \(\kappa\), a static adversary cannot predict the output better than \(\text{negl}(x)\) probability in \(\min(x, t) + 1\) epochs.

**Theorem B.15 (GRandPiper secure random beacon).** GRandPiper protocol is a \(O(\min(x, t))\)-secure random beacon protocol assuming a static adversary.

**Proof.** The proof follows from Lemma B.13 for bias-resistance, Lemma B.12 for guaranteed output delivery, and Lemma B.14 for unpredictability.

**B.3 GRandPiper Security Analysis**

**Theorem B.16 (Security of iVSS).** The verifiable secret sharing scheme proposed in Figure 6 is a secure verifiable secret sharing scheme assuming a bulletin board.

**Proof Sketch.** Consider any secure VSS scheme VSS. The view \(V_i\) of an honest node is \(V_i = \langle \text{VSS.C, VSS.mi, VSS.pi}\rangle\) to every node \(p_i\) in both VSS and the iVSS protocol. Any \(t\)-bounded adversary with access to \(v\) views in both the protocols, has an equal probability of extracting the secret. The case where the adversary forges the digital signatures to obtain \(t + 1\) acks, which happens with negligible probability, is an extra case to consider for the commitment and correctness properties.

Formally, assume a secure VSS scheme satisfying Definition 2.4. Secrecy: If the dealer \(L\) is honest, then no honest node will blame and the maximum number of blames is at most \(t\). Thus, only up to \(t\) blames will be opened privately by the leader. Therefore, the view \(V_T\) of an adversary corrupting \(T \subset [n]\) nodes with \(|T| \leq t\) has the same view in both the protocols. Correctness: If the dealer \(L\) is honest, then all honest nodes have their shares for the secret \(s\), and similar to VSS, will output the same secret \(s\) except with \(\text{negl}(x)\) probability, where the probability is over forging digital signatures. Commitment: If an ack certificate is formed, irrespective of the leader being honest or Byzantine, at least one honest node has not observed \(\geq t + 1\) blames, and has received valid shares for every blame. This honest node, say \(p_i\) has all the shares for every honest node that does not have a share. Therefore, all honest nodes together have \(t + 1\) shares, which guarantees reconstruction to the unique secret \(s\) that was committed except with \(\text{negl}(x)\) probability. If no ack certificate is formed, then all the honest nodes, agree on \(\perp\), thus satisfying the Commitment requirement with high probability of \(1 - \text{negl}(x)\), where the probability is over forging digital signatures and the adversary generating incorrect witnesses.

**Lemma B.17.** If an honest node sends an ack for a sharing block \(SB\) in epoch \(e\), then (i) all honest nodes receive the sharing block \(SB\) in epoch \(e\), (ii) all honest nodes receive their respective secret shares corresponding to sharing block \(SB\) within \(\Delta\) time of entering epoch \(e + 1\).

**Proof.** Suppose an honest node \(p_i\) sends an ack for sharing block \(SB = \langle \text{Commitment, VSS.C, } e, z_{se}\rangle_{E_e}\) at time \(\tau\) in epoch \(e\).
Node $p_i$ must have received up to $t$ blame messages. This implies at least one honest node $p_j$ received a valid share VSS.s and sharing block $SB$ within $3\Delta$ time in epoch $e$ and invoked Deliver($Commitment,SB,z_{se},e$). Let $\tau'$ be the time when node $p_j$ invoked Deliver($Commitment,SB,z_{se},e$). The earliest node $p_i$ sends an ack for $SB$ is when it waits until epoch-$\text{timer}_e \geq 5\Delta$ (i.e., $6\Delta$ in epoch $e$) and does not detect any equivocation by $L_e$ or any blame messages. Due to $\Delta$ delay between honest nodes entering into epoch $e$, this time corresponds to $\tau' + 2\Delta$ in the worst case. This implies no honest node received an epoch $e$ equivocation by time $\tau' + 2\Delta$. By Fact B.1, all honest nodes receives the sharing block $SB$. This proves part (i) of the Lemma.

