

# AUTOMORPHISMS AND ISOGENY GRAPHS OF ABELIAN VARIETIES, WITH APPLICATIONS TO THE SUPERSPECIAL RICHELLOT ISOGENY GRAPH

ENRIC FLORIT AND BENJAMIN SMITH

ABSTRACT. We investigate special structures due to automorphisms in isogeny graphs of principally polarized abelian varieties, and abelian surfaces in particular. We give theoretical and experimental results on the spectral and statistical properties of  $(2, 2)$ -isogeny graphs of superspecial abelian surfaces, including stationary distributions for random walks, bounds on eigenvalues and diameters, and a proof of the connectivity of the Jacobian subgraph of the  $(2, 2)$ -isogeny graph. Our results improve our understanding of the performance and security of some recently-proposed cryptosystems, and are also a concrete step towards a better understanding of general superspecial isogeny graphs in arbitrary dimension.

## 1. INTRODUCTION

When studying the internal structure of isogeny classes of abelian varieties from an algorithmic point of view, we work with *isogeny graphs*: the vertices are isomorphism classes of abelian varieties, and the edges are isomorphism classes of isogenies, often of some fixed degree. For elliptic curves, these graphs have already had a wealth of applications. Mestre [32] used his *méthode des graphes* to compute a basis of the space  $S_2(N)$  of modular forms of weight 2, level  $N$ , and trivial character. Kohel [28] used isogeny graphs to compute endomorphism rings of elliptic curves over finite fields, and Fouquet and Morain turned this around to improve point-counting algorithms for elliptic curves [17]. Bröker, Lauter, and Sutherland [8] developed an algorithm for computing modular polynomials using isogeny graph structures; Sutherland [41] has used the difference between the structures of ordinary and supersingular isogeny graphs to give a remarkable and efficient deterministic supersingularity test for elliptic curves.

More recently, isogeny graphs have become a setting for post-quantum cryptographic algorithms, especially in the supersingular case. Charles, Goren, and Lauter proposed a cryptographic hash function with provable security properties based on combinatorial properties of the supersingular elliptic 2-isogeny graph [12]. Ros-tovtsev and Stolbunov proposed a key exchange scheme based on ordinary isogeny graphs [38, 40]; this was vastly accelerated by Castryck, Lange, Martindale, Panny, and Renes by transposing it to a subgraph of the supersingular isogeny graph, where it is known as CSIDH [10]. Jao and De Feo's SIDH key exchange algorithm [25, 14], the basis of SIKE [2] (a third-round alternate candidate in the NIST post-quantum cryptography standardization process), is based on the difficulty of finding paths

in the elliptic supersingular 2- and 3-isogeny graphs. These applications all depend, both in their constructions and in their security arguments, on a precise understanding of the combinatorial properties of supersingular isogeny graphs.

It is natural to try to extend these applications to the setting of isogeny graphs of higher-dimensional principally polarized abelian varieties (PPAVs). First steps in this direction have been made by Charles, Goren, and Lauter [11], Takashima [42], Flynn and Ti [16], and Castryck, Decru, and Smith [9]. Costello and Smith have proposed an attack on cryptosystems based on the difficulty of computing isogenies between higher-dimensional superspecial abelian varieties [13].

But so far, the efficiency and security of these algorithms is conjectural—even speculative—because of a lack of information on combinatorial properties of supersingular isogeny graphs in higher dimension, such as their connectedness, their diameter, and their expansion constants. For example, the hash functions typically depend on the rapid convergence of random walks to the uniform distribution on the isogeny graph; but while this is well-known for the elliptic case, it is not yet well-understood even in  $g = 2$ . Indeed, even the connectedness of the superspecial graph for  $g = 2$  has only recently been proven by Jordan and Zaytman [26].

Our ultimate aim is a deeper understanding of the combinatorial and spectral properties of the superspecial graph, such as its diameter and the limit distribution of random walks. In this article we give some general theoretical results, but our experimental results are focused on the *Richelot isogeny graph*: that is, the case  $g = 2$  and  $\ell = 2$ . Richelot isogeny graphs are the most amenable to explicit computation (apart from elliptic graphs), and already exhibit a particularly rich structure.

After recalling basic results in §2, we explore the impact of automorphisms of PPAVs on edge weights in the isogeny graph for general  $g$  and  $\ell$  in §3. Automorphisms are a complicating factor that can almost be ignored in elliptic isogeny graphs, since only two vertices (corresponding to  $j$ -invariants 0 and 1728) have automorphisms other than  $\pm 1$ . In higher dimensions, however, extra automorphisms are much more than an isolated corner-case: every general product PPAV  $\mathcal{A} \times \mathcal{B}$  has an involution  $[1]_{\mathcal{A}} \times [-1]_{\mathcal{B}}$  which may induce nontrivial weights in the isogeny graph, and entire families of simple PPAVs can come equipped with extra automorphisms, as we will see in §6 for dimension  $g = 2$ . The *ratio principle* proven in Lemma 1, which relates automorphism groups of  $(\ell, \dots, \ell)$ -isogenous PPAVs with the weights of the directed edges between them in the isogeny graph, is an essential tool for our later investigations.

We consider the spectral and statistical properties of isogeny graphs, still in the most general setting, in §4. Here we prove results which, combined with an understanding of the automorphism groups of vertices, allow us to compute stationary distributions for random walks in the superspecial isogeny graph—and also in interesting subgraphs of the superspecial graph, such as the Jacobian subgraph. After stating general theoretical bounds on eigenvalues, we give experimental data for diameters and second eigenvalues of superspecial Richelot isogeny graphs (and Jacobian subgraphs) for  $17 \leq p \leq 601$ .

We recall Bolza’s classification of automorphism groups of genus-2 Jacobians in §6, and apply it in the context of Richelot isogeny graphs (extending the results of Katsura and Takashima [27]). This allows us to prove that the Jacobian subgraph

of the Richelot isogeny graph is connected and aperiodic, and to bound its diameter relative to the diameter of the entire superspecial graph.

Our results have an immediate impact on the security and efficiency arguments in [42], [16], [9], and [13]. For example, we can estimate the frequency which elliptic products are encountered during random walks in the superspecial graph, which is essential for understanding the true efficiency of the attack in [13]; and we can understand the stationary distribution for random walks restricted to the Jacobian subgraph (which were used in [9]). Our results also offer a concrete step towards a better understanding of the situation for general superspecial isogeny graphs—that is, in arbitrary dimension  $g$ , and with  $(\ell, \dots, \ell)$ -isogenies for arbitrary primes  $\ell$ .

## 2. ISOGENY GRAPHS

**Definition 1.** Let  $\mathcal{A}/\mathbb{k}$  be a principally polarized abelian variety (PPAV) and  $\ell$  a prime, not equal to the characteristic of  $\mathbb{k}$ . A subgroup of  $\mathcal{A}[\ell]$  is **Lagrangian** if it is maximally isotropic with respect to the  $\ell$ -Weil pairing. An  $(\ell, \dots, \ell)$ -**isogeny** is an isogeny  $\mathcal{A} \rightarrow \mathcal{A}'$  of PPAVs whose kernel is a Lagrangian subgroup of  $\mathcal{A}[\ell]$ .

If  $\mathcal{A}$  is a  $g$ -dimensional PPAV, then every Lagrangian subgroup of  $\mathcal{A}[\ell]$  is necessarily isomorphic to  $(\mathbb{Z}/\ell\mathbb{Z})^g$ , though the converse does not hold. Since its kernel is Lagrangian, an  $(\ell, \dots, \ell)$ -isogeny  $\phi : \mathcal{A} \rightarrow \mathcal{A}'$  respects the principal polarizations: if  $\lambda$  and  $\lambda'$  are the principal polarizations on  $\mathcal{A}$  and  $\mathcal{A}'$ , respectively, then the pullback of  $\phi^*(\lambda')$  is equal to  $\ell\lambda$ .

Given another  $g$ -dimensional PPAV  $\mathcal{A}'$ , we say two Lagrangian subgroups  $K$  of  $\mathcal{A}[\ell]$  and  $K'$  of  $\mathcal{A}'[\ell]$  yield **isomorphic isogenies**  $\phi$  and  $\phi'$ , if there are isomorphisms  $\alpha : \mathcal{A} \rightarrow \mathcal{A}'$  and  $\beta : \mathcal{A}/K \rightarrow \mathcal{A}'/K'$  respecting the principal polarizations, such that the following diagram commutes:

$$\begin{array}{ccc} \mathcal{A} & \xrightarrow{\alpha} & \mathcal{A}' \\ \phi \downarrow & & \downarrow \phi' \\ \mathcal{A}/K & \xrightarrow{\beta} & \mathcal{A}'/K' \end{array}$$

In this case, the dual isogenies  $\phi^\dagger$  and  $\phi'^\dagger$  are also isomorphic.

**Definition 2.** Fix a positive integer  $g$  and a prime  $p$ . The  $(\ell, \dots, \ell)$ -**isogeny graph**, denoted  $\Gamma_g(\ell; p)$ , is the directed weighted multigraph defined as follows.

- The **vertices** are isomorphism classes of PPAVs defined over  $\overline{\mathbb{F}}_p$ . If  $\mathcal{A}$  is a PPAV, then  $[\mathcal{A}]$  denotes the corresponding vertex.
- The **edges** are isomorphism classes of  $(\ell, \dots, \ell)$ -isogenies, **weighted** by the number of distinct kernels yielding isogenies in the class. The weight of an edge  $[\phi]$  is denoted by  $w([\phi])$ .

If  $[\phi] : [\mathcal{A}] \rightarrow [\mathcal{A}']$  is an edge, then  $w([\phi]) = n$  if and only if there are  $n$  Lagrangian subgroups  $K \subset \mathcal{A}[\ell]$  such that  $\mathcal{A}' \cong \mathcal{A}/K$  (this definition is independent of the choice of representative isogeny  $\phi$ ). Equivalently, if there is an  $(\ell, \dots, \ell)$ -isogeny  $\phi : \mathcal{A} \rightarrow \mathcal{A}'$ , then  $w([\phi])$  is equal to the size of the orbit of  $\ker \phi$  under the action of  $\text{Aut}(\mathcal{A})$  on the set of Lagrangian subgroups of  $\mathcal{A}[\ell]$ .

The isogeny graph breaks up into components; there are at least as many connected components as there are isogeny classes over  $k$ . We are particularly interested in the superspecial isogeny class.

**Definition 3.** A PPAV  $\mathcal{A}/\overline{\mathbb{F}}_p$  of dimension  $g$  is **superspecial** if its Hasse–Witt matrix vanishes identically. Equivalently,  $\mathcal{A}$  is superspecial if it is isomorphic as an unpolarized abelian variety to a product of supersingular elliptic curves.

For general facts and background on superspecial and supersingular abelian varieties, we refer to Li and Oort [30], and Brock’s thesis [6] (especially in lower dimensions).

