Abstract. In $1$-out-of-$q$ Oblivious Transfer (OT) protocols, a sender Alice is able to send one of $q \geq 2$ messages to a receiver Bob, all while being oblivious to which message was transferred. Moreover, the receiver learns only one of these messages. Oblivious Transfer combiners take $n$ instances of OT protocols as input, and produce an OT protocol that is secure if sufficiently many of the $n$ original OT instances are secure. We present new 1-out-of-\(q\) OT combiners that are perfectly secure against active adversaries. Our combiners arise from secret sharing techniques. We show that given an $\mathbb{F}_q$-linear secret sharing scheme on a set of $n$ participants and adversary structure $A$, we can construct $n$-server, 1-out-of-$q$ OT combiners that are secure against an adversary corrupting either Alice and a set of servers in $A$, or Bob and a set of servers $B$ with $\bar{B} \notin A$. If the normalized total share size of the scheme is $\ell$, then the resulting OT combiner requires $\ell$ calls to OT protocols, and the total amount of bits exchanged during the protocol is $(q^2 + q + 1)\ell \log q$.

We also present a construction based on 1-out-of-2 OT combiners that uses the protocol of Crépeau, Brassard and Robert (FOCS 1986). This construction provides smaller communication costs for certain adversary structures, such as threshold ones: For any prime power $q \geq n$, there are $n$-server, 1-out-of-$q$ OT combiners that are perfectly secure against active adversaries corrupting either Alice or Bob, and a minority of the OT candidates, exchanging $O(qn \log q)$ bits in total.

Keywords: Oblivious transfer · OT combiners · Secret sharing schemes

1 Introduction

Oblivious Transfer (OT) protocols involve two parties, a sender and a receiver, which we also respectively name Alice and Bob. The functionality provided by OT consists in allowing the sender to transfer part of its inputs to the receiver, while guaranteeing that the sender is oblivious to which part of its inputs is actually obtained by the receiver. It also guarantees that the receiver is not able learn more information than it is entitled to as per the protocol.

OT protocols were first introduced by Rabin [42] in 1981. In 1-out-of-2 OT protocols [22], the sender holds two messages, and the receiver chooses to receive one of them from the sender. Security here consists in the sender being oblivious to the message that was actually transferred, and the receiver getting information on only one of the messages. The type of OT that we study here is called 1-out-of-$q$ OT. It is a generalization of 1-out-of-2 OT, first presented by Crépeau,
Brassard and Robert [18] in 1986. It lets the sender hold \( q \geq 2 \) messages instead of just two, and allows the receiver to fetch only one of those messages. The relevance of OT protocols in cryptography lies in their role as a fundamental primitive in many cryptographic constructions. The main functionalities OT has found an application to are secure multi-party computation, zero-knowledge proofs and bit commitment schemes (see [10,31,32,45], for example).

The security of OT protocols is necessarily conditional, since perfectly secure OT protocols would yield unconditionally-secure two-party computation by [31], which is impossible to obtain for some functions (see [11,17]). Hence, the security of OT protocols is based on computational hardness assumptions such as the hardness of RSA [12], the DDH assumption [110], code-based assumptions [21] and also lattice-based assumptions [40]. Alternatively, the security of OT can be guaranteed by the existence of a noisy channel between both parties [19], the use of hardware tokens [24], restrictions on the storage [13], and other ways. The conditional security of OT protocols implies that the security guarantees of OT could be compromised. The standard method to mitigate this concern consists in grounding security on various assumptions at once, by simultaneously using several implementations. This motivates the use of OT combiners.

The notion of combiner consists of blending various cryptographic implementations into one, so that the resulting combination is secure even if some of the original implementations are insecure. Combiners have been previously studied in other areas of cryptography, for instance in multi-factor authentication, where many authentication methods are used concurrently, as well as in cascading of block ciphers or hybrid key encapsulation.

Using an OT combiner, a set of \( n \) candidate implementations of OT can be merged to realize a single OT protocol. In other words, an OT combiner can be used to instantiate a protocol between a sender Alice and a receiver Bob that realizes OT by internally using \( n \) candidate OT implementations. The resulting protocol is secure as long as sufficiently many of the initial implementations were secure to begin with.

An OT combiner is black-box if, during the combined protocol, the candidate OT implementations are used in a black-box way, i.e. ignoring their internal workings. In this work, we only consider black-box OT combiners. Under this assumption, as in [10], we view OT combiners as server-aided OT protocols. This means that we model each of the OT candidate implementations as a server that implements the 1-out-of-\( q \) OT functionality, i.e. that receives \( q \) messages \( m_0, \ldots, m_{q-1} \) from Alice and an index \( b \) from Bob, and outputs the message \( m_b \) to Bob. We then say that an OT combiner is \( n \)-server if it takes \( n \) OT candidates as input. An OT combiner is single-use if each OT candidate is used only once during the execution of the protocol. In contrast, an OT combiner is multi-use if, during the protocol, an OT candidate can be used more than once.

1.1 Related Work

The study of OT combiners was initiated by Harnik, Kilian, Naor, Reingold and Rosen [20] in 2005. They define the notion of \((n, t)\)-OT combiner, which consists
in taking \( n \) candidate 1-out-of-2 OT implementations and combining them into a 1-out-of-2 OT protocol that is secure provided at most \( t \) of the OT candidates are faulty. They show that, when \( t < n/2 \), there exist \((n, t)\)-OT combiners that are unconditionally secure against passive (i.e. semi-honest) adversaries. They prove the tightness of this bound and show that such OT combiners cannot exist for \( n = 2, t = 1 \).