For part (ii), node $p_i$ can send ack on two occasions: (a) when it does not detect any equivocation or blame until its epoch-$\text{timer}_e \geq 5\Delta$, and (b) when leader $L_{e+1}$ sent valid secret shares for every blame message it forwarded and does not detect any equivocation by time $\tau$.

In case (a), node $p_i$ did not detect any equivocation or blame messages until its epoch-$\text{timer}_e \geq 5\Delta$ at time $\tau$. Observe that all honest nodes must have received valid shares corresponding to the sharing block $SB$ within $3\Delta$ time in epoch $e$; otherwise node $p_i$ must have received blame message by time $\tau$ (since honest nodes may enter epoch $e$ with $\Delta$ time difference and send blame message if no valid secret shares received within $3\Delta$ time in epoch $e$). In addition, no honest node received an equivocating sharing block $SB'$ within $3\Delta$ time in epoch $e$; otherwise, node $p_i$ must have received a share for $SB'$ (via Deliver) by time $\tau$. Thus, all honest nodes receive their respective secret shares corresponding to sharing block $SB$ in epoch $e$ (i.e., within $\Delta$ time of entering epoch $e + 1$).

In case (b), node $p_i$ receives valid secret shares from leader $L_{e+1}$ for every blame (up to $t$ blame) messages it forwarded and detected no equivocation by time $\tau$. Observe that node $p_i$ received $f \leq t$ blame messages and received valid shares for every blame message it forwarded. This implies at least $n - t - f$ honest nodes have received valid shares for sharing block $SB$ from leader $L_{e+1}$ within $3\Delta$ in epoch $e$; otherwise, node $p_i$ would have received more than $f$ blame message by the time its epoch-$\text{timer}_e = 5\Delta$. Since, node $p_i$ forwards $f$ received secret shares corresponding to $f$ received blame message in epoch $e$ and honest nodes enter epoch $e + 1$ within $\Delta$ time, all honest nodes receive their respective secret shares corresponding to sharing block $SB$ within $\Delta$ time of entering epoch $e + 1$.

**Theorem B.18 (Consistent Beacon).** For any epoch $e$, all honest nodes reconstruct the same randomness $R_e$ and output the same beacon $O_e$.

**Proof.** Honest nodes output the same randomness $R_e$ and output the same beacon $O_e$ in epoch $e$ if all honest nodes receive $t+1$ valid homomorphic shares for the same set of secrets. This condition is satisfied if all honest nodes (i) have consistent $Q(p_i)$, $\forall p_i \in \mathcal{P}$ and consistent $P_r$ in each epoch, (ii) $\langle Dequeue(Q(p_i)) \neq \bot, \forall p_i \in \mathcal{P} \setminus \mathcal{P}_r \rangle$ in each epoch, and (iii) share valid homomorphic shares corresponding to dequeued secret shares.

For part (i), we show all honest nodes have consistent $Q(p_i)$, $\forall p_i \in \mathcal{P}$ and consistent $P_r$ in every epoch.

We prove part (i) by induction on epochs. Consider the base case for epochs $1$ to $t$. During setup phase, each node is assigned $m = n + t$ tuples (with each tuple containing secret shares, witnesses and commitments) for each $Q(p_i)$, $\forall p_i \in \mathcal{P}$ (i.e., $m + n$ secrets in total). Since, removing a Byzantine node requires $t + 1$ epochs, all honest nodes have $P_r = \emptyset$ for epochs $1$ to $t$. In addition, no honest node update $Q(p_i)$ during epochs $1$ to $t$. Thus, for epochs $1$ to $t$, all honest nodes have consistent $Q(p_i)$, $\forall p_i \in \mathcal{P}$ and $P_r$.

We assume part(i) holds until epoch $e - 1$.