**Definition 4.** The  $(\ell, \dots, \ell)$ -isogeny graph of  $g$ -dimensional superspecial PPAVs over  $\overline{\mathbb{F}}_p$  is denoted by  $\Gamma_g^{SS}(\ell; p)$ . We will often refer to  $\Gamma_g^{SS}(\ell; p)$  as the superspecial graph, with  $g$ ,  $\ell$ , and  $p$  implicit.

The graph  $\Gamma_g^{SS}(\ell; p)$  is regular, and Jordan and Zaytman recently proved that  $\Gamma_g^{SS}(\ell; p)$  is connected (see [26]; though this result was already implicit, in a different language, in [34, Lemma 7.9]). If an elliptic curve is supersingular, then it is isomorphic to a curve defined over  $\mathbb{F}_{p^2}$ . Similarly, if  $\mathcal{A}/\overline{\mathbb{F}}_p$  is superspecial, then it is isomorphic to a PPAV defined over  $\mathbb{F}_{p^2}$  (so in our experiments involving superspecial graphs, we work over  $\mathbb{F}_{p^2}$  for various  $p$ ).

### 3. ISOGENIES AND AUTOMORPHISMS

Isogeny graphs are weighted directed graphs, and before going any further, we should pause to understand the weights. The weights of the edges are closely related to the automorphism groups of the vertices that they connect, as we shall see.

Let  $\phi : \mathcal{A} \rightarrow \mathcal{A}/K$  be an  $(\ell, \dots, \ell)$ -isogeny with kernel  $K$ . Let  $\alpha$  be an automorphism of  $\mathcal{A}$ , write  $K_\alpha$  for  $\alpha(K)$ , and let  $\phi' : \mathcal{A} \rightarrow \mathcal{A}/K_\alpha$  be the quotient isogeny; then  $\alpha$  induces an isomorphism  $\alpha_* : \mathcal{A}/K \rightarrow \mathcal{A}/K_\alpha$  such that  $\alpha_* \circ \phi = \phi' \circ \alpha$ .

If  $K_\alpha = K$ , then  $\mathcal{A}/K = \mathcal{A}/K_\alpha$ , so  $\alpha_*$  is an automorphism of  $\mathcal{A}/K$ . Going further, if  $S$  is the stabiliser of  $K$  in  $\text{Aut}(\mathcal{A})$ , then  $S$  induces an isomorphic subgroup  $S'$  of  $\text{Aut}(\mathcal{A}/K)$ .

If  $K_\alpha \neq K$  then  $\alpha$  does not induce an automorphism of  $\mathcal{A}/K$ : the quotients  $\mathcal{A}/K$  and  $\mathcal{A}/K_\alpha$  are different, so  $\alpha_*$  is an isomorphism but not an automorphism. Let  $\phi_\alpha = \alpha_*^{-1} \circ \phi'$ . The isogenies  $\phi$  and  $\phi_\alpha$  have identical domains and codomains, but distinct kernels; thus, they both represent the same edge in the isogeny graph, and  $w([\phi]) > 1$ . Going further, if  $O_K$  is the orbit of  $K$  under  $\text{Aut}(\mathcal{A})$ , then there are  $\#O_K$  distinct kernels of isogenies representing  $[\phi]$ : that is,  $w([\phi]) = \#O_K$ .

Looking at the dual isogenies, we see that  $\alpha^{-1} \circ (\phi_\alpha)^\dagger \circ \phi = [\ell]_{\mathcal{A}}$ , so  $\phi^\dagger$  and  $\phi_\alpha^\dagger$  have the same kernel. Hence, while automorphisms of  $\mathcal{A}$  may lead to increased weight on the edge  $[\phi]$ , they have no effect on the weight of the dual edge  $[\phi^\dagger]$ .

Every PPAV has  $[-1]$  in its automorphism group, but  $[-1]$  fixes every kernel and commutes with every isogeny. Since  $[-1]$  has no impact on edges or weights in the isogeny graph, we lose nothing by quotienting it out of the picture.

**Definition 5.** If  $\mathcal{A}$  is a PPAV, then its **reduced automorphism group** is

$$\text{RA}(\mathcal{A}) := \text{Aut}(\mathcal{A}) / \langle [-1] \rangle.$$

Since  $\langle [-1] \rangle$  is contained in the centre of  $\text{Aut}(\mathcal{A})$ , the quotient  $\text{RA}(\mathcal{A})$  acts on the set of Lagrangian subgroups of  $\mathcal{A}[\ell]$ . This is crucial in what follows.

**Lemma 1.** *Let  $\phi : \mathcal{A} \rightarrow \mathcal{A}'$  be an  $(\ell, \dots, \ell)$ -isogeny, and let  $S$  be the stabiliser of  $\ker(\phi)$  in  $\text{RA}(\mathcal{A})$ .*

- (1) *The isogeny  $\phi$  induces a subgroup  $S'$  of  $\text{RA}(\mathcal{A}')$  isomorphic to  $S$ , and  $S'$  is the stabiliser of  $\ker \phi^\dagger$  in  $\text{RA}(\mathcal{A}')$ .*
- (2) *If  $s := \#S$  (so  $s = \#S'$ ), then in the  $(\ell, \dots, \ell)$ -isogeny graph we have*

$$w([\phi]) = \#\text{RA}(\mathcal{A})/s \quad \text{and} \quad w([\phi^\dagger]) = \#\text{RA}(\mathcal{A}')/s.$$

*In particular,*

$$(1) \quad \#\text{RA}(\mathcal{A}) \cdot w([\phi^\dagger]) = \#\text{RA}(\mathcal{A}') \cdot w([\phi]).$$

*Proof.* Let  $K := \ker(\phi)$  be the kernel of  $\phi$ . As discussed above, for each  $\alpha$  in  $\text{Aut}(\mathcal{A})$  we have an induced isomorphism  $\alpha_* : \mathcal{A}' \rightarrow \mathcal{A}/\alpha(K)$ , and if  $\alpha$  stabilises  $K$ , then  $\alpha_*$  is an automorphism of  $\mathcal{A}'$ . As  $\alpha$  stabilises  $\mathcal{A}[\ell]$ , this gives an inclusion of  $S$  into  $S'$ . The reverse inclusion comes from the symmetric argument on the dual.

The second statement follows from the orbit-stabiliser theorem. Note we only need to consider the action by reduced automorphisms, as  $[-1]$  acts trivially on all subgroups of  $\mathcal{A}$ .  $\square$

To understand the isogeny graph, then, we need to understand the reduced automorphism groups of its vertices. A generic PPAV  $\mathcal{A}$  has  $\text{Aut}(\mathcal{A}) = \langle [-1] \rangle$ , so  $\text{RA}(\mathcal{A}) = 1$ . The simplest examples of nontrivial reduced automorphism groups are the elliptic curves with  $j$ -invariants 0 and 1728. Moving into higher dimensions, nontrivial reduced automorphism groups are more common: for example, if  $\mathcal{A} = \mathcal{E} \times \mathcal{E}'$  is a product of elliptic curves, then  $[1]_{\mathcal{E}} \times [-1]_{\mathcal{E}'}$  is a nontrivial involution in  $\text{RA}(\mathcal{E} \times \mathcal{E}')$ . We will see many more examples of nontrivial reduced automorphism groups below.

For now, it is good to keep in mind the graph  $\Gamma_2^{SS}(2; 11)$ , shown in Figure 1. It contains the following five nodes:

- $\mathcal{A}_1 = \mathcal{J}(\mathcal{C}_1)$ , for  $\mathcal{C}_1: y^2 = x^6 - 1$ , with  $\text{RA}(\mathcal{A}_1) = D_{2 \times 6}$ .
- $\mathcal{A}_2 = \mathcal{J}(\mathcal{C}_2)$ , for  $\mathcal{C}_2: y^2 = (x^3 - 1)(x^3 - 3)$ , with  $\text{RA}(\mathcal{A}_2) = S_3$ .
- $\mathcal{E}_{1728}^2$ , where  $\mathcal{E}_{1728}: y^2 = x^3 - x$ , and  $\#\text{RA}(\mathcal{E}_{1728}^2) = 16$ .
- $\mathcal{E}_0^2$ , where  $\mathcal{E}_0: y^2 = x^3 - 1$ , and  $\#\text{RA}(\mathcal{E}_0^2) = 36$ .
- $\Pi = \mathcal{E}_0 \times \mathcal{E}_{1728}$ , with  $\#\text{RA}(\Pi) = 12$ .

The weights indicated in the figure indeed satisfy Equation (1). For instance, there is a unique isogeny  $\phi: \mathcal{E}_{1728}^2 \rightarrow \mathcal{E}_0^2$  (up to isomorphism), and

$$\frac{w([\phi])}{w([\phi^\dagger])} = \frac{4}{9} = \frac{16}{36} = \frac{\#\text{RA}(\mathcal{E}_{1728}^2)}{\#\text{RA}(\mathcal{E}_0^2)}.$$

*Remark 1.* Reduced automorphism groups are usually defined for hyperelliptic curves, not abelian varieties, but if  $\mathcal{A} = \mathcal{J}(\mathcal{C})$  is the Jacobian of a hyperelliptic curve and  $\iota$  is the hyperelliptic involution, then  $\text{RA}(\mathcal{J}(\mathcal{C}))$  is canonically isomorphic to  $\text{RA}(\mathcal{C}) = \text{Aut}(\mathcal{C})/\langle \iota \rangle$ ; so our definition is consistent for hyperelliptic Jacobians.

#### 4. RANDOM WALKS

Let  $G = (V, E, w)$  be a directed weighted multigraph with finite vertex set  $V$ . The weight of an edge  $e$  is denoted by  $w(e) > 0$ . Given subsets  $S, T \subset V$ , we denote the set of edges from  $S$  to  $T$  by  $E(S, T)$ , omitting the curly braces when  $S$  or  $T$  is a singleton  $\{u\}$ . For each pair of vertices  $u, v \in V$  we write  $w_{uv} = \sum_{e \in E(u, v)} w(e)$ ,

FIGURE 1. The graph  $\Gamma_2^{SS}(2; 11)$ , with isogeny weights.

and for each vertex  $u \in V$  we have  $\deg u = \sum_{e \in E(u, V)} w(e)$ . The set of neighbors of a vertex  $u \in V$  is denoted  $N(u)$ .

We define a **random walk** on  $G$  with starting vertex  $v_0 \in V$  in the usual way: for each natural  $t \geq 0$  and pair of vertices  $u, v \in V$ , we have

$$P(v_{t+1} = v \mid v_t = u) = \frac{w_{uv}}{\deg u},$$

with the remark that this probability is zero whenever  $E(u, v) = \emptyset$ . The random walk transition matrix is the matrix  $M$  given by  $M_{v,u} = \frac{w_{uv}}{\deg u}$ .