Next, we present the main results on OT combiners that, like [26], take 1-out-of-2 OT implementations and combine them into a 1-out-of-2 OT protocol. There are other combiners, not covered here, in which the OT functionality is obtained by combining different primitives like oblivious linear function evaluation [41] or private information retrieval [36] protocols.

Meier, Przydatek and Wullschleger [37] present OT combiners that implement the 1-out-of-2 OT functionality and are unconditionally secure against passive adversaries that corrupt either Alice and a number \( t_A \) of OT candidates, or Bob and \( t_B \) OT candidates for any \( t_A + t_B < n \). These protocols were later called \((n, t_A, t_B)\)-OT combiners. Their combiner is multi-use, and it makes two calls to each OT candidate. We call \( \mathcal{P}_n = \{1, \ldots, n\} \) the set of OT candidates.

Harnik, Ishai, Kushilevitz and Nielsen [25] present the first single-use OT combiner. A statistically secure \((n, t, t)\)-OT combiner is given for \( t = \Omega(n) \), which makes a constant number of calls to each OT candidate. Their solution is set in the 1-out-of-2 scenario. Additionally, [25] gives a computationally secure OT combiner against active adversaries. Subsequently, Ishai, Prabhakaran and Sahai [28] show that this construction can be turned into an \((n, t, t)\)-OT combiner that is statistically secure against active adversaries for \( t = \Omega(n) \). Ishai, Maji, Sahai and Wullschleger [27] present a single-use \((n, t, t)\)-OT combiner that is statistically secure against passive adversaries for \( t = n/2 - \omega(\log \kappa) \), where \( \kappa \) is the security parameter.

Following [27], Cascudo, Damgård, Farràs and Ranellucci [16] achieve single-use 1-out-of-2 OT combiners. They generalize the security notion in [25] by defining the notion of perfect security against active \((\mathcal{A}, \mathcal{B})\)-adversaries for some \( \mathcal{A}, \mathcal{B} \subseteq 2^{\mathcal{P}_n} \), which we also adopt in this article. This definition considers an active adversary that can corrupt either Alice and a set \( A \in \mathcal{A} \) of OT candidates, or Bob and a set \( B \in \mathcal{B} \) of OT candidates, obtaining their inputs and full control of their outputs. Their OT combiner achieves perfect (unconditional, zero-error) security against \( \mathcal{R}_2 \) adversaries, i.e., adversaries with pairs \((\mathcal{A}, \mathcal{B})\) satisfying that \( A \cup B \neq \mathcal{P}_n \) for every \( A \in \mathcal{A} \) and \( B \in \mathcal{B} \).

All the works mentioned above combine various primitives into 1-out-of-2 OT. It is also possible to use of 1-out-of-2 OT to obtain 1-out-of-\( q \) OT for any integer \( q \geq 2 \), by taking as many as \( q - 1 \) or \( \log q \) OT candidates. However, in these constructions, a single faulty 1-out-of-2 OT candidate results in an insecure 1-out-of-\( q \) OT protocol. This motivates the search for 1-out-of-\( q \) OT combiners with better security guarantees.

Our OT combiners are built with the use a specific kind of secret sharing schemes that has been studied in previous works. Given a Boolean function \( f : \{0, 1\}^n \rightarrow \{0, 1\} \), consider the access structure on the set of partici-
pants $P = \{1, \ldots, n\} \times \{0, 1\}$ whose minimal subsets are $\{(1, x_1), \ldots, (n, x_n)\}$ with $f(x_1, \ldots, x_n) = 1$ and the subsets $\{(i, 0), (i, 1)\}$ for $1 \leq i \leq n$. Efficient constructions are known \cite{94} for some of these structures. Liu, Vaikuntanathan and Wee \cite{35} presented more efficient schemes, and showed a connection between these schemes and Conditional Disclosure of Secrets (CDS) protocols \cite{23}, namely for CDS protocols for the INDEX predicate. That connection was later used to construct better general constructions for secret sharing \cite{23, 34, 8}. In this work, we study access structures determined by functions $f : \{0, \ldots, q-1\}^n \to \{0, 1\}$, a case studied in \cite{2, 3, 23}, for example.

1.2 Our Work

This work is dedicated to the construction of efficient 1-out-of-$q$ OT combiners for any $q \geq 2$. We extend the security and consistency notions in \cite{16} from the 1-out-of-2 case to the 1-out-of-$q$ case, and we present OT combiners that attain perfect security against active $(A, B)$-adversaries. As far as we know, this is the first work dedicated to the construction of efficient 1-out-of-$q$ OT combiners with active security for any $q \geq 2$. Our main result is the following theorem, which is constructive.

**Theorem 1.1.** Let $\mathbb{F}_q$ be a finite field, let $\Sigma$ be an $\mathbb{F}_q$-linear secret sharing scheme on $\mathcal{P}_n$ with adversary structure $A$ and normalized total share size $\ell$, and let $B \subseteq 2^{\mathcal{P}_n}$ satisfying that $(A, B)$ is $R_2$. Then there exists an $n$-server, 1-out-of-$q$ OT combiner for messages in $\mathbb{F}_q$ that is perfectly secure against any active $(A, B)$-adversary and requires exchanging $(q^2 + q + 1)\ell \log q$ bits. If $\Sigma$ is ideal, then the OT combiner is single-use.

The communication cost of this theorem does not take into account the communication cost of the OT instantiations, because our combiner is black-box. Our 1-out-of-$q$ OT combiner can also be used as 1-out-of-$m$ OT combiner for any integer $m < q$, which reduces a bit the communication cost. As a corollary of this theorem and \cite{16}, we have that $(A, B)$ admits a 1-out-of-$q$ OT combiner if and only if $(A, B)$ is $R_2$. It was already known for $q = 2$ \cite{16}, but not for greater $q$.