Consider an epoch $e > t$. In epoch $e$, all honest nodes update only $Q(L_{e-1})$. If $L_{e-1}$ proposed a valid block $B_j$ (with $b_j = (H(SB), \text{ack-cert}(SB))$ for some commitment $SB$ and $B_j$ is committed by epoch $e$, all honest nodes update $Q(L_{e-1})$ with $n$ tuples containing secret shares, witnesses and commitments in $SB$ (by Lemma B.17, all honest nodes receive commitments and secret shares in $SB$ before epoch $e$). Otherwise, all honest nodes update $P_r$ to exclude $L_{e-1}$, i.e., $P_r \leftarrow P_r \cup \{L_{e-1}\}$. Thus, all honest nodes should have consistent $Q(L_{e-1})$ by epoch $e$. Since honest nodes do not update $Q(p_i \neq L_{e-1})$ and do not add $p_j$ into $P_r$ in epoch $e$, by induction hypothesis, all honest nodes should have consistent $Q(p_i) \forall p_i \in \mathcal{P}$ and consistent $P_r$ in epoch $e$. This proves part(i).

Next, we show $\langle Dequeue(Q(p_i)) \neq \bot, \forall p_i \in \mathcal{P} \setminus \mathcal{P}_r \rangle$ in epoch $e$. Suppose for the sake of contradiction, $\langle Dequeue(Q(p_i)) = \bot, \forall p_i \in \mathcal{P} \setminus \mathcal{P}_r \rangle$ in epoch $e$. Observe that, honest nodes update $Q(p_i)$ or include $p_i$ in $P_r$ $t + 1$ epochs after node $p_i$ becomes an epoch leader. Let $e'$ be the last epoch in which node $p_i$ last proposed with $e' \leq e - t$. However, if node $p_i$ did not propose in $e'$, all honest nodes would have removed $p_i$ by epoch $e' + t \leq e$ and $p_i \in P_r$ in epoch $e$. A contradiction.

Finally, we show all honest nodes send valid homomorphic shares for the dequeued secret shares. Observe that honest nodes only dequeue secret shares corresponding to a committed block that contains a valid ack certificate. By Lemma B.17 part(ii), all honest nodes receive valid secret shares before honest nodes update their queues. Thus, all nodes will dequeue common secret shares and will receive at least $t + 1$ valid homomorphic shares for a common secrets and reconstruct the same randomness $R_e$ and output the same beacon $O_e$.

**Lemma B.19 (Liveness).** If the leader $L_e$ of an epoch $e$ is honest, then (i) an ack certificate for its sharing block $SB$ will form in epoch $e - 1$, and (ii) all honest nodes commit $(H(SB), \text{ack-cert}(SB))$ in epoch $e$.

**Proof.** Consider an honest leader $L_e$ for an epoch $e$. Let $\tau$ be the time when leader $L_e$ enters epoch $e - 1$. Leader $L_e$ waits for $\Delta$ time after entering epoch $e - 1$ and must have sent valid shares VSS.s and sharing block $SB$ containing commitments to node $p_j \forall p_j \in \mathcal{P}$ at time $\tau + \Delta$.

Since honest nodes enter epoch $e - 1$ within $\Delta$ time, all honest nodes must have entered epoch $e - 1$ by time $\tau + \Delta$. Leader $L_e$ could have entered epoch $e - 1 \Delta$ time before some honest nodes or Leader $L_e$ could have entered epoch $e - 1 \Delta$ time after some honest nodes. In any case, all honest nodes must have received valid secret shares.
and sharing block $SB$ within $3\Delta$ after entering epoch $e - 1$. Thus, no honest nodes send blame in epoch $e - 1$ and will receive no blame messages from honest nodes within $6\Delta$ time in epoch $e - 1$ (i.e., until epoch-time $e - 1 > 5\Delta$).

Consider an honest node $p_i$. If node $p_i$ receives no blame messages from Byzantine nodes, it will send an ack for sharing block $SB$ to $Le$. On the other hand, if node $p_i$ receives up to $t$ blame messages from Byzantine nodes, it forwards blame messages to $Le$. Honest Leader $Le$ sends the shares corresponding to the blame messages to node $p_i$, which node $p_i$ receives within $8\Delta$ in epoch $e - 1$. Moreover, there is no equivocation from leader $Le$. Thus, node $p_i$ sends an ack for sharing block $SB$ to $Le$.