If  $G$  is a strongly connected aperiodic graph, then the Perron–Frobenius Theorem tells us there is a unique positive vector  $\varphi = (\varphi(u))_{u \in V}$  with  $\|\varphi\|_1 = 1$  such that  $M\varphi = \varphi$  (see [29, Proposition 1.14 and Theorem 4.9]). This vector  $\varphi$  is called the **stationary distribution** of  $G$ . Moreover, for any starting distribution  $\psi$  on the vertices of  $G$ , we have  $\lim_{n \rightarrow \infty} M^n \psi = \varphi$ .<sup>1</sup>

When  $G$  is an *undirected* graph, the stationary distribution is the vector  $\varphi$  where

$$\varphi(u) = \frac{\deg u}{2|E|} \quad \text{for } u \in V;$$

we see immediately that this is indeed the stationary distribution, because

$$\varphi(u) = \frac{\deg u}{2|E|} = \sum_{v \in N(u)} \frac{1}{\deg v} \frac{\deg v}{2|E|}.$$

However, when  $G$  is a *directed* graph, there is no closed-form formula for the stationary distribution of the random walk. Even the principal ratio  $\frac{\max_{u \in V} \varphi(u)}{\min_{u \in V} \varphi(u)}$  of the distribution can be difficult to bound, and it can be exponentially large even when degree bounds such as  $\delta \leq \deg u \leq \Delta$ , for all  $u \in V$ , are known [1].

**4.1. Directed graphs and linear imbalance.** The following definition tries to restrict the amount of allowed “directedness” in a graph, so that we are able to find closed-form stationary distributions for isogeny graphs. It applies directly to the graph  $\Gamma_2^{SS}(2; 11)$  displayed in Figure 1.

<sup>1</sup>If we drop the connectivity hypothesis, then  $\varphi$  is neither positive nor unique. Meanwhile, a periodic graph will still have a stationary distribution, but convergence to it is not granted.

**Definition 6.** Let  $G = (V, E, w)$  be a directed weighted graph. We say  $G$  has **linear imbalance** if there exists a vertex partition  $V = A_1 \sqcup \cdots \sqcup A_n$  and a bijection

$$E(u, v) \xrightarrow{(\cdot)^\dagger} E(v, u)$$

for each pair of adjacent vertices  $u, v \in V$ , such that

- (1) If  $u, v \in A_i$ , then for each  $e \in E(u, v)$ ,  $w(e) = w(e^\dagger)$ .
- (2) For each  $i \neq j$  there exists an integer  $m_{ij}$ , such that if  $u \in A_i$ ,  $v \in A_j$ , and  $e \in E(u, v)$ , then  $w(e) = m_{ij} \cdot w(e^\dagger)$ .

In particular  $m_{ji} = m_{ij}^{-1}$ , and we can set  $m_{ii} = 1$ .

We can see  $G$  as an undirected graph if we forget the weights, due to the existence of the bijections  $E(u, v) \xrightarrow{(\cdot)^\dagger} E(v, u)$ . However, the presence of weights changes the definition of the random walk on  $G$ , and in particular the stationary distribution will be different. We now want to compute this distribution.

**Proposition 1.** Let  $G = (V, E)$  be a linear imbalance graph with partition  $V = A_1 \sqcup \cdots \sqcup A_n$ . Assume that each class  $A_i$  induces a regular subgraph, i.e., there exist integers  $d_1, \dots, d_n$  such that for all  $u \in A_i$ ,  $\deg u = d_i$ .

Suppose there exists a non-zero solution  $(\alpha_1, \dots, \alpha_n)$  to the system of equations

$$(2) \quad \frac{m_{ji}}{d_j} \alpha_j = \frac{1}{d_i} \alpha_i \quad \text{for every } i, j \text{ such that } E(A_i, A_j) \neq \emptyset.$$

Define the vectors  $\tilde{\varphi} = (\tilde{\varphi}(u))_{u \in V}$  by  $\tilde{\varphi}(u) = \alpha_i$  if  $u \in A_i$ , and  $\varphi = \tilde{\varphi} / \|\tilde{\varphi}\|_1$ .

The vector  $\varphi$  is a stationary distribution for the random walk on  $G$ . Moreover, the random walk on  $G$  is a reversible Markov chain.

*Proof.* We need to check that

$$\tilde{\varphi}(u) = \sum_{v \in N(u), e \in E(u, v)} \frac{w(e^\dagger)}{\deg v} \tilde{\varphi}(v).$$

Say  $u \in A_i$ , and label its neighbors  $v_1, \dots, v_{t_u}$  (inside the classes  $A_{j_1}, \dots, A_{j_{t_u}}$ ). Then the previous equation becomes

$$\tilde{\varphi}(u) = \sum_{v \in N(u), e \in E(u, v)} \frac{w(e^\dagger)}{\deg v} \tilde{\varphi}(v) = \sum_{k=1}^{t_u} \frac{m_{j_k i} w_{uv_k}}{d_{j_k}} \tilde{\varphi}(v_k).$$

Substituting the values of  $\tilde{\varphi}(u)$  and  $\tilde{\varphi}(v_k)$ , we get the equation

$$\alpha_i = \sum_{k=1}^{t_u} \frac{m_{j_k i} w_{uv_k}}{d_{j_k}} \alpha_{j_k}.$$

Using Equations (2), we get

$$\alpha_i = \sum_{k=1}^{t_u} \frac{w_{uv_k}}{d_i} \alpha_i = \left( \sum_{k=1}^{t_u} w_{uv_k} \right) \frac{1}{d_i} \alpha_i,$$

which is trivially true.

We say a Markov chain is reversible if, for all states  $u, v$ , we have

$$\varphi(u)P(u, v) = \varphi(v)P(v, u)$$

where  $P(u, v)$  is the probability of walking from  $u$  to  $v$ . In our case, this equation becomes

$$\alpha_i \frac{w_{uv}}{d_i} = \alpha_j \frac{w_{vu}}{d_j}$$

whenever  $u \in A_i, v \in A_j$ , which is always satisfied (after dividing both sides by  $w_{vu}$ ). This proves the reversibility of the chain.  $\square$

Proposition 1 imposes a total of  $\binom{n}{2}$  equations, which may or may not yield a solution. However, we can reduce the number of necessary equations if the graph is connected and has composable linear imbalance.

**Definition 7.** Let  $G$  and  $A_i$  be as above. Construct an undirected graph  $\mathcal{A} = (\mathcal{V}, \mathcal{E})$  with vertices  $\mathcal{V} = \{a_1, \dots, a_n\}$  and with edges  $\mathcal{E} = \{\{a_i, a_j\} \mid E(A_i, A_j) \neq \emptyset\}$ . We say  $G$  has **composable linear imbalance** if for any two neighboring vertices  $a_i, a_j$  and for any path in  $\mathcal{A}$  (with distinct edges and vertices)  $a_i = a_{i_0} \rightarrow a_{i_1} \rightarrow \dots \rightarrow a_{i_k} = a_j$  from  $a_i$  to  $a_j$  we have

$$m_{ji} = m_{ji_{k-1}} m_{i_{k-1}i_{k-2}} \cdots m_{i_1i}.$$

Every undirected graph has composable linear imbalance by defining any partition on its set of vertices. Or, alternatively, a linear imbalance graph is undirected if and only if  $m_{ij} = 1$  for all  $i, j$ .

**Lemma 2.** Let  $G = (V, E)$  be a connected graph satisfying the same conditions as in Proposition 1. If  $G$  has composable linear imbalance, then the set of equations

$$(3) \quad \frac{m_{ji}}{d_j} \alpha_j = \frac{1}{d_i} \alpha_i$$

can be reduced to a set of  $n - 1$  equations, where  $n$  is the number of classes in the vertex partition of  $G$ .

*Proof.* Recall  $V = A_1 \sqcup \dots \sqcup A_n$ , and let  $\mathcal{A}$  be the graph associated to this partition. Let  $\mathcal{T}$  be any spanning tree of  $\mathcal{A}$ .

Consider the system of  $n - 1$  equations  $\frac{m_{ji}}{d_j} \alpha_j = \frac{1}{d_i} \alpha_i$  whenever  $\{a_i, a_j\}$  is an edge in  $\mathcal{T}$ . We claim this system is equivalent to the full system. Indeed, for any two vertices  $a_i, a_j \in \mathcal{T}$  such that  $E(A_i, A_j) \neq \emptyset$ , let

$$a_i = a_{i_0} \rightarrow a_{i_1} \rightarrow \dots \rightarrow a_{i_k} = a_j$$

be a path in  $\mathcal{T}$  from  $a_i$  to  $a_j$ . Using the newly defined system, we get the equation

$$\frac{1}{d_i} \alpha_i = \frac{m_{ji_{k-1}} m_{i_{k-1}i_{k-2}} \cdots m_{i_1i}}{d_j} \alpha_j,$$

which by composability gives us the desired equation  $\frac{1}{d_i} \alpha_i = \frac{m_{ji}}{d_j} \alpha_j$ .  $\square$

*Remark 2.* This result can be illustrated by computing the stationary distribution for the random walk over  $\Gamma_1^{SS}(\ell; p)$  with  $p \equiv 11 \pmod{12}$  (the other possibilities for  $p$  are special cases of this). We partition the set of vertices  $V$  into three sets,  $A_0 = V \setminus \{\mathcal{E}_0, \mathcal{E}_{1728}\}$ ,  $A_1 = \{\mathcal{E}_0\}$ , and  $A_2 = \{\mathcal{E}_{1728}\}$ . This partition gives the graph composable linear imbalance, with  $m_{01} = 3$ ,  $m_{02} = 2$ , and  $m_{12} = 2/3$ . The graph  $\mathcal{A}$  is a triangle<sup>2</sup>, which imposes three linear equations in three variables, but we get

<sup>2</sup>It is actually a tree in many cases, but the computation is the same.

a spanning tree  $\mathcal{T}$  by removing any edge. For instance, we get the equations

$$\frac{1}{\ell+1}\alpha_0 = \frac{3}{\ell+1}\alpha_1, \quad \frac{1}{\ell+1}\alpha_0 = \frac{2}{\ell+1}\alpha_2$$

which are satisfied by  $(\alpha_0, \alpha_1, \alpha_2) = (1, 1/3, 1/2)$ .