This OT combiner makes use of the OT implementations a total of $\ell$ times. That is, the number of OT calls and the communication complexity increase linearly with the normalized total share size of $\Sigma$. Therefore, in our construction, the search of efficient OT combiners can be reduced to the search of efficient linear secret sharing schemes. We can guarantee efficient 1-out-of-$q$ OT combiners for those pairs of $R_2$ adversary structures $(A, B)$ for which there exist $\mathbb{F}_q$-linear secret sharing schemes with adversary structure $\mathcal{C}$ satisfying $A \subseteq \mathcal{C}$ and $B \subseteq \mathcal{C}^* = \{C \subseteq \mathcal{P}_n : \mathcal{P}_n \setminus C \notin \mathcal{C}\}$. In the threshold adversary structure case, we have the following result.

**Corollary 1.2.** Let $q$ be a prime power and let $2 \leq n \leq q$. There exists a single-use, $n$-server, 1-out-of-$q$ OT combiner that is perfectly secure against active adversaries corrupting either Alice or Bob, and a minority of the OT candidates. The amount of bits exchanged during the protocol is $(q^2 + q + 1)n \log q$. 

4
In the process of building our 1-out-of-q OT combiners, we study secret sharing schemes associated to affine spaces. Namely, let \( W \subseteq \mathbb{F}_q^n \) be an affine space, and let \( f : \mathbb{F}_q^n \to \{0, 1\} \) be the Boolean function with \( f(x_1, \ldots, x_n) = 1 \) if and only if \( (x_1, \ldots, x_n) \in W \). We present ideal linear secret sharing schemes on the set of \( nq \) participants \( \{1, \ldots, n\} \times \mathbb{F}_q \) in which a subset \( \{(1, v_1), \ldots, (n, v_n)\} \) is authorized if and only if \( f(v_1, \ldots, v_n) = 1 \). Moreover, from our schemes, it is possible to build \( n \)-server CDS protocols for \( f \) with domain of secrets \( \mathbb{F}_q \), and with optimal message size and certain robustness, in the sense of [2].

We also describe a 1-out-of-q OT combiner with similar security properties that uses the 1-out-of-2 OT construction by Crépeau, Brassard and Robert [18] in this setting. It consists in combining 1-out-of-2 OT combiners. This construction relies on \( \mathbb{F}_2 \)-linear secret sharing schemes and 1-out-of-2 OT protocols. For threshold adversary structures and single-bit messages, the communication complexity is \( (3q - 1)n \log n \). This construction does not restrict the number of messages \( q \) to a prime power, and it allows for arbitrary \( q \geq 2 \). It is highly multi-use, and each of the 1-out-of-2 OT instances is executed \( q \log n \) times. To support messages larger than one bit, the protocol is replicated and combined with zigzag functions [18].

In general, given an \( \mathcal{R}_2 \) pair \((A, B)\), the convenience of one of the constructions proposed here over others will depend on the share size of \( \mathbb{F} \)-linear secret sharing schemes for \((A, B)\) for \( \mathbb{F} = \mathbb{F}_2 \) or \( \mathbb{F} = \mathbb{F}_q \). Notice that the power of linear secret sharing schemes over fields of different characteristics is incomparable. Indeed, there is a super-polynomial separation between any two fields with different characteristics [9].

**Theorem 1.3.** Let \( q \) be a prime power, let \( 2 \leq n \leq q \) and \( t < n/2 \). There exists an \( n \)-server, 1-out-of-\( q \) OT combiner, with messages of bitsize \( s \geq 1 \), that is perfectly secure against active adversaries corrupting either Alice or Bob and less than \( t \) OT candidates, that requires exchanging \( O(qns^{1.6} \log n) \) bits, and that requires \( O(q^{1.6} \log n) \) calls to each 1-out-of-2 OT instance.

For messages of \( \log q \) bits, \( q \geq n \), and for \( t < n/2 \), Corollary 1.2 provides 1-out-of-\( q \) OT-combiners for \( t \)-threshold structures \( A \) and \( B \) that are single-use and for which the number of exchanged bits is \( O(q^2 n \log q) \). The construction of Theorem 1.3 requires less communication, \( O(qn \log n \log^* q) \), but requires \( O(q \log n \log^2 q) \) calls to each one of the 1-out-of-2 OT instances.

### 1.3 Overview of our Constructions

Next, we describe the structure of the main constructions of this work (in Sections 4 and 7). We have \( n \) servers \( S_1, \ldots, S_n \), each one performing the 1-out-of-\( q \) OT functionality. Bob holds \( b \in \{0 \ldots q - 1\} \), and Alice holds some messages \( m_0, \ldots, m_{q-1} \). At the end of the protocol, Bob can recover \( m_b \), while Alice does not get information about \( b \).