Thus, all honest nodes send ack for sharing block $SB$ and leader $Le$ receives $t + 1$ ack message for sharing block $SB$ within $10\Delta$ ($Le$ may start epoch $e - 1$ time before node $p_i$ in epoch $e - 1$. This proves part (i) of the Lemma.

Since leader $Le$ proposes a valid proposal $(H(SB), AC_e(SB))$ in epoch $e$, part (ii) follows immediately from Fact B.6.

Lemma B.20 (Guaranteed Beacon Output). For any epoch $e \geq 1$, all the honest nodes output a new beacon output $O_e$.

Proof. Due to the round-robin leader selection, the honest nodes propose in at least $n - t$ epochs out of $n$ epochs. By Lemma B.19, all honest nodes commit $n$ secret shares in every honest epoch and updates their queues after $t + 1$ epochs. Thus, $\text{Dequeue}(Q(p_i)) \neq \perp \forall p_i \in \mathcal{P} \setminus \mathcal{P}_r$, where $p_i$ is an honest node. From the proof of Theorem B.18, all honest nodes have consistent queues and $\mathcal{P}_r$ in each epoch. At the end of each epoch, all honest nodes dequeue common secret shares and send homomorphic sums to all other nodes. Thus, honest nodes will have $t + 1$ valid homomorphic sums and will output new beacon outputs in every epochs.

Lemma B.21 (Communication Complexity). Let $f \leq t$ be the number of actual Byzantine faults, $k$ be the size of accumulator and $w$ be the size of witness. The amortized communication complexity of the protocol is $O(kf n^2 + (k + w)n^2)$ bits per epoch.

Proof. In the Block validation protocol, distributing $O(kn)$-sized commitment costs $O(kn^2)$ bits in communication. Sending corresponding $O(kn)$-sized secret shares and $O(wn)$-sized witness incur $O((k + w)n^2)$ communication. Up to $f$ Byzantine nodes can always blame even if the epoch leader is honest. Thus, an epoch leader needs to send $O(kfn)$-sized secret shares while privately opening the secret shares. The nodes also forward privately opened secret secrets to nodes that blamed. This step costs $O(kfn^2)$ communication in an honest epoch. When the leader is Byzantine, it can create a scenario when up to $t$ nodes send blame and hence, this step has $O(kn^2)$ cost. Out of $n$ consecutive epochs, there can be at most $f$ Byzantine epochs and $n - f$ honest epochs. Hence, this step has amortized complexity of $O(kfn^2)$.

By Lemma B.8, the SMR protocol has a cost of $O((k + w)n^2)$ bits for input of size $O(kn)$. The homomorphic sum of secret shares is $k$ and homomorphic sum of witness is $w$. Thus, all-to-all broadcast of homomorphic sums incurs $O((k + w)n^2)$. Thus, the amortized communication complexity is $O(kfn^2 + (k + w)n^2)$ bits per epoch.

Theorem B.22 (Secure VSS). Assuming a secure VSS scheme VSS, the BRandPiper protocol is a secure verifiable secret sharing protocol with the dealer as the leader of an epoch, and the rest of the nodes as the verifiers.

Proof Sketch. The view of an adversary $\mathcal{A}$ in BRandPiper is the same as the view of an adversary running one instance of iVSS assuming a bulletin board. Therefore, an adversary that can break the secrecy property in BRandPiper protocol can also break the secrecy in iVSS, which in turn can break the secrecy property from VSS (Theorem B.16). The commitment property has an additional failure probability arising from the case where the adversary can forge $t + 1$ signatures which occurs with $\negl(k)$ probability.