**Corollary 1.** *Let  $G = (V, E)$  be a connected linear imbalance graph with a vertex partition  $V = A_1 \sqcup \cdots \sqcup A_n$ . Suppose that for each  $1 \leq i \leq n$  there exists a positive real number  $g_i$  such that for all  $i, j$ ,  $m_{ij} = \frac{g_i}{g_j}$ . Then  $G$  has composable linear imbalance, and it has stationary distribution  $\varphi = \tilde{\varphi}/\|\tilde{\varphi}\|_1$ , where*

$$\tilde{\varphi}(u) = \frac{d_i}{g_i} = \frac{\deg(u)}{g_i} \quad \text{whenever } u \in A_i.$$

*Proof.* The fact that  $G$  has composable linear imbalance is trivial from the equalities  $m_{ij} = \frac{g_i}{g_j}$ . From Lemma 2, the equations  $\frac{m_{ji}}{d_j}\alpha_j = \frac{1}{d_i}\alpha_i$  are satisfied for all  $i, j$  with  $E(A_i, A_j) \neq \emptyset$ . But these equations correspond to  $\frac{g_i}{d_j}\alpha_j = \frac{g_i}{d_i}\alpha_i$  which are trivially satisfied by setting  $\alpha_i = d_i/g_i$ .  $\square$

We discuss now the mixing rate of a graph  $G$  satisfying the hypotheses of last result. Let  $M_G$  be the random walk matrix. We define an inner product on  $\mathbb{R}^{|V(G)|}$ , denoted by  $\langle \cdot, \cdot \rangle_\varphi$ , by

$$\langle f, g \rangle_\varphi = \sum_{u \in V(G)} f(u)g(u)\varphi(u).$$

**Lemma 3** ([29], Lemma 12.2). *The reversible property of the random walk on  $G$  implies:*

- (1) *The inner product space  $(\mathbb{R}^{|V(G)|}, \langle \cdot, \cdot \rangle_\varphi)$  has an orthonormal basis  $\{f_j\}_{j=1}^{|V(G)|}$  of real-valued left eigenvectors of  $M_G$ , corresponding to real eigenvalues  $\{\lambda_j\}$ .*
- (2) *Given a random walk  $u = u_0 \rightarrow \cdots \rightarrow u_n \rightarrow \cdots$ , for all  $v \in V(G)$  we have*

$$(4) \quad \frac{\Pr[u_n = v]}{\varphi(v)} = 1 + \sum_{j=2}^{|V(G)|} f_j(u)f_j(v)\lambda_j^n.$$

In particular, if the graph  $G$  is connected and aperiodic, then we know

$$1 = \lambda_1 > \lambda_2 \geq \cdots \geq \lambda_{|V(G)|} > -1.$$

Letting  $\lambda_*(G) = \max\{|\lambda| \mid \lambda \text{ is an eigenvalue of } M_G, \lambda \neq 1\}$ , we have the following result bounding the mixing rate of the random walk.

**Proposition 2.** *Consider a random walk  $u = u_0 \rightarrow \cdots \rightarrow u_n \rightarrow \cdots$ , and let  $v \in V(G)$  be any vertex. If  $u \in A_i$  and  $v \in A_j$ , we have*

$$|\Pr[u_n = v] - \varphi(v)| \leq \lambda_*(G)^n \sqrt{\frac{\deg(v) g_i}{\deg(u) g_j}}.$$

*Proof.* We adapt the proof of [29, Theorem 12.3]. Using (4) and the Cauchy-Schwarz inequality we get

$$\left| \frac{\Pr[u_n = v]}{\varphi(v)} - 1 \right| \leq \sum_{j=2}^{|V(G)|} |f_j(u)f_j(v)|\lambda_j^n \leq \lambda_*(G)^n \left( \sum_{j=2}^{|V(G)|} f_j^2(u) \sum_{j=2}^{|V(G)|} f_j^2(v) \right)^{1/2}.$$

Let  $\delta_w$  be the function

$$\delta_w(u) = \begin{cases} 1 & \text{if } w = u, \\ 0 & \text{if } w \neq u. \end{cases}$$

This function can be written in the following way, using the orthonormal basis of functions  $\{f_j\}_{j=1}^{|V(G)|}$ :

$$\delta_w = \sum_{j=1}^{|V(G)|} \langle \delta_w, f_j \rangle_{\varphi} f_j = \sum_{j=1}^{|V(G)|} f_j(w) \varphi(w) f_j.$$

From this we obtain

$$\begin{aligned} \varphi(w) &= \langle \delta_w, \delta_w \rangle_{\varphi} = \left\langle \sum_{j=1}^{|V(G)|} f_j(w) \varphi(w) f_j, \sum_{j=1}^{|V(G)|} f_j(w) \varphi(w) f_j \right\rangle_{\varphi} \\ &= \varphi(w)^2 \sum_{j=1}^{|V(G)|} f_j^2(w), \end{aligned}$$

which implies  $\sum_{j=2}^{|V(G)|} f_j^2(w) < \varphi(w)^{-1}$ . Combining this with the first stated inequality we get

$$|\Pr[u_n = v] - \varphi(v)| \leq \lambda_{\star}(G)^n \sqrt{\frac{\varphi(v)}{\varphi(u)}},$$

which yields the result after substituting the values of  $\varphi$  obtained in Corollary 1.  $\square$

Proposition 2 is the analog of classical results on random walk mixing in undirected graphs: [31, Theorem 5.1] for the general case, [21, Theorem 3.3] for regular graphs, and [18, Theorem 1] for supersingular isogeny graphs.

**4.2. Isogeny graphs as linear imbalance graphs.** Our results so far allow us to give the stationary distribution and convergence rate for superspecial isogeny graphs. But we can state a much more general result, and apply the same theory to interesting isogeny subgraphs.

**Theorem 1.** *Let  $G$  be a finite, connected and aperiodic subgraph of  $\Gamma_g(\ell; p)$ , such that for each edge  $[\phi]$  in  $G$ , its dual edge  $[\phi^{\dagger}]$  is also in  $G$ .*

- (1) *The stationary distribution of the random walk in  $G$  is given by  $\varphi_G = \tilde{\varphi}_G / \|\tilde{\varphi}_G\|_1$ ,*

$$\tilde{\varphi}_G(\mathcal{A}) = \frac{\deg_G(\mathcal{A})}{\#RA(\mathcal{A})},$$

*where  $\deg_G(\mathcal{A})$  denotes the number of isogenies in  $G$  with domain  $\mathcal{A}$ .*

- (2) *The mixing rate is  $\lambda_{\star}(G)$ . More precisely, if  $\mathcal{A}_0 \rightarrow \dots \rightarrow \mathcal{A}_n \rightarrow \dots$  is a random walk, and  $\mathcal{A}$  is any vertex of  $G$ , then the convergence to the stationary distribution is given by*

$$(5) \quad |\Pr[\mathcal{A}_n \cong \mathcal{A}] - \varphi_G(\mathcal{A})| \leq \lambda_{\star}(G)^n \sqrt{\frac{\deg_G \mathcal{A} \#RA(\mathcal{A}_0)}{\deg_G \mathcal{A}_0 \#RA(\mathcal{A})}}.$$

*Proof.* For Part (1): Lemma 1 tells us that  $G$  has linear imbalance, by partitioning its set of vertices according to the reduced automorphism group of each variety. Indeed, for any two neighbouring PPAVs  $\mathcal{A}$  and  $\mathcal{A}'$  in  $\Gamma_g(\ell; p)$ , we have

$$\frac{\#E(\mathcal{A}, \mathcal{A}')}{\#E(\mathcal{A}', \mathcal{A})} = \frac{\#\text{RA}(\mathcal{A})}{\#\text{RA}(\mathcal{A}')}.$$

We can refine this partition further so that all nodes in a single class have the same degree. This way, all hypotheses of Proposition 1 and Corollary 1 are satisfied, yielding the stated distribution. Part (2) then follows from Proposition 2.  $\square$

Theorem 1 is true for all superspecial isogeny graphs  $\Gamma_g^{SS}(\ell; p)$ , as they are connected and non-bipartite [26, Corollary 18] and hence aperiodic. In fact, we can always produce a loop if  $g$  is even: if  $\phi: \mathcal{E} \rightarrow \mathcal{E}'$  is an elliptic  $\ell$ -isogeny, then the product  $(\ell, \dots, \ell)$ -isogeny

$$(6) \quad (\mathcal{E} \times \mathcal{E}')^{g/2} \xrightarrow{\phi \times \phi^\dagger \times \dots \times \phi \times \phi^\dagger} (\mathcal{E} \times \mathcal{E}')^{g/2}$$

is a loop in  $\Gamma_g^{SS}(\ell; p)$ . If  $g$  is odd, we let  $\psi_1: \mathcal{E} \rightarrow \mathcal{E}$ ,  $\psi_2: \mathcal{E} \rightarrow \mathcal{E}$  be two elliptic curve isogenies of respective degrees  $\ell^e$  and  $\ell^f$  with  $e$  and  $f$  coprime (this exists, since  $\Gamma_1^{SS}(\ell; p)$  is non-bipartite [26, Corollary 18] and so aperiodic). Then, by constructing the previous isogeny  $\phi \times \phi^\dagger \times \dots \times \phi \times \phi^\dagger$  in genus  $g-1$ , we get two isogenies

$$\begin{aligned} &(\phi \times \phi^\dagger)^e \times \dots \times (\phi \times \phi^\dagger)^e \times \psi_1, \\ &(\phi \times \phi^\dagger)^f \times \dots \times (\phi \times \phi^\dagger)^f \times \psi_2, \end{aligned}$$

where exponentiation means composition ( $\phi \times \phi^\dagger$  is an endomorphism of  $\mathcal{E} \times \mathcal{E}'$ ), representing two cycles of coprime lengths  $e$  and  $f$  in  $\Gamma_g^{SS}(\ell; p)$ .

**4.3. Bounds on eigenvalues.** If we fix  $g$  and  $\ell$ , and we have a constant  $\lambda = \lambda(g, \ell) < 1$  such that  $\lambda_*(\Gamma_g^{SS}(\ell; p)) \leq \lambda$  for all  $p$ , then we get a family of graphs with good expansion properties<sup>3</sup>. Combining this with Equation (5), we conclude that the diameter of each graph is  $O(\log p)$ , a property that also holds for regular expander graphs.

Given a  $d$ -regular undirected graph  $G$  with  $\lambda_*(G)$  as second largest eigenvalue (in absolute value), we have  $d \cdot \lambda_*(G) \geq 2\sqrt{d-1} - o(1)$ . If  $d \cdot \lambda_*(G) \leq 2\sqrt{d-1}$ , the graph is then said to be **Ramanujan** [21]. Ramanujan graphs have optimal expansion properties.

Isogeny graphs of supersingular elliptic curves are Ramanujan [35], and it was hoped that this property would extend to the more general graphs  $\Gamma_g^{SS}(\ell; p)$  [13, Hypothesis 1]. We have shown  $\Gamma_g^{SS}(\ell; p)$  does not fit into the definition of an *expander graph* for  $g \geq 2$ , due to the presence of non-trivial reduced automorphism groups. However, we may still ask for bounds on  $\lambda_*(\Gamma_g^{SS}(\ell; p))$ , as a Ramanujan property of sorts. Now, letting  $N_g(\ell)$  be the out-degree of the vertices in  $\Gamma_g^{SS}(\ell; p)$ , we ask a question: for which  $g$ ,  $\ell$  and  $p$ , if any, does the bound

$$N_g(\ell) \cdot \lambda_*(\Gamma_g^{SS}(\ell; p)) \leq 2\sqrt{N_g(\ell) - 1}$$

hold?