Bob creates \( n \) shares of \( b \) with a secret sharing scheme \( \Sigma \), and sends one share to each server. That is, the server \( S_i \) receives a share \( b_i \), which will be the selection
input of the OT functionality of $S_i$. Independently, Alice creates shares of her messages. Alice creates $nq$ shares of the message $m_0$ with some special secret sharing scheme $S_0$. These shares $m_{0}^{(i,j)}$ are indexed by $(i,j) \in \{1,\ldots,n\} \times \{0,\ldots,q-1\}$. Then, Alice creates shares of the rest of messages $m_k$ each with a different scheme $S_k$, obtaining the shares $m_k^{(i,j)}$ with $(i,j) \in \{1,\ldots,n\} \times \{0,\ldots,q-1\}$. All these shares are packed in strings $u_j^i = m_{0}^{(i,j)} || m_{1}^{(i,j)} || \cdots || m_{q-1}^{(i,j)}$, and Alice sends $u_j^0,\ldots,u_j^{q-1}$ to server $S_i$ for each $1 \leq i \leq n$. Then, server $S_i$ performs the $1$-out-of-$q$ OT functionality with the inputs received from Alice and Bob. Namely, $S_i$ outputs $u_{b_i}^i$ to Bob. Finally, Bob collects all messages sent by the servers, and recovers $m_b$. A diagram of the protocol for the case $q = 4$ and $n = 3$ is presented in Figure 1.

![Diagram of a 1-out-of-4 OT combiner for $n = 3$.](image)

In this setting, $\Sigma$ and $S_0,\ldots,S_{q-1}$ must be chosen in such a way that the functionality is performed correctly. Roughly speaking, if $b_1,\ldots,b_n$ is a valid sharing of $b$ by $\Sigma$, then it must be possible to recover $m_b$ from $u_{b_1}^1,\ldots,u_{b_n}^n$. Hence, the subsets $\{(1,b_1),\ldots,(n,b_n)\}$ must be authorized sets of $S_i$ if $b_1,\ldots,b_n$ is a valid share of $b$. Regarding security, if Bob can recover $m_b$, he must not be able to obtain any information about other $m_k$ for $k \neq b$. Hence, in this case, $u_{b_1}^1,\ldots,u_{b_n}^n$ must not provide any information about $m_k$, and so $\{(1,b_1),\ldots,(n,b_n)\}$ must be a forbidden subset of $S_b$.

Additionally, our OT combiners guarantee protection against adversaries taking control of Alice and some servers $A \in A$, or Bob and some servers $B \in B$. This protection is guaranteed by restricting the access structures of the secret sharing schemes $\Sigma$ and $S_k$ to these requirements, while preserving correctness (see an introduction to secret sharing in Section 2.1). In general, given a secret sharing scheme $\Sigma$, it is not known if there exist efficient schemes $S_0,\ldots,S_{q-1}$ adapted to the shares of $\Sigma$.

One of the main contributions of this work is that, when $\Sigma$ is ideal and $\mathbb{F}_q$-linear, we find schemes $S_0,\ldots,S_{q-1}$ that are ideal, $\mathbb{F}_q$-linear, and satisfy...
the desired security restrictions, and thus we obtain an efficient, single-use, \( n \)-server, 1-out-of-\( q \) OT combiner. Hence, given an \( \mathcal{R}_2 \) pair of adversary structures \((\mathcal{A}, \mathcal{B})\), if \( \mathcal{A} \) admits an ideal \( \mathbb{F}_q \)-linear secret sharing scheme, then the resulting OT combiner is perfectly secure against active \((\mathcal{A}, \mathcal{B})\)-adversaries. Here, the main difficulty lies in constructing the schemes \( S_k \). As mentioned above, subsets \( \{(1, b_1), \ldots, (n, b_n)\} \) for sharings of \( b \) must be authorized for \( b = k \) and forbidden if \( b \neq k \). Additionally, since we guarantee perfect security against an active adversary controlling Alice and servers \( \{S_i\}_{i \in A} \) for any \( A \in \mathcal{A} \), it must not be possible to obtain \( b \) from \( \{b_i\}_{i \in A} \). And, since we guarantee perfect security against an active adversary controlling Bob and servers \( \{S_i\}_{i \in B} \) for any \( B \in \mathcal{B} \), the subset \( \{(1, b_1), \ldots, (n, b_n)\} \cup \{(i, j) : i \in B, 0 \leq j < q\} \) must be forbidden in \( S_k \) for every \( k \neq b \).

In the construction of Theorem 1.1 we use the fact that if a secret sharing scheme \( \Sigma \) is \( \mathbb{F}_q \)-linear, then the family of sharings of \( b \in \mathbb{F}_q \) form an affine space in \( \mathbb{F}_q^n \). Our schemes \( S_k \), as the ones in [16] for \( q = 2 \), exploit this property. However, the case \( q = 2 \) differs from the case \( q > 2 \) in the following sense. For every \( \mathbb{F}_2 \)-affine space \( W \), there exists an ideal \( \mathbb{F}_2 \)-linear secret sharing scheme whose minimal authorized subsets are vectors in \( W \). However, for \( q > 2 \), \( \mathbb{F}_q \)-affine spaces do not admit ideal \( \mathbb{F}_q \)-linear secret sharing schemes, in general.

We circumvent this problem by finding a sufficient condition for a secret sharing scheme to be used as a building block of our OT combiner. We call this condition \( W \)-OT-compatibility. Then we prove that the schemes \( S_k \) that are the natural extension of the ones in [16] are indeed \( W \)-OT-compatible.

In case that \( \Sigma \) is a non-ideal \( \mathbb{F}_q \)-linear secret sharing scheme with adversary structure \( \mathcal{A} \), we can still construct OT combiners that are perfectly secure against active \((\mathcal{A}, \mathcal{B})\)-adversaries. However, they are multi-use, as they require some servers to perform more than one OT execution. The number of OT executions coincides with the normalized total share size of \( \Sigma \). In this case, we transform \( \Sigma \) into an ideal \( \mathbb{F}_q \)-linear scheme \( \Sigma' \) defined on an extended set of participants, and we run the protocol for the ideal case with \( \Sigma' \).