Formally, we prove the security of VSS by proving the individual properties:

Secrecy: For an honest leader $Le$ of epoch $e$, no honest node will blame, and therefore an adversary $\mathcal{A}$ will only learn the $t$ shares of its own corruption, and not learn any new share by blaming. Therefore the probability of $\mathcal{A}$ violating the secrecy property is $\negl(k)$ from the underlying VSS scheme, since the views are identical to that of iVSS.

Correctness: For an honest leader $Le$ of epoch $e$, from Lemma B.19, all the honest nodes commit the $SB$ with shares for the secret. During the reconstruction for the beacon, every honest node $p_i \in \mathcal{P}$ use the same share for $SB$ within $\mathcal{P}_r$. This scheme is identical to the Pedersen VSS [38] of violating the secrecy property is $\negl(k)$, thereby ensuring that the correctness property is maintained.

Commitment: If an honest node commits a valid block $SB$ from a Byzantine leader $Le$ in some epoch $e$, then all honest nodes commit $SB$ from the SMR property in Theorem B.5. Therefore during reconstruction, a Byzantine node $p_j \in \mathcal{P}$ cannot provide a valid witness $VSS.\pi_{Le,j}$ for an incorrect share with probability better than $\negl(k)$, thereby ensuring that the correctness property is maintained.

Concrete Instantiations. Consider instantiating VSS using the Pedersen commitment based VSS [32] using the polynomial commitment scheme. This scheme is identical to the Pedersen VSS [38] which is an information-theoretic VSS scheme except that the polynomial commitment based on $q$-SDH is used. The polynomial commitment scheme however is identical to the Pedersen commitment and is unconditionally hiding. Since our SMR is adaptively secure, and our VSS scheme is unconditionally hiding, BRandPiper is also adaptively secure. For the binding part, as shown in [32], one can show a reduction to an adversary violating the binding property to an adversary violating the $q$-SDH assumption.

Lemma B.23 (Bias-resistance). For any epoch $e \geq 1$, the probability that a $t$-bounded adversary $\mathcal{A}$ can fix any $c$ bits of the BRandPiper beacon output $O_e$ is $\negl(c) + \negl(k)$.

Proof Sketch. The output in any epoch $e$ is $O_e \leftarrow H(R_e)$, where $R_e$ is the homomorphic sum of secrets from at least $t + 1$ honest nodes. From the secrecy guarantee in Theorem B.22, we know that no adversary $\mathcal{A}$ can predict the value of these honest nodes until reconstruction with probability better than $\negl(k)$. At
the same time, no adversary \( \mathcal{A} \) can change the committed value for any \( p_i \) during reconstruction due to the commitment guarantee from Theorem B.22 with probability better than \( \text{negl}(\kappa) \). Therefore, a \( t \)-bounded adversary cannot do better than guessing whose probability is \( \text{negl}(c) + \text{negl}(\kappa) \) to fix \( c \) bits in the output \( O_e \) for any epoch \( e \geq 1 \).

**Lemma B.24 (Rushing Adversary Advantage).** For any epoch \( e \), a rushing adversary can reconstruct output \( O_e \) at most \( 2\Delta \) time before honest nodes.

The proof remains identical to Lemma B.11.

**Lemma B.25 (BRandPiper 1-absolute unpredictability).** The BRandPiper random beacon protocol is an 1-absolute unpredictable random beacon.

**Proof Sketch.** Since our SMR protocol is adaptively secure and our protocol is as secure as VSS, we can instantiate VSS with Pedersen VSS which is information theoretically secure but at the cost of communication complexity to prove adaptive security of BRandPiper. By instantiating VSS with eVSS [32], we do not know how to show adaptive security using existing proof techniques. However, no adaptive attacks against eVSS are known either.