<sup>3</sup>Note that they should not be called *expander* graphs: this term is reserved for regular undirected graphs.

Jordan and Zaytman [26] have given a first counterexample:  $\Gamma_2^{SS}(2; 11)$  is not Ramanujan, as the second largest eigenvalue of the adjacency matrix is  $7 + \sqrt{3}$ , which is larger than  $2\sqrt{N_2(2) - 1} = 2\sqrt{15 - 1}$ .

We have gathered evidence that the same behaviour also occurs for (at least) all graphs  $\Gamma_2^{SS}(2; p)$  for primes  $11 \leq p \leq 601$ . For all these primes, the superspecial Richelot isogeny graph fails to be Ramanujan, and in fact most values of  $\lambda_*$  (except for a few small primes) are very close to  $11.5/15$ . Giving a theoretical reason for this behaviour is left as future work.

The eigenvalues and diameters of each graph can be found in Appendix A. In Section 7 we prove that both the subgraph of Jacobians and the subgraph of elliptic products satisfy the hypotheses to have convergence to a stationary distribution, and so our data also includes their eigenvalues and diameters.

We now refine the previously stated conjectures on superspecial graphs.

**Conjecture 1.** *For all  $g$  and  $\ell$ , there exists a fixed  $\lambda = \lambda(g, \ell) < 1$  such that*

$$\lambda_*(\Gamma_g^{SS}(\ell; p)) \leq \lambda \quad \text{for every prime } p \geq 5.$$

*In the case  $g = 2$  and  $\ell = 2$ , we conjecture that*

$$\frac{11}{15} \leq \lambda_*(\Gamma_2^{SS}(2; p)) \leq \frac{12}{15} \quad \text{for every prime } p \geq 41.$$

**4.4. Distributions of subgraphs.** If we perform a random walk on  $\Gamma_2^{SS}(2; p)$ , we will encounter a certain number of products of elliptic curves along the way. We can try to predict the ratio of elliptic products to visited nodes: a first guess could be that this ratio matches the proportion of such nodes in the entire graph, which is asymptotic to  $\frac{10}{p}$  (see [9, Proposition 2]).

However, this is not the empirical proportion that we observe in our experiment, which consists in performing 10,000 random walk steps in  $\Gamma_2^{SS}(2; p)$  and counting the number  $N$  of elliptic products encountered in our path. The ratio  $N/10,000$  of elliptic products to visited nodes is closer to  $\frac{5}{p}$ , as seen in Table 1.

$p$	101	307	503	701	907	1103
$N$	415	201	130	64	50	44
Ratio	$4.1915/p$	$6.1707/p$	$6.539/p$	$4.4864/p$	$4.535/p$	$4.8532/p$

TABLE 1. Number of elliptic products encountered in a 10,000-step random walk for several primes. The third row shows the proportion scaled relative to each prime.

Theorem 1, in combination with the classification of reduced automorphism groups below, gives us the true proportion of elliptic product nodes in random walks. We have  $\frac{p^3}{2880} + O(p^2)$  Jacobians with trivial reduced automorphism group (this is the picture for “almost all” nodes in the graph: only  $O(p^2)$  have nontrivial reduced automorphisms), and there are  $\frac{p^2}{288} + O(p)$  elliptic products. However, all but  $O(p)$  of those products have a reduced automorphism group of order 2, confirming that the (asymptotic) expected proportion of elliptic products in a random walk is equal to  $\frac{1}{2} \times \frac{10}{p} = \frac{5}{p}$ . Similarly, we could compute proportions for each abelian surface type given in Section 6.

If we combine this with the conjectured upper bound for  $\lambda_*(\Gamma_2^{SS}(2;p))$ , then we can give the interpretation that elliptic products are evenly distributed in the graph, in the sense that any node is within very few steps of an elliptic product (much less than diametral distance).

## 5. THE RICHELOT ISOGENY GRAPH

From now on, we focus on the case  $g = 2$  and  $\ell = 2$ . Richelot [36, 37] gave the first explicit construction for  $(2, 2)$ -isogenies, so the  $(2, 2)$ -isogeny graph of principally polarized abelian surfaces (PPASes) is called the *Richelot isogeny graph*.

Let  $\mathcal{A}_0$  be a PPAS with full rational 2-torsion. There are 15 rational Lagrangian subgroups  $K_1, \dots, K_{15}$  of  $\mathcal{A}_0[2]$ , and each is the kernel of a rational  $(2, 2)$ -isogeny

$$\phi_i : \mathcal{A}_0 \rightarrow \mathcal{A}_i := \mathcal{A}_0/K_i.$$

This means that every vertex in the  $(2, 2)$ -isogeny graph has out-degree 15. In general, none of the isogenies or codomains are isomorphic.

The algorithmic construction of the isogenies and codomains depends fundamentally on whether  $\mathcal{A}_0$  is a Jacobian or an elliptic product. We recall the Jacobian case in §5.1, and the elliptic product case in §5.2.

**5.1. Richelot isogenies.** Let  $\mathcal{C} : y^2 = F(x)$  be a genus-2 curve, with  $F$  a square-free polynomial of degree 5 or 6. The Lagrangian subgroups of  $\mathcal{J}(\mathcal{C})[2]$  correspond to factorizations of  $F$  into quadratics (of which one may be linear, if  $\deg(F) = 5$ ):

$$\mathcal{C} : y^2 = F(x) = F_1(x)F_2(x)F_3(x),$$

up to permutation of the  $F_i$  and constant multiples. We call such factorizations *quadratic splittings*.

Fix one such quadratic splitting  $\{F_1, F_2, F_3\}$ ; then the corresponding subgroup  $K \subset \mathcal{J}(\mathcal{C})[2]$  is the kernel of a  $(2, 2)$ -isogeny  $\phi : \mathcal{J}(\mathcal{C}) \rightarrow \mathcal{J}(\mathcal{C})/K$ . For each  $1 \leq i \leq 3$ , we write  $F_i(x) = F_{i,2}x^2 + F_{i,1}x + F_{i,0}$ . Now let

$$\delta = \delta(F_1, F_2, F_3) := \begin{vmatrix} F_{1,0} & F_{1,1} & F_{1,2} \\ F_{2,0} & F_{2,1} & F_{2,2} \\ F_{3,0} & F_{3,1} & F_{3,2} \end{vmatrix}.$$

If  $\delta(F_1, F_2, F_3) \neq 0$ , then  $\mathcal{J}(\mathcal{C})/K$  is isomorphic to a Jacobian  $\mathcal{J}(\mathcal{C}')$ , which we can compute using Richelot's algorithm (see [5] and [39, §8]). First, let

$$\begin{aligned} G_1(x) &:= \delta^{-1} \cdot (F_2'(x)F_3(x) - F_3'(x)F_2(x)), \\ G_2(x) &:= \delta^{-1} \cdot (F_3'(x)F_1(x) - F_1'(x)F_3(x)), \\ G_3(x) &:= \delta^{-1} \cdot (F_1'(x)F_2(x) - F_2'(x)F_1(x)). \end{aligned}$$

Now the isogenous Jacobian is  $\mathcal{J}(\mathcal{C}')$ , where  $\mathcal{C}'$  is the curve

$$\mathcal{C}' : y^2 = G(x) = G_1(x)G_2(x)G_3(x)$$

and the quadratic splitting  $\{G_1, G_2, G_3\}$  corresponds to the kernel of the dual isogeny  $\phi^\dagger : \mathcal{J}(\mathcal{C}') \rightarrow \mathcal{J}(\mathcal{C})$ . The  $F_i$  and  $G_i$  are related by the identity

$$F_1(x_1)G_1(x_2) + F_2(x_1)G_2(x_2) + F_3(x_1)G_3(x_2) + (x_1 - x_2)^2 = 0.$$

Bruin and Doerksen present a convenient form for a divisorial correspondence  $\mathcal{R} \subset \mathcal{C} \times \mathcal{C}'$  inducing the isogeny  $\phi$  (see [7, §4]):

$$(7) \quad \mathcal{R} : \begin{cases} F_1(x_1)G_1(x_2) + F_2(x_1)G_2(x_2) = 0, \\ F_1(x_1)G_1(x_2)(x_1 - x_2) = y_1y_2, \\ F_2(x_1)G_2(x_2)(x_1 - x_2) = -y_1y_2. \end{cases}$$

If  $\delta(F_1, F_2, F_3) = 0$ , then  $\mathcal{J}(\mathcal{C})/K$  is isomorphic to an elliptic product  $\mathcal{E} \times \mathcal{E}'$ . Let  $D(\lambda)$  be the discriminant of the quadratic polynomial  $F_1 + \lambda F_2$ , and let  $\lambda_1$  and  $\lambda_2$  be the roots of  $D(\lambda)$ ; then  $F_1 + \lambda_1 F_2 = U^2$  and  $F_1 + \lambda_2 F_2 = V^2$  for some linear polynomials  $U$  and  $V$ . Now  $F_1 = \alpha_1 U^2 + \beta_1 V^2$  and  $F_2 = \alpha_2 U^2 + \beta_2 V^2$  for some  $\alpha_1, \beta_1, \alpha_2$ , and  $\beta_2$ , and since in this case  $F_3$  is a linear combination of  $F_1$  and  $F_2$ , we must have  $F_3 = \alpha_3 U^2 + \beta_3 V^2$  for some  $\alpha_3$  and  $\beta_3$ . Now, rewriting the defining equation of  $\mathcal{C}$  as

$$\mathcal{C} : Y^2 = \prod_{i=1}^3 (\alpha_i U^2 + \beta_i V^2),$$

it is clear that the elliptic curves

$$\mathcal{E} : Y^2 = \prod_{i=1}^3 (\alpha_i X + \beta_i Z) \quad \text{and} \quad \mathcal{E}' : Y^2 = \prod_{i=1}^3 (\beta_i X + \alpha_i Z)$$

are the images of double covers  $\pi : \mathcal{C} \rightarrow \mathcal{E}$  and  $\pi' : \mathcal{C} \rightarrow \mathcal{E}'$  defined by  $\pi((X : Y : Z)) = (U : Y : V)$  and  $\pi'((X : Y : Z)) = (V : Y : U)$ , respectively. The product of these covers induces the isogeny  $\phi : \mathcal{J}(\mathcal{C}) \rightarrow \mathcal{E} \times \mathcal{E}'$ .