### 1.4 Paper Organization

In Section 2, we lay out the preliminaries on secret sharing and OT combiners. Section 3 states the correctness and security definitions of OT combiners. In Section 4, we present our single-use 1-out-of-\( q \) OT combiner. The results of this section imply Corollary 1.2. Section 5 analyzes the secret sharing schemes used in our constructions, and Section 6 presents the correctness and security proofs of this combiner. In Section 7, we extend our construction to the general case where, obtaining a multi-use OT combiner. Results in Sections 4 and 7 imply Theorem 1.1. Finally, we present constructions of 1-out-of-\( q \) OT combiners built from 1-out-of-2 OT combiners in Section 8.
2 Preliminaries

In this section, we lay out the background theory needed in the rest of the article. In Sections 2.1 and 2.2, we give an account of secret sharing and we present OT combiners in Section 2.3.

From now on, unless it is stated otherwise, $q$ denotes an arbitrary positive prime power. By abuse of notation, we denote the finite field of $q$ elements as $\mathbb{F}_q = \{0, \ldots, q - 1\}$. The power set of a set $P$ is $2^P := \{A : A \subseteq P\}$. Given an integer $n \geq 2$, we denote $\mathcal{P}_n := \{1, \ldots, n\}$ and $\mathcal{P}_{n,q} := \mathcal{P}_n \times \mathbb{F}_q = \{(i,j) : i \in \mathcal{P}_n, j \in \mathbb{F}_q\}$. We also consider the partition $\mathcal{P}_{n,q} = \mathcal{P}_1 \cup \ldots \cup \mathcal{P}_n$, where $\mathcal{P}_i := \{(i,0), (i,1), \ldots, (i,q-1)\}$ for $i = 1, \ldots, n$. For any $A \subseteq \mathcal{P}_n$ we denote $\bar{A} = \mathcal{P}_n \setminus A$. For any $A \subseteq 2^{\mathcal{P}_n}$ we define its dual as $A^* = \{A \subseteq \mathcal{P}_n : \bar{A} \notin A\}$.

2.1 Secret Sharing Schemes

For convenience, we take the definition of secret sharing scheme from [16], which is equivalent to the standard one [5]. For an introduction to this field, see [5,39].

Definition 2.1 ([16]). A secret sharing scheme $\Sigma$ on a set of participants $P = \{1, \ldots, n\}$ consists of the following two algorithms

\[(x_1, \ldots, x_n) \leftarrow \text{Share}_\Sigma(s,r) : \text{Probabilistic algorithm that takes as input a secret } s, \text{ belonging to a finite set } E_0, \text{ and some randomness } r \text{ in a set } \Omega. \text{ It returns an array of values } (x_1, \ldots, x_n), \text{ where each } x_i \text{ belongs to some finite set } E_i. \]

This array is called a sharing of $s$, and each of its elements is a share of $s$. $s \leftarrow \text{Reconstruct}_\Sigma((i,x_i)_{i \in A}) : \text{Algorithm that takes a set of pairs } (i,x_i)_{i \in A} \text{ as input for some } A \subseteq P, \text{ where } x_i \in E_i. \text{ It returns either a secret } s, \text{ or } \bot.$

The normalized total share size is $\sum_{i=1}^{n} \log |E_i|/\log |E_0|$. The indexes $i$ of shares $x_i$ in the input to Reconstruct$_\Sigma$ are omitted when implicitly clear. With this notation, we continue with more definitions. Let $A \subseteq P$. We say that

- $A$ is authorized for $\Sigma$ if, for every secret $s$, provided the shares $(x_i)_{i \in A}$ are part of a sharing of $s$, the function Reconstruct$_\Sigma((i,x_i)_{i \in A})$ recovers $s$ with probability one. That is, if, for every secret $s$,

\[\Pr[\text{Reconstruct}_\Sigma((\text{Share}_\Sigma(s,r))_{A}) = s] = 1.\]

- $A$ is forbidden for $\Sigma$ when the shares $(x_i)_{i \in A}$ of participants in $A$ do not reveal any information on the secret value $s$. That is, if, for every $s, s' \in E_0$, and every $(x_i)_{i \in A} \in \prod_{i \in A} E_i$,

\[\Pr[(\text{Share}_\Sigma(s,r))_{A} = (x_i)_{i \in A}] = \Pr[(\text{Share}_\Sigma(s',r))_{A} = (x_i)_{i \in A}] = 0.\]
We define the access structure of a scheme $\Sigma$ as the family of all its authorized subsets, and the adversary structure of $\Sigma$ is the family of its forbidden subsets. We say that $\Sigma$ is perfect if every subset $A \subseteq P$ is either authorized or forbidden. A perfect scheme with total normalized share size $n$ is called ideal.

Due to [20], access (resp. adversary) structures are just monotone increasing (resp. decreasing) families of subsets. For an access structure $\Gamma$, we define the minimal access structure of $\Gamma$ by $\min \Gamma = \{ A \in \Gamma : B \not\subseteq A \text{ for all } B \in \Gamma \}$. Analogously, given an adversary structure $A$, we define the maximal adversary structure of $A$ by $\max A = \{ A \in A : A \not\supseteq B \text{ for all } B \in A \}$. Given two adversary structures $A, B \subseteq 2^P$, we say that the pair $(A, B)$ is $R_2$ if $A \cup B \neq P$ for every $A \in A$ and $B \in B$. Notice that a pair $(A, B)$ is $R_2$ if and only if $B \subseteq A^\ast$.