Let \( \tau \) be some time at which all honest nodes are in an epoch \( e \geq 1 \). We show that an adversary \( \mathcal{A} \) cannot predict \( O_{e+1} \). Due to the secrecy property in Theorem B.22 and the fact that the beacon output \( O_{e+1} \) is derived from the reconstruction of \( R_{e+1} \), which is a homomorphic sum of inputs from at least \( n - t > t \) nodes, any adversary \( \mathcal{A} \) cannot predict \( O_{e+1} \). The values from the honest nodes are guaranteed to be truly random (by definition). Therefore, the output \( O_{e+1} \) is unpredictable for an adversary \( \mathcal{A} \).

An adversary \( \mathcal{A} \) can get a 1 epoch advantage since there can exists times \( \tau \) where some honest nodes are in epoch \( e \) and others are in epoch \( e - 1 \). At this point, a rushing adversary knows the output \( O_e \) before the honest nodes.

**Theorem B.26 (BRandPiper Secure Random Beacon).** BRandPiper protocol is a 1-secure random beacon.

## C CLOCK SYNCHRONIZATION FOR NEW NODES

In this section, we present a clock synchronization protocol to synchronize some additional nodes when majority of honest nodes are synchronized. Such a synchronization is useful during reconfiguration when a new node joins the system. Prior known clock synchronization protocol [1] can be used to synchronize all nodes with a communication cost of \( O(kn^2) \) without threshold signatures. This holds true even when synchronizing a single node in the system where a majority of nodes are already synchronized.

Our clock synchronization protocol to add new nodes (refer Figure 11) makes use of VSS secret sharing scheme presented in Section 4.2.2. Our approach requires a total communication complexity of \( O(kn^3) \); however, this can be split over \( O(n) \) iterations with \( O(kn^2) \) communication. This will be useful in our beacon protocol to maintain quadratic communication complexity in each round.

Our protocol uses the fact that \( O(t) \) secret shares can be homomorphically combined to a single secret share of size \( O(1) \) and \( t + 1 \) homomorphic secret shares can be be opened to get a \( O(k) \) sized secret. The opened secret can be broadcast among all nodes to synchronize the clocks of all honest nodes including the new joining node within \( \Delta \) time from each other.

The first honest node to reset epoch-timer for some epoch \( e \) will broadcast sync message containing \( R_e \), which makes all other honest nodes reset their epoch-timer, \( e \), within \( \Delta \) time. Observe that since the size of homomorphic \( R_e \) is \( O(k) \) bits, an all-to-all broadcast has a cost of \( O(kn^2) \) bits.

## D RECONFIGURATION

In this section, we present reconfiguration mechanisms for our beacon protocols to restore the resilience of the protocol after removing some Byzantine nodes. We make following modification to the protocols. Each node maintains a variable \( n_l \) that records the number of additional nodes that can be added to the system. Variable \( n_l \) is incremented each time a Byzantine node is added to set \( \mathcal{P}_f \) and is decreased by one when a new node joins the system. The value of \( n_l \) can be at most \( t \).

The generic reconfiguration protocol is presented in Figure 12. The reconfiguration protocol applies to both beacon protocols. Later, we make appropriate modifications for each beacon protocols.

**Lemma D.1 (Liveness).** If \( n_l > 0 \) at some epoch \( e^* \) and there are new nodes intending to join the system in epochs \( \geq e^* \), then eventually a new node will be added to the system.

**Proof.** Suppose \( n_l > 0 \) and a new node \( p_i \) intends to join the system. Suppose for the sake of contradiction, no new node including \( p_i \) is added to the system. However, since node \( p_i \) intends to join the system, it must have sent inquire requests to all nodes in the system and at least \( t + 1 \) honest nodes will respond to the inquire request since \( n_l > 0 \) at the end of some epoch \( e^* \geq e^* \).

Let node \( p_i \) send join request along with an inquire certificate and nodes receive the request in epoch \( e \geq e^* \). The first honest leader \( L_{e^*} \) of epoch \( e^{*} \geq e \) will include the joint request in its block proposal if no new node has been added to the system since epoch \( e \) and there does not exist any block proposal with a join request in the last \( t + 1 \) epochs in its highest ranked chain and by Fact B.6, the block proposal with join request will be committed. A contradiction.