**5.2. Isogenies from elliptic products.** Consider a generic pair of elliptic curves over  $k$ , defined by

$$\mathcal{E} : y^2 = (x - s_1)(x - s_2)(x - s_3)$$

and

$$\mathcal{E}' : y^2 = (x - s'_1)(x - s'_2)(x - s'_3).$$

We have  $\mathcal{E}[2] = \{0_{\mathcal{E}}, P_1, P_2, P_3\}$  and  $\mathcal{E}'[2] = \{0_{\mathcal{E}'}, P'_1, P'_2, P'_3\}$  where  $P_i := (s_i, 0)$  and  $P'_i := (s'_i, 0)$ . For each  $1 \leq i \leq 3$ , we let

$$\psi_i : \mathcal{E} \longrightarrow \mathcal{E}_i := \mathcal{E}/\langle P_i \rangle \quad \text{and} \quad \psi'_i : \mathcal{E}' \longrightarrow \mathcal{E}'_i := \mathcal{E}'/\langle P'_i \rangle$$

be the quotient 2-isogenies. These can be computed using Vélu's formulæ [44].

The fifteen Lagrangian subgroups of  $(\mathcal{E} \times \mathcal{E}') [2]$  fall naturally into two kinds. Nine of the kernels correspond to products of 2-isogeny kernels in  $\mathcal{E}[2]$ . Namely, for each  $1 \leq i, j \leq 3$  we have a subgroup

$$K_{i,j} := \langle (P_i, 0_{\mathcal{E}'}) , (0_{\mathcal{E}}, P'_i) \rangle \subset (\mathcal{E} \times \mathcal{E}') [2],$$

and a quotient isogeny

$$\phi_{i,j} : \mathcal{E} \times \mathcal{E}' \longrightarrow (\mathcal{E} \times \mathcal{E}') / K_{i,j} \cong \mathcal{E}_i \times \mathcal{E}'_j.$$

Of course,  $\phi_{i,j} = \psi_i \times \psi_j$ ; we can thus compute  $\phi_{i,j}$ , and the codomains  $\mathcal{E}_i \times \mathcal{E}'_j$ , using Vélu's formulæ as above.

The other six kernels correspond to 2-Weil anti-isometries  $\mathcal{E}[2] \cong \mathcal{E}'[2]$ : they are

$$K_{\pi} := \{(0_{\mathcal{E}}, 0_{\mathcal{E}'}) , (P_1, P'_{\pi(1)}) , (P_2, P'_{\pi(2)}) , (P_3, P'_{\pi(3)})\} \quad \text{for } \pi \in \text{Sym}(\{1, 2, 3\}),$$

with quotient isogenies

$$\phi_\pi : \mathcal{E} \times \mathcal{E}' \rightarrow \mathcal{A}_\pi := (\mathcal{E} \times \mathcal{E}')/K_\pi.$$

If the anti-isometry  $P_i \mapsto P'_{\pi(i)}$  is induced by an isomorphism  $\mathcal{E} \rightarrow \mathcal{E}'$ , then  $\mathcal{A}_\pi$  is isomorphic to  $\mathcal{E} \times \mathcal{E}'$ ; otherwise, it is the Jacobian of a genus-2 curve  $\mathcal{C}_\pi$ , which we can compute using the formulæ below (taken from [22, Proposition 4]).

Writing  $\alpha_i := x(P_i)$  and  $\beta_i := x(P'_{\pi(i)})$  for  $1 \leq i \leq 3$ , let

$$\begin{aligned} a_1 &:= \frac{(\alpha_3 - \alpha_2)^2}{\beta_3 - \beta_2} + \frac{(\alpha_2 - \alpha_1)^2}{\beta_2 - \beta_1} + \frac{(\alpha_1 - \alpha_3)^2}{\beta_1 - \beta_3}, \\ b_1 &:= \frac{(\beta_3 - \beta_2)^2}{\alpha_3 - \alpha_2} + \frac{(\beta_2 - \beta_1)^2}{\alpha_2 - \alpha_1} + \frac{(\beta_1 - \beta_3)^2}{\alpha_1 - \alpha_3}, \\ a_2 &:= \alpha_1(\beta_3 - \beta_2) + \alpha_2(\beta_1 - \beta_3) + \alpha_3(\beta_2 - \beta_1), \\ b_2 &:= \beta_1(\alpha_3 - \alpha_2) + \beta_2(\alpha_1 - \alpha_3) + \beta_3(\alpha_2 - \alpha_1), \\ A &:= \Delta' \cdot a_1/a_2 \text{ where } \Delta' := (\beta_2 - \beta_3)^2(\beta_1 - \beta_3)^2(\beta_1 - \beta_2)^2, \\ B &:= \Delta \cdot b_1/b_2 \text{ where } \Delta := (\alpha_2 - \alpha_3)^2(\alpha_1 - \alpha_3)^2(\alpha_1 - \alpha_2)^2, \end{aligned}$$

and finally

$$\begin{aligned} F_1 &:= A(\alpha_2 - \alpha_1)(\alpha_1 - \alpha_3)X^2 + B(\beta_2 - \beta_1)(\beta_1 - \beta_3)Z^2, \\ F_2 &:= A(\alpha_3 - \alpha_2)(\alpha_2 - \alpha_1)X^2 + B(\beta_3 - \beta_2)(\beta_2 - \beta_1)Z^2, \\ F_3 &:= A(\alpha_1 - \alpha_3)(\alpha_3 - \alpha_2)X^2 + B(\beta_1 - \beta_3)(\beta_3 - \beta_2)Z^2. \end{aligned}$$

Now the curve  $\mathcal{C}_\pi$  may be defined by

$$\mathcal{C}_\pi : Y^2 = -F_1(X, Z)F_2(X, Z)F_3(X, Z).$$

The dual isogeny  $\phi_\pi^\dagger : \mathcal{J}(\mathcal{C}_\pi) \rightarrow \mathcal{E} \times \mathcal{E}'$  corresponds to the quadratic splitting  $\{F_1, F_2, F_3\}$ .

## 6. AUTOMORPHISM GROUPS OF ABELIAN SURFACES

In this section we recall the explicit classification of (reduced) automorphism groups of PPASes. In contrast with elliptic curves, where (up to isomorphism) only two curves have nontrivial reduced automorphism group, with PPASes we see much richer structures involving many more vertices in  $\Gamma_2(2; p)$ .

**6.1. Jacobians of genus-2 curves.** Bolza [3] has shown that there are seven possible reduced automorphism groups for Jacobian surfaces (provided  $p > 5$ ). Figure 2 gives Bolza's taxonomy, defining names ("types") for each of the reduced automorphism groups.

We can identify the isomorphism class of a Jacobian  $\mathcal{J}(\mathcal{C})$  using the Clebsch invariants  $A, B, C, D$  of  $\mathcal{C}$ , which are homogeneous polynomials of degree 2, 4, 6, and 10 in the coefficients of the sextic defining  $\mathcal{C}$ . These invariants should be seen as coordinates on the weighted projective space  $\mathbb{P}(2, 4, 6, 10)$ : that is,

$$(A : B : C : D) = (\lambda^2 A : \lambda^4 B : \lambda^6 C : \lambda^{10} D)$$

for all nonzero  $\lambda$  in  $\mathbb{k}$ . The Clebsch invariants can be computed using a series of transvectants involving the sextic (see [33, §1]), but it is more convenient to use (for example) `ClebschInvariants` in Magma [4] or `clebsch.invariants` from the `sage.schemes.hyperelliptic_curves.invariants` library of Sage [43]. If  $\mathcal{C}/\overline{\mathbb{F}}_p$  is superspecial, then  $(A : B : C : D)$  are in  $\mathbb{F}_{p^2}$ .

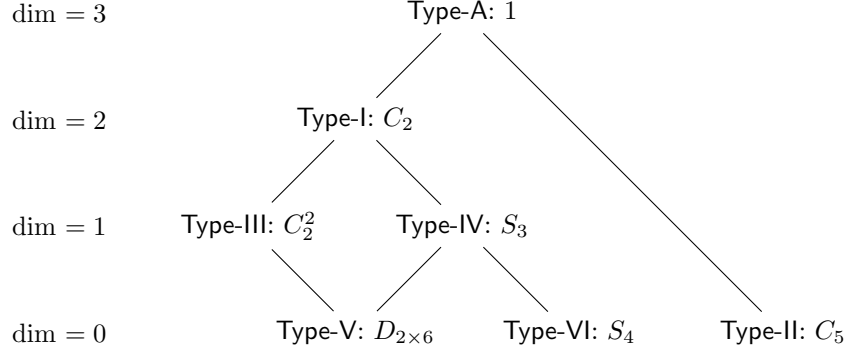

FIGURE 2. The taxonomy of reduced automorphism groups for genus-2 Jacobians. Dimensions on the left are of the loci on each level in the 3-dimensional moduli space of PPASes. Lines connect sub-types and super-types; specialization moves down the page.

To determine  $\text{RA}(\mathcal{J}(\mathcal{C}))$  for a given genus-2  $\mathcal{C}$ , we use necessary and sufficient conditions on the Clebsch invariants derived by Bolza [3, §11], given here in Table 2. These criteria involve some derived invariants: following Mestre’s notation [33], let

$$\begin{aligned} A_{11} &= 2C + \frac{1}{3}AB, & A_{12} &= \frac{2}{3}(B^2 + AC), & A_{23} &= \frac{1}{2}B \cdot A_{12} + \frac{1}{3}C \cdot A_{11}, \\ A_{22} &= D, & A_{31} &= D, & A_{33} &= \frac{1}{2}B \cdot A_{22} + \frac{1}{3}C \cdot A_{12} \end{aligned}$$

(recall again that  $\text{char } \mathbb{k}$  is not 2 or 3). Finally, the  $R$ -invariant is defined by

$$R^2 = \frac{1}{2} \begin{vmatrix} A_{11} & A_{12} & A_{31} \\ A_{12} & A_{22} & A_{23} \\ A_{31} & A_{23} & A_{33} \end{vmatrix}.$$

Type	$\text{RA}(\mathcal{J}(\mathcal{C}))$	Conditions on Clebsch invariants
Type-A	1	$R \neq 0, (A : B : C : D) \neq (0 : 0 : 0 : 1)$
Type-I	$C_2$	$R = 0$ and $A_{11}A_{22} \neq A_{12}$
Type-II	$C_5$	$(A : B : C : D) = (0 : 0 : 0 : 1)$
Type-III	$C_2^2$	$BA_{11} - 2AA_{12} = -6D, D \neq 0,$ $CA_{11} + 2BA_{12} = AD, 6C^2 \neq B^3$
Type-IV	$S_3$	$6C^2 = B^3, 3D = 2BA_{11},$ $2AB \neq 15C, D \neq 0$
Type-V	$D_{2 \times 6}$	$6B = A^2, D = 0, A_{11} = 0, A \neq 0$
Type-VI	$S_4$	$(A : B : C : D) = (1 : 0 : 0 : 0)$

TABLE 2. The classification of reduced automorphism groups of Jacobian surfaces, with necessary and sufficient conditions on the Clebsch invariants for each type.