### 2.2 Linear Secret Sharing Schemes

Linear Secret Sharing schemes (LSSS) are a type of secret sharing schemes that is key to building our 1-out-of-$q$ OT constructions. For convenience, we use the definition in [5,16], where secrets are elements of a finite field.

**Definition 2.2.** Let $\Sigma$ be a secret sharing scheme, where secrets take values in $E_0$, and shares in $E_1 \times \cdots \times E_n$. Let $F$ be a finite field. Then $\Sigma$ is $F$-linear if the following conditions hold

1. the randomness $r$ is chosen uniformly over a set $\Omega$,
2. $E_0 = F$ and $\Omega, E_1, \ldots, E_n$ are vector spaces of finite dimension over $F$, and
3. $\text{Share}_\Sigma$ is an $F$-linear surjective map

$$\text{Share}_\Sigma : E_0 \times \Omega \to E_1 \times \cdots \times E_n.$$  

For each $i \in P$, the $i$-th share space is $E_i = F^{\ell_i}$ for some positive integer $\ell_i$. Linear schemes are perfect and have normalized total share size $\ell = \sum_{i=1}^n \ell_i$.

Every adversary structure admits an $F_q$-LSSS for every $q$ [20]. However, almost all access structures require $F_q$-LSSS with normalized share size at least $2^{n/3-o(n)}$ for every $q$ [11]. The characterization of adversary structures admitting efficient LSSSs is an open problem.

Given a secret value $s \in F_q$, we have that $[s]_\Sigma \in F_q^{\ell}$, where $F_q^{\ell} = F_q^{\ell_1} \times \cdots \times F_q^{\ell_n}$. In this case, if we denote by $V$ the set of all possible shares $[0]_\Sigma$ of $0 \in F_q$, then $V = \{ \text{Share}_\Sigma(0, r) : r \in \Omega \}$ is a vector subspace of $F_q^{\ell}$. Similarly, if we denote by $W_k$ the set of all possible shares $[k]_\Sigma$ of a secret value $k \in F_q$, we have that $W_k = [k]_\Sigma + V$ is an affine subspace of $F_q^{\ell}$, where $[k]_\Sigma$ denotes any share of $k$ using $\Sigma$. Note that $W_0 = V$ and $W_0 \cup \cdots \cup W_{q-1} = F_q^{\ell}$.

**Lemma 2.3.** Let $\Sigma$ be an $F_q$-LSSS with $\dim E_0 = 1$. A subset $A \subseteq P$ is forbidden for $\Sigma$ if and only if there exists a vector $r \in \Omega$ for which $\text{Share}_\Sigma(1, r) = (x_1, \ldots, x_n)$ satisfies $x_i = 0$ for every $i \in A$. 

9
2.3 OT combiners

In 1-out-of-\(q\) OT protocols, the sender Alice is assumed to hold \(q\) messages \(m_0, \ldots, m_{q-1}\), and the receiver Bob chooses a message index \(b \in \mathbb{F}_q\). At the end of a protocol implementing this functionality, Bob receives \(m_b\) and Alice receives nothing.

Here we lay out the fundamental theory of OT combiners. Before proceeding further, and as in [16], we need to introduce the *ideal 1-out-of-\(q\) OT functionality* \(\mathcal{F}_{OT}\). We make use of the ideal functionality \(\mathcal{F}_{OT}\) in our security definitions. It consists of an ideal version of a 1-out-of-\(q\) OT protocol that implements the functionality correctly and that does not allow any kind of corruption. Hence, \(\mathcal{F}_{OT}\) is an abstraction of an ideal OT protocol. Without loss of generality, in this work all 1-out-of-\(q\) OT protocols that are considered secure are assumed to follow the blueprint of \(\mathcal{F}_{OT}\). Figure 2 depicts the \(\mathcal{F}_{OT}\) ideal functionality. Next, we formally define OT combiners, following the notation of [16].

<table>
<thead>
<tr>
<th>Sender</th>
<th>Receiver</th>
</tr>
</thead>
<tbody>
<tr>
<td>Messages (m_0, \ldots, m_{q-1})</td>
<td>Chosen index (b \in \mathbb{F}_q)</td>
</tr>
<tr>
<td>(\text{ready})</td>
<td>(\text{transfer}, b)</td>
</tr>
<tr>
<td>(\text{send}, m_0, \ldots, m_{q-1})</td>
<td>(m_b)</td>
</tr>
</tbody>
</table>

**Fig. 2.** The ideal 1-out-of-\(q\) Oblivious Transfer functionality.

**Definition 2.4.** Let \(S_1, \ldots, S_n\) be candidate OT implementations. An OT combiner is an efficient two-party protocol \(\pi = \pi(S_1, \ldots, S_n)\), with access to the candidates \(S_1, \ldots, S_n\), that implements the OT functionality. An OT combiner is 1-out-of-\(q\) if it implements the 1-out-of-\(q\) OT functionality.

From this point onward, we assume OT combiners to be 1-out-of-\(q\), \(n\)-server, and black-box. Under this assumption, we can formalize the notion of OT combiner according to the following definition.

**Definition 2.5.** We define an \(n\)-server, black-box, 1-out-of-\(q\) OT combiner \(\pi = \pi(S_1, \ldots, S_n)\) by means of the next three polynomial-time algorithms:
Choose \((b)\): Probabilistic algorithm run by the receiver Bob and taking as input a message index \(b \in \mathbb{F}_q\). It returns an \(n\)-tuple \((b_1, \ldots, b_n)\), where each \(b_i\) is to be sent to server \(S_i\).