If some node has already been added to the system since epoch \( e^* \), this trivially satisfies the statement. Thus, we obtain a contradiction.

**D.1 Reconfiguration for GRandPiper**

Node \( p_k \) generates a PVSS (PVSS.\( \mathcal{E} \), PVSS.\( \tilde{E} \), PVSS.\( \pi \) \leftarrow PVSS.ShGen(\( R \)) of a random value chosen from the input space of PVSS for nodes \( \mathcal{P} \cup \{p_k\} \setminus \mathcal{P}_f \). During the join phase in the reconfiguration protocol (refer Figure 12), it sends a join request to all nodes \( \mathcal{P} \setminus \mathcal{P}_f \) with entity \( \mathcal{M} \) set to the above PVSS. In addition, all nodes update...
Let clock synchronization protocol start in epoch $e$. Node $p_1 \in \mathcal{P}$ performs the following:

1. **Share secrets.** Leaders $\{L_e, \ldots, L_{e+t}\}$ use block validation (refer Figure 8) and the BFT protocol to commit secrets $(s_e, \ldots, s_{e+t})$ respectively. E.g., Leader $L_e$ uses the block validation protocol while in epoch $e-1$ to share a single secret $s_e$ chosen uniformly at random and collect an ack certificate $\mathcal{AC}(SB)$ on the commitment $SB$ for secret $s_e$. In epoch $e$, Leader $L_e$ proposes block $B_e := (H(SB), \mathcal{AC}(SB))$.

2. **Reconstruct.** When epoch-time $e+t$ expires, perform the following:
   - Build homomorphic sum share $SV_i$, witness VSS-$n_i$, and commitment $VSS.C_e$ using secret shares for $(s_e, \ldots, s_{e+t})$. Send $SV_i$ and VSS-$n_i$ to all the nodes.
   - Upon receiving share $SV_i$ and witness VSS-$n_j$ for $VSS.C_e$, ensure that $VSS.Sh_{Vrfy}(SV_j, VSS.n_j, VSS.C_e) = 1$.
   - Upon receiving $t+1$ valid homomorphic sum shares in $SV$, obtain $R_e \leftarrow VSS.Recon(SV)$. 

3. **Synchronize.** The first time node $p_j$ receives a valid homomorphic secret $R_e$, either through reconstruction or on receiving sync message from other nodes, (i) it resets its epoch-time to the beginning of epoch $e+2t+1$, and (ii) broadcasts a sync message containing $R_e$ to all other nodes.

**Figure 11: Clock synchronization protocol**

A new node $p_k$ that intends to join the system uses the following procedure to join the system.

1. **Inquire.** Node $p_k$ inquires all nodes in the system to send the set of active nodes, i.e., $\mathcal{P} \setminus \mathcal{P}_r$. Upon receiving the inquire request, an honest node $p_i$ responds to the request only if $n_i > 0$. Node $p_i$ sends $\mathcal{P} \setminus \mathcal{P}_r$ at the end of some epoch $e'$ in which the inquire request was received. Node $p_k$ waits for at least $t+1$ consistent responses from the same epoch $e'$ and forms an inquire certificate. An inquire certificate is valid if it contains $t+1$ inquire responses that belong to the same epoch $e'$ and contains the same set of active nodes.

2. **Join.** Node $p_k$ sends a join request to all nodes $\mathcal{P} \setminus \mathcal{P}_r$ along with the inquire certificate and an additional entity $M$ specific to the beacon protocols.

3. **Propose.** Upon receiving the join request, the leader $L_e$ of current epoch $e$ adds the join request containing inquire certificate and entity $M$ in its block proposal $B_e$ if (i) $L_e$ does not observe a block proposal with a join request in last $t+1$ epochs in its highest ranked chain and (ii) no new node has been added since epoch $e'$.