**6.2. Products of elliptic curves.** Elliptic products always have nontrivial reduced automorphism groups, because  $\text{RA}(\mathcal{E} \times \mathcal{E}')$  always contains the involution

$$\sigma := [1]_{\mathcal{E}} \times [-1]_{\mathcal{E}'}$$

Note that  $\sigma$  fixes every Lagrangian subgroup of  $(\mathcal{E} \times \mathcal{E}') [2]$  (though this is not true for  $(\mathcal{E} \times \mathcal{E}') [\ell]$  if  $\ell > 2$ ), so  $\sigma$  always has an impact on the Richelot isogeny graph.

Proposition 3 shows that there are seven possible reduced automorphism groups for elliptic product surfaces (provided  $p > 3$ ), and Figure 3 gives a taxonomy of reduced automorphism groups analogous to that of Figure 2. We identify the isomorphism class of an elliptic product  $\mathcal{E} \times \mathcal{E}'$  using the  $j$ -invariants  $j(\mathcal{E})$  and  $j(\mathcal{E}')$  (an unordered pair when  $\mathcal{E} \not\cong \mathcal{E}'$ , and a single  $j$ -invariant when  $\mathcal{E} \cong \mathcal{E}'$ ).

**Proposition 3.** *If  $\mathcal{A}$  is an elliptic product surface, then (provided  $p > 3$ ) there are seven possibilities for the isomorphism type of  $\text{RA}(\mathcal{A})$ .*

- (1) *If  $\mathcal{A} \cong \mathcal{E} \times \mathcal{E}'$  for some  $\mathcal{E} \not\cong \mathcal{E}'$ , then one of the following holds:*
  - *Type-II:  $\{j(\mathcal{E}), j(\mathcal{E}')\} \cap \{0, 1728\} = \emptyset$ , and  $\text{RA}(\mathcal{A}) \cong C_2$ .*
  - *Type-II<sub>0</sub>:  $j(\mathcal{E}) = 0$  or  $j(\mathcal{E}') = 0$ , and  $\text{RA}(\mathcal{A}) \cong C_6$ .*
  - *Type-II<sub>123</sub>:  $j(\mathcal{E}) = 1728$  or  $j(\mathcal{E}') = 1728$ , and  $\text{RA}(\mathcal{A}) \cong C_4$ .*
  - *Type-II<sub>0,123</sub>:  $\{j(\mathcal{E}), j(\mathcal{E}')\} = \{0, 1728\}$ , and  $\text{RA}(\mathcal{A}) \cong C_{12}$ .*
- (2) *If  $\mathcal{A} \cong \mathcal{E}^2$  for some  $\mathcal{E}$ , then one of the following holds:*
  - *Type- $\Sigma$ :  $j(\mathcal{E}) \notin \{0, 1728\}$ , and  $\text{RA}(\mathcal{A}) \cong C_2^2$ .*
  - *Type- $\Sigma_0$ :  $j(\mathcal{E}) = 0$ , and  $\text{RA}(\mathcal{A}) \cong C_6 \times S_3$ .*
  - *Type- $\Sigma_{123}$ :  $j(\mathcal{E}) = 1728$ , and  $\text{RA}(\mathcal{A}) \cong C_2^2 \rtimes C_4$ .*

*Proof.* Recall that if  $\mathcal{E}$  is an elliptic curve, then: if  $j(\mathcal{E}) = 0$  then  $\text{Aut}(\mathcal{E}) = \langle \rho \rangle \cong C_6$ ; if  $j(\mathcal{E}) = 1728$  then  $\text{Aut}(\mathcal{E}) = \langle \iota \rangle \cong C_4$ ; and otherwise  $\text{Aut}(\mathcal{E}) = \langle [-1] \rangle \cong C_2$ .

For Part (1): if  $\mathcal{E} \not\cong \mathcal{E}'$ , then  $\text{Aut}(\mathcal{E} \times \mathcal{E}') \cong \text{Aut}(\mathcal{E}) \times \text{Aut}(\mathcal{E}')$ . If  $\text{Aut}(\mathcal{E}) = \langle \alpha \rangle$  and  $\text{Aut}(\mathcal{E}') = \langle \beta \rangle$ , then  $\text{Aut}(\mathcal{E} \times \mathcal{E}') = \langle \alpha \times [1], [1] \times \beta \rangle$ . Notice that  $\beta^d = [-1]$  for  $d = 1, 2$  or  $3$ , so if  $j(\mathcal{E}) \notin \{0, 1728\}$ , then  $\text{RA}(\mathcal{E} \times \mathcal{E}') \cong \text{Aut}(\mathcal{E}')$ , which proves the first three cases. For the remaining Type-II<sub>0,123</sub> case, the automorphism  $[\rho] \times [\iota]$  has exact order 12, proving  $\text{RA}(\mathcal{E} \times \mathcal{E}') \cong C_{12}$ .

For Part (2): in this case  $\text{Aut}(\mathcal{E}^2)$  certainly contains  $\text{Aut}(\mathcal{E})^2$  as a subgroup, but we also have the involution  $\tau: (P, Q) \mapsto (Q, P)$ . The existence of  $\tau$  makes  $\text{Aut}(\mathcal{E}^2)$  non-abelian, because  $(\beta \times \gamma) \circ \tau = \tau \circ (\gamma \times \beta)$  for any  $\beta, \gamma \in \text{Aut}(\mathcal{E})$ . If  $\text{Aut}(\mathcal{E}) = \langle \alpha \rangle$ , then  $\text{Aut}(\mathcal{E}^2) = \langle \alpha \times [1], [1] \times \alpha, \tau \rangle$  is the wreath product  $\text{Aut}(\mathcal{E}) \wr \langle \tau \rangle$ , i.e., the semidirect product  $(\text{Aut}(\mathcal{E}) \times \text{Aut}(\mathcal{E})) \rtimes \langle \tau \rangle$ . More explicitly: if  $\text{Aut}(\mathcal{E}) = \langle \alpha \rangle$ , then

$$\text{Aut}(\mathcal{E}^2) \cong \langle a, b, \tau \mid a^d = b^d = \tau^2 = 1, ab = ba, a\tau = \tau b \rangle,$$

where  $a = \alpha \times [1]$ ,  $b = [1] \times \alpha$ , and  $d \in \{2, 4, 6\}$  is the order of  $\alpha$ . Taking the quotient by  $[-1]_{\mathcal{E}^2}$ , we identify the reduced automorphism groups using GAP's `IdGroup` [19].  $\square$

**6.3. Implications for isogeny graphs.** The vertices in  $\Gamma_g(\ell; p)$  corresponding to PPAVs with nontrivial reduced automorphism groups form interesting and inter-related structures. We highlight a few of these facts for  $g = 2$  and  $\ell = 2$ .

Katsura and Takashima observe that if we take a Jacobian vertex  $[\mathcal{J}(\mathcal{C})]$  in  $\Gamma_2(2; p)$ , then the number of elliptic-product neighbours of  $[\mathcal{J}(\mathcal{C})]$  is equal to the number of involutions  $\alpha$  in  $\text{RA}(\mathcal{J}(\mathcal{C}))$  induced by involutions in  $\text{Aut}(\mathcal{J}(\mathcal{C}))$  (see [27, Proposition 6.1]). In particular: general Type-A vertices and the unique Type-II vertex have *no* elliptic product neighbours; Type-I and Type-IV vertices, and the

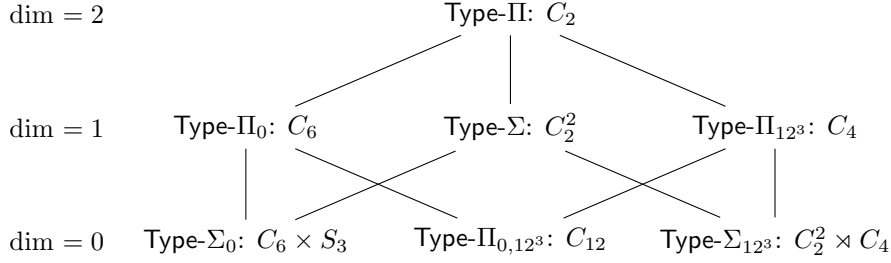

FIGURE 3. The taxonomy of reduced automorphism groups of elliptic products. Dimensions on the left are of the loci on each level in the 3-dimensional moduli space of PPASes. Lines connect sub-types and super-types; specialization moves down the page.

unique **Type-VI** vertex, have *one* elliptic product neighbour; and the **Type-III** vertices and the unique **Type-V** vertex have *two* elliptic-square neighbours. By explicit computation of Richelot isogenies we can (slightly) extend Katsura and Takashima's results to give the complete description of weighted edges with codomain types for each of the vertex types in Table 3. The inter-relation of reduced automorphism groups and neighbourhoods of vertices and edges in the Richelot isogeny graph is further investigated (and illustrated) in [15].

*Remark 3.* Each **Type-IV** vertex has a triple edge to an elliptic-product neighbour. In fact, the factors of the product are always 3-isogenous (cf. [20, §3]). The unique **Type-VI** vertex is a specialization of **Type-IV**, and in this case the **Type-II** neighbour specializes to the square of an elliptic curve with  $j$ -invariant 8000 (which has an endomorphism of degree 3). The unique **Type-V** vertex is also a specialization of **Type-IV**, and in this case the **Type-II** neighbour specializes to the square of an elliptic curve of  $j$ -invariant 54000 (which as an endomorphism of degree 3); one of the **Type-IV** neighbours degenerates to the square of an elliptic-curve with  $j$ -invariant 0, while the other two merge, yielding a weight-2 edge; and one of the **Type-I** neighbours specializes to the **Type-V** vertex, yielding a loop, while the other two merge, yielding a weight-6 edge.

*Remark 4.* Each of the **Type-III** vertices, and the unique **Type-V** vertex, have *two* elliptic-square neighbours, and these are the squares of a pair of 2-isogenous elliptic curves (see [20, §4]). Note that in this way, **Type-III** vertices in  $\Gamma_2(2; p)$  correspond to undirected edges (i.e., edges modulo dualization of isogenies) in  $\Gamma_1(2; p)$ .

Ibukiyama, Katsura, and Oort have computed the precise number of superspecial genus-2 Jacobians (up to isomorphism) of each reduced automorphism type [24, Theorem 3.3]. We reproduce their results for  $p > 5$ , completing them with the number of superspecial elliptic products of each automorphism type (which can be easily derived from the well-known formula for the number of supersingular elliptic curves over  $\mathbb{F}_{p^2}$ ) in Table 4.

*Remark 5.* Note that if  $p \equiv \pm 2 \pmod{5}$ , then the unique **Type-II** vertex is supersingular but *not* superspecial.

TABLE 3. Number of edges, weights, and types of neighbours for vertices in  $\Gamma_2(2; p)$  by reduced automorphism type. Observe that the edge numbers multiplied by their weights always sum to 15. Note that the neighbour types may change under specialization (or for particular values of  $p$ ), acquiring reduced automorphisms. See [15] for more detail.