Send \((m_0, \ldots, m_{q-1})\): Probabilistic algorithm run by the sender Alice, taking as input \(q\) chosen messages \(m_0, \ldots, m_{q-1}\). It returns a \(qn\)-tuple \((u^0, \ldots, u^{q-1})\) to be sent to server \(S_i\).

Rec \((b, (v_1, \ldots, v_n))\): Algorithm run by the receiver Bob, that takes as input the chosen message index \(b \in \mathbb{F}_q\) and \(n\) elements \(v_1, \ldots, v_n\), where each \(v_i\) is received from server \(S_i\). It returns a message \(m\).

Given an OT combiner \(\pi = (\pi.\text{Choose}, \pi.\text{Send}, \pi.\text{Rec})\) and given \(n\) servers \(S_1, \ldots, S_n\) implementing the 1-out-of-\(q\) OT functionality, we regard \(\pi\) as a protocol between a sender Alice and a receiver Bob. In this case, the resulting OT protocol \(\pi(S_1, \ldots, S_n)\) develops sequentially in five phases:

**Choice phase**: The receiver Bob chooses a message index \(b \in \mathbb{F}_q\).

Bob generates the tuple \((b_1, \ldots, b_n) \leftarrow \pi.\text{Choose}(b)\).

Bob sends \((\text{transfer}, b_i)\) to server \(S_i\) for \(i = 1, \ldots, n\).

**Ready phase**: On receiving \(b_i\) from Bob, the server \(S_i\) sends \((\text{ready})\) to Alice.

**Sending phase**: The sender Alice chooses \(q\) messages \(m_0, \ldots, m_{q-1}\).

Alice generates the corresponding tuple \((u^0, \ldots, u^{q-1}) \leftarrow \pi.\text{Send}(m_0, \ldots, m_{q-1})\).

After receiving \((\text{ready})\) from every server, Alice sends the generated shares \((\text{send}, u^0, \ldots, u^{q-1})\) to \(S_i\) for \(i = 1, \ldots, n\).

**Transfer phase**: The server \(S_i\) sends \((\text{sent}, u^{b_i}_i)\) to Bob.

**Output phase**: Bob reconstructs the message \(m_b\) from the shares \(u^{b_1}_1, \ldots, u^{b_n}_n\) he received by executing \(\pi.\text{Rec}(b, (u^{b_1}_1, \ldots, u^{b_n}_n))\).

### 3 Correctness and Security Definitions

In this section, we state the definitions used to capture the correctness and security properties of our constructions. In the following discussions, \(P_n\) represents the set of servers.

#### 3.1 Correctness Definition

The correctness property of OT combiners refers to the fact that, assuming all servers correctly implement the OT functionality and that both parties are honest, the protocol produced by the combiner implements the OT functionality correctly. Hence, we have to show that the message retrieved by Bob in the execution of the OT combiner is exactly the one that he should receive as per the OT functionality. This is expressed by the zero-error property formalized in the following definition, which is adapted from [16].
Definition 3.1. An OT combiner \( \pi \) is zero-error if, for every message index \( b \in \mathbb{F}_q \) and for any \( q \) messages \( m_0, \ldots, m_{q-1} \), we have that

\[
m_b \leftarrow \pi.\text{Rec}(b, (u^b_1, \ldots, u^b_n)),
\]

where \((b_1, \ldots, b_n) \leftarrow \pi.\text{Choose}(b)\) and \((u^j_1)_{(i,j) \in P_{n,q}} \leftarrow \pi.\text{Send}(m_0, \ldots, m_{q-1})\).

3.2 Security Definitions

An OT combiner is unconditionally secure if its security rests solely on the security assumptions of the OT candidate implementations [16]. That is, if, provided the security of enough OT candidates holds, the resulting OT protocol is perfectly secure. Therefore, unconditional security guarantees that any attack on an OT combiner must forcibly break the security of sufficiently many of the OT candidate implementations in order to be successful. As in [16], an OT combiner is called perfectly secure if it is both unconditionally secure and correct.

In order to capture the notion of unconditional security, we formalize it into a simulator-based security definition [33]. We now give the definition of security that we employ in our work, namely perfect security against active \((A, B)\)-adversaries, which is adapted from [16] and uses the Universal Composability framework [14].

Given two adversary structures \( A, B \subseteq 2^{P_n} \), our security definition protects against two types of active adversaries: one that corrupts the sender Alice and a set of servers \( A \in A \), and one that corrupts the receiver Bob and a set of servers \( B \in B \). This respectively corresponds to the case that a set \( A \in A \) of the OT candidates are insecure for the receiver, and to the case that a set \( B \in B \) of the OT candidates are insecure for the sender. To deal with the Alice corruption case, we define the notion of perfect security for the receiver against active \( A \)-adversaries, and in the Bob corruption case we define the notion of perfect security for the sender against active \( B \)-adversaries.

In the Alice corruption case, we consider a malicious (i.e., active) adversary \( \text{Adv} \) that controls the sender Alice, that interacts with an honest receiver \( \mathbb{B} \), and that is able to eavesdrop and fully operate each server in a set \( A \in A \). Our security aim here is to protect the confidentiality of the receiver’s choice \( b \in \mathbb{F}_q \). Hence, the ability to corrupt the servers in \( A \) must give \( \text{Adv} \) no information on \( b \).

This definition uses the simulation paradigm [33], and compares the execution of the protocol in the real world and in the ideal world. In the real world, \( \text{Adv} \) and \( \mathbb{B} \) interact through an OT combiner protocol \( \pi \). In the ideal world, the whole view and output of \( \text{Adv} \) is controlled by the simulator \( \text{Sim} \), and \( \text{Sim} \) and \( \mathbb{B} \) interact exclusively through the ideal OT functionality \( \mathcal{F}_{\text{OT}} \). Because of this, in the ideal experiment the adversary \( \text{Adv} \) does not receive any information on the choice \( b \in \mathbb{F}_q \) of \( \mathbb{B} \) from the interaction.