4. **Update.** If the block $B_e$ with the join request from node $p_k$ is proposed in epoch $e$ gets committed by epoch $e+t$, update $n_i \leftarrow n_i-1$ in epoch $e+t$ and send $\mathcal{P} \setminus \mathcal{P}_r$ to node $p_k$. Henceforth, $p_k$ becomes a passive node and receives all protocol messages from active nodes.

5. **Synchronize.** Nodes execute clock synchronization protocol (refer Figure 11) from epoch $e+t+2$ to synchronize node $p_k$. All nodes including node $p_k$ are synchronized in epoch $e+3t+3$. At epoch $e+3t+3$ update $\mathcal{P} \leftarrow \mathcal{P} \cup \{p_k\}$. Henceforth, node $p_k$ becomes an active node and participates in the protocol. Additionally, node $p_k$ participates in the reconstruction protocol only if it has required secret shares.

If node $p_k$ fails to join the system, it restarts reconfiguration process again after some time.

**Figure 12: Reconfiguration protocol**

$Q(p_k)$ with the PVSS provided by node $p_k$ once its join request gets committed.

An adaptive adversary can corrupt any node as long as $t+1$ honest nodes have full queue $Q(p_j) \neq \emptyset \forall p_j \in \mathcal{P} \setminus \mathcal{P}_r$, i.e., if the adversary already corrupted $t$ nodes some of which are removed, the adversary can corrupt old honest nodes only when node $p_k$ has full queue $(i.e., Q(p_j) \neq \emptyset \forall p_j \in \mathcal{P} \setminus \mathcal{P}_r)$. This happens when all nodes in $\mathcal{P} \setminus \mathcal{P}_r$ become a leader at least once after node $p_k$ becomes a leader. Due to random leader election, the expected number of epochs required for all nodes to be selected as leaders is $\sum_{i=0}^{n} \frac{1}{i} = \Theta(n \log n)$.

**Remark.** GRandPiper beacon protocol can employ a rotating leader election for BFT SMT with randomized leaders for reconstruction phase. With this change, the adaptive resilience of GRandPiper is restored in $n + t + 1$ epochs compared to expected $n \log n$ epochs.

**Theorem D.2.** GRandPiper protocol maintains safety and liveness after reconfiguration.

**Proof.** Let node $p_1$ be the new joining node. GRandPiper protocol is safe and live before reconfiguration. Since we assume the adversary can corrupt a new node as long as $t+1$ honest nodes have full queue, i.e., $Q(p_j) \neq \emptyset \forall p_j \in \mathcal{P} \setminus \mathcal{P}_r$, there will always be $t+1$ honest nodes with correct secret shares. Hence, the protocol maintains safety and liveness after reconfiguration.

**D.2 Reconfiguration for BRandPiper**

Node $p_k$ that intends to join the system uses the reconfiguration protocol (Figure 12) to join the system. During the join phase, node $p_k$ does not need to send any additional commitment i.e., sets $M := \emptyset$. Once node $p_k$ becomes the active node, it is then allowed to become a leader using round-robin leader election and shares VSS commitments to $n$ secrets when it becomes the leader. All active nodes use the secret shares for node $p_k$ only when they have committed the commitment shared by node $p_k$.

Like the reconfiguration for GRandPiper protocol, an adaptive adversary can corrupt any node as long as $t+1$ honest nodes have full queue $Q(p_j) \neq \emptyset \forall p_j \in \mathcal{P} \setminus \mathcal{P}_r$. I.e., if the adversary already corrupted $t$ nodes some of which are removed, the adversary can corrupt old honest nodes only when node $p_k$ has full queue (i.e., $Q(p_j) \neq \emptyset \forall p_j \in \mathcal{P} \setminus \mathcal{P}_r$). This happens when all nodes in $\mathcal{P} \setminus \mathcal{P}_r$ becomes a leader at least once after node $p_k$ becomes a leader. Due to the round-robin leader election, node $p_k$ will have full queue after $n + t + 1$ epochs after it has become an active node.

**Theorem D.3.** BRandPiper protocol maintains safety and liveness after reconfiguration.

The proof remains identical to Theorem D.2.