## 7. CONNECTIVITY AND DIAMETERS

We mentioned in §4 that Theorem 1 can be applied to study distributions in interesting isogeny subgraphs of the superspecial isogeny graph. Let us then distinguish three subgraphs of  $\Gamma_g^{SS}(\ell; p)$ , each taken to be the induced subgraph defined by its set of vertices:

- $\Gamma_g^{SS}(\ell; p)^J$ , the subgraph of Jacobians;
- $\Gamma_g^{SS}(\ell; p)^P$ , the subgraph of reducible PPAVs (product varieties); and
- $\Gamma_g^{SS}(\ell; p)^E$ , the subgraph of products of elliptic curves.

(Observe that  $\Gamma_2^{SS}(\ell; p)^P = \Gamma_2^{SS}(\ell; p)^E$ ). Understanding the connectivity of such subgraphs can be useful both when analysing the algorithms that work with them, and when studying the distribution of vertices in the full supersingular graph.

**Proposition 4.** *The graphs  $\Gamma_g^{SS}(\ell; p)^P$  and  $\Gamma_g^{SS}(\ell; p)^E$  are connected and aperiodic for all  $g$ ,  $\ell$ , and  $p$ . In particular, both graphs satisfy the hypotheses of Theorem 1.*

*Proof.* It is enough to see that  $\Gamma_g^{SS}(\ell; p)^E$  is connected and aperiodic, since it is a subgraph of  $\Gamma_g^{SS}(\ell; p)^P$  and given a product variety we can find a product isogeny

Type	Number of vertices in $\Gamma_2^{SS}(\ell; p)$
Type-A	$\frac{1}{2880}(p-1)(p^2 - 35p + 346) - \frac{1}{16}\epsilon_{1,p} - \frac{1}{4}\epsilon_{2,p} - \frac{2}{9}\epsilon_{3,p} - \frac{1}{5}\epsilon_{5,p}$
Type-I	$\frac{1}{48}(p-1)(p-17) + \frac{1}{4}\epsilon_{1,p} + \epsilon_{2,p} + \epsilon_{3,p}$
Type-II	$\epsilon_{5,p}$
Type-III	$\frac{3}{2}N_p + \frac{1}{2}\epsilon_{1,p} - \frac{1}{2}\epsilon_{2,p} - \frac{1}{2}\epsilon_{3,p}$

TABLE 4. The number of vertices in  $\Gamma_2^{SS}(\ell; p)$  of each reduced automorphism type. Here  $\epsilon_{1,p} = 1$  if  $p \equiv 3 \pmod{4}$ , 0 otherwise;  $\epsilon_{2,p} = 1$  if  $p \equiv 5, 7 \pmod{8}$ , 0 otherwise;  $\epsilon_{3,p} = 1$  if  $p \equiv 2 \pmod{3}$ , 0 otherwise;  $\epsilon_{5,p} = 1$  if  $p \equiv 4 \pmod{5}$ , 0 otherwise; and  $N_p = (p-1)/12 - \epsilon_{1,p}/2 - \epsilon_{3,p}/3$  is the number of supersingular elliptic curves over  $\mathbb{F}_{p^2}$  with reduced automorphism group  $C_2$ .

to an elliptic product by the connectivity of  $\Gamma_g^{SS}(\ell; p)$ . We obtain connectivity from the fact that  $\Gamma_g^{SS}(\ell; p)^E$  has a spanning subgraph which is a quotient of the tensor product of  $g$  copies of the supersingular isogeny graph  $\Gamma_1^{SS}(\ell; p)$  [23]. We have already proved aperiodicity, since in §4.2 we constructed loops and paths of coprime lengths in  $\Gamma_g^{SS}(\ell; p)^E$ .  $\square$

Proposition 4 generalizes immediately to any connected component of the general graph  $\Gamma_g(\ell; p)$  that contains elliptic products. We should be able to give a similar statement for the Jacobian subgraph even without the superspecial condition, but the technique that we use only allows us to prove it for the case  $g = 2$ ,  $\ell = 2$ .

**Theorem 2.** *The graph of Jacobians  $\Gamma_2^{SS}(2; p)^J$  is connected and aperiodic. In particular, it satisfies the hypotheses of Theorem 1.*

*Proof.* To see  $\Gamma_2^{SS}(2; p)^J$  is connected, it is enough to check that the subgraph containing all Type-I Jacobians is connected. Indeed, any two Jacobians  $J_1$  and  $J_2$  are connected by a path in  $\Gamma_2^{SS}(2; p)$ , and we only need to ensure that subpaths between Type-I Jacobians can be modified to avoid elliptic products. This is always possible by Lemma 4 below.

The aperiodicity for primes  $p \geq 13$  comes from the fact that there are always Type-III Jacobians, which always have a  $(2, 2)$ -endomorphism. One checks easily that  $\Gamma_2^{SS}(2; p)^J$  has at least one loop when  $p$  is 7 or 11. Indeed, for  $p = 7$  the unique Type-VI vertex has a  $(2, 2)$ -endomorphism  $\phi$  with weight  $w([\phi]) = 9$ , while for  $p = 7$  the unique Type-V vertex has a  $(2, 2)$ -endomorphism  $\psi$  with  $w([\psi]) = 3$ .  $\square$

**Lemma 4.** *Given a path  $[J_0] \rightarrow [\mathcal{E} \times \mathcal{E}'] \rightarrow [\mathcal{A}]$  in  $\Gamma_2(2;p)$ , where  $J_0$  is a Jacobian,  $\mathcal{E} \times \mathcal{E}'$  is an elliptic product, and  $\mathcal{A}$  is any PPAS, there exists either:*

(1) *A length-2 path*

$$[J_0] \rightarrow [J_1] \rightarrow [\mathcal{A}],$$

*where  $J_1$  is a Jacobian, if the original path represents a  $(4, 2, 2)$ -isogeny, or*

(2) *A length-4 path*

$$[J_0] \rightarrow [J_1] \rightarrow [J_2] \rightarrow [J_3] \rightarrow [\mathcal{A}],$$

*where each  $J_i$  is a Jacobian, if the original walk represents a  $(4, 4)$ -isogeny.*

*Proof.* Case 1. The original path represents a  $(4, 2, 2)$ -isogeny,  $\phi$ . Up to isomorphism, there are 3 ways of factoring  $\phi$  into a composition of two  $(2, 2)$ -isogenies:

- $\phi : J_0 \rightarrow \mathcal{E} \times \mathcal{E}' \rightarrow \mathcal{A}$ ,
- $\phi_1 : J_0 \rightarrow \mathcal{A}_1 \rightarrow \mathcal{A}$ , and
- $\phi_2 : J_0 \rightarrow \mathcal{A}_2 \rightarrow \mathcal{A}$ .

The isogenies  $J_0 \rightarrow \mathcal{A}_i$  each have one nontrivial kernel point in common with  $J_0 \rightarrow \mathcal{E} \times \mathcal{E}'$ . We know that  $[J_0]$  has at most two elliptic-product neighbours (see Table 3). After a coordinate transformation, we can suppose that  $J_0 \rightarrow \mathcal{E} \times \mathcal{E}'$  is a Richelot isogeny with  $\ker(J_0 \rightarrow \mathcal{E} \times \mathcal{E}') = \{x^2 - a^2, x^2 - b^2, x^2 - c^2\}$ . Relabelling  $(a, b, c)$  if necessary, we can assume the point common to  $\ker(J_0 \rightarrow \mathcal{E} \times \mathcal{E}')$ ,  $\ker(J_0 \rightarrow \mathcal{A}_1)$ , and  $\ker(J_0 \rightarrow \mathcal{A}_2)$  corresponds to  $x^2 - a^2$ , and thus

$$\ker(J_0 \rightarrow \mathcal{A}_1) = \{x^2 - a^2, x^2 - (b+c)x + bc, x^2 + (b+c)x + bc\}$$

and

$$\ker(J_0 \rightarrow \mathcal{A}_2) = \{x^2 - a^2, x^2 - (b-c)x - bc, x^2 + (b-c)x - bc\}.$$

It is easy to check that the determinants of these two triples cannot both vanish unless the original curve is singular.

Case 2. The original walk represents a  $(4, 4)$ -isogeny,  $\phi$ . We can always choose a neighbour  $[J_2] \neq [J_0]$  of  $[\mathcal{E} \times \mathcal{E}']$  such that  $J_0 \rightarrow \mathcal{E} \times \mathcal{E}' \rightarrow J_2$  and  $J_2 \rightarrow \mathcal{E} \times \mathcal{E}' \rightarrow \mathcal{A}$  both represent  $(4, 2, 2)$ -isogenies. Now apply Case 1 to each of these, eliminating  $\mathcal{E} \times \mathcal{E}'$  from the middle of each length-2 path, and compose the results.  $\square$

*Remark 6.* When  $J_0$  is Type-III or Type-V in the  $(4, 2, 2)$  case, it is possible that we obtain  $[J_0] = [J_1]$ , so we actually simplify to a length-1 path  $[J_0] \rightarrow [\mathcal{A}]$ . On top of that, it is even possible that  $[J_0] = [J_2]$  in the  $(4, 4)$  case, which would also simplify the original length-2 path (and the modified length-4 one) to the much shorter  $[J_0] \rightarrow [\mathcal{A}]$ .

**Corollary 2.** *The Jacobian graph  $\Gamma_2^{SS}(2;p)^J$  satisfies the following inequalities:*

$$\text{diam}(\Gamma_2^{SS}(2;p)) - 2 \leq \text{diam}(\Gamma_2^{SS}(2;p)^J) \leq 2 \text{diam}(\Gamma_2^{SS}(2;p)).$$

*Proof.* The first inequality comes from the fact that every elliptic product has a Richelot isogeny to a Jacobian. For the second one, apply the last lemma repeatedly to bound the distance between any two nodes in  $\Gamma_2^{SS}(2;p)^J$ .  $\square$

The lower bound of Corollary 2 inequality is tight, as seen for  $\Gamma_2^{SS}(2;521)$ . Our experimental results suggest that the upper bound may have some margin for improvement.

#### APPENDIX A. EXPERIMENTAL DIAMETERS AND $\lambda_*$ FOR $\Gamma_2^{SS}(2; p)$

The following table consists of experimental data computed for the graphs  $G = \Gamma_2^{SS}(2; p)$ ,  $J = \Gamma_2^{SS}(2; p)^J$  and  $E = \Gamma_2^{SS}(2; p)^E$ . The computed values are the

diameters  $d(G)$ ,  $d(J)$  and  $d(E)$ , and the (scaled) second-largest eigenvalues of each graph. In particular, the second eigenvalues of  $\Gamma_2^{SS}(2; p)$  support Conjecture 1. We use the notation  $\tilde{\lambda}_* = 15\lambda_*$ .

$p$	$d(G)$	$d(J)$	$d(E)$	$\tilde{\lambda}_*(G)$	$\tilde{\lambda}_*(J)$	$\tilde{\lambda}_*(E)$