To provide security against malicious senders, \( \text{Sim} \) takes all the information viewed by \( \text{Adv} \) in the ideal world, which is the one herself produced, so as to transform it to a view that should be indistinguishable to the information seen by \( \text{Adv} \) in the real world. Hence, \( \text{Sim} \) also simulates the private inputs of \( \mathbb{B} \) on the corrupted servers.
Definition 3.2. Let $\pi$ be an $n$-server, 1-out-of-$q$ OT combiner protocol, and let $\mathcal{F}_{OT}$ denote the ideal 1-out-of-$q$ OT functionality. Let $\text{Adv}$ denote an adversary-controlled malicious sender, which is assumed to corrupt all the servers indexed by some set $A \in \mathcal{A}$. Let $\mathcal{B}$ denote an honest receiver, and let $\text{Sim} = (\text{Sim}_1, \text{Sim}_{\text{out}})$ be a stateful simulator. We define the probabilistic experiments $\text{Real}_{\text{Adv},\mathcal{B}}()$ and $\text{Ideal}_{\text{Adv},\mathcal{B},\text{Sim}}()$ as follows:

$$\text{Real}_{\text{Adv},\mathcal{B}}():$$

- $b \leftarrow \mathcal{B}()$
- $(b_1, \ldots, b_n) \leftarrow \pi.\text{Choose}(b)$
- $((u_i^0)_{i \in \mathcal{A}, j \in \mathcal{F}_q}, (z_i)_{i \in \mathcal{A}}) \leftarrow \text{Adv}((b_i)_{i \in \mathcal{A}})$
- $\text{Ideal}_{\text{Adv},\mathcal{B},\text{Sim}}():$

- $b \leftarrow \mathcal{B}()$
- $(\text{ready}) \leftarrow \mathcal{F}_{OT}(\text{transfer}, b)$
- $((u_i^0)_{i \in \mathcal{A}, j \in \mathcal{F}_q}, (z_i)_{i \in \mathcal{A}}) \leftarrow \text{Adv}((b_i)_{i \in \mathcal{A}})$

We say that $\pi$ is perfectly secure for the receiver against active $\mathcal{A}$-adversaries if, for every set $A \in \mathcal{A}$, for all adversarial senders $\text{Adv}$ corrupting the set of servers indexed by $A$, and for all honest receivers $\mathcal{B}$, there exists a simulator $\text{Sim}$ such that the output values of $\text{Real}_{\text{Adv},\mathcal{B}}()$ and $\text{Ideal}_{\text{Adv},\mathcal{B},\text{Sim}}()$ are identically distributed, where the probabilities are taken over the random coins of $\pi$, $\text{Adv}$, $\mathcal{B}$ and $\text{Sim}$.

In the Bob corruption case, we consider a malicious (i.e., active) adversary $\text{Adv}$ that controls the receiver Bob, that interacts with an honest sender $\mathcal{A}$, and that is able to eavesdrop on and fully operate each server in a set $B \in \mathcal{B}$. Our security aim here is to protect the confidentiality of the sender’s messages $m_0, \ldots, m_{q-1}$. Hence, the ability to corrupt the servers in one set $B \in \mathcal{B}$ of servers must give Bob no information on $m_0, \ldots, m_{q-1}$ other than possibly one chosen message. As the previous definition, this definition uses the simulation paradigm \cite{22} and compares the execution of the protocol in the real world and in the ideal world.

In the real world, $\mathcal{A}$ and $\text{Adv}$ interact through an OT combiner protocol $\pi$. The sender $\mathcal{A}$, who is assumed to act honestly, holds messages $m_0, \ldots, m_{q-1}$ and uses the OT combiner $\pi$ to generate the input $u_i^0, \ldots, u_i^{q-1}$ that is sent to server $S_i$ for every $i \in \mathcal{P}_n$. The adversary $\text{Adv}$ is assumed to completely corrupt every server in a set $B \in \mathcal{B}$, and so he sees all the inputs $(u_i^0)_{i \in B, j \in \mathcal{F}_q}$. He also acts as the receiver, generating an input $b_i$ for the rest of servers $i \in \mathcal{B}$. Since the servers $i \in \mathcal{B}$ are assumed to behave as the ideal $\mathcal{F}_{OT}$ functionality, $\text{Adv}$ receives $(u_i^{b_i})_{i \in \mathcal{B}}$ and learns no other information from that interaction.

In the ideal world, the whole view and output of $\text{Adv}$ is controlled by the simulator $\text{Sim}$, and $\text{Sim}$ and $\mathcal{A}$ interact through the ideal OT functionality $\mathcal{F}_{OT}$. By processing all the output that the adversary $\text{Adv}$ generates, $\text{Sim}$ produces a message index $\bar{b}$ and handles it to the $\mathcal{F}_{OT}$ functionality. Then, after the sender $\mathcal{A}$ has sent the messages $m_0, \ldots, m_{q-1}$ to $\mathcal{F}_{OT}$, the adversary $\text{Adv}$ receives the message $m_{\bar{b}}$. To provide security against malicious receivers, $\text{Sim}$ takes all the
information viewed by Adv in the ideal world, so as to transform it to a view that should be indistinguishable to the one of the real world.

**Definition 3.3.** Let π be an n-server, 1-out-of-q OT combiner, and let \( \mathcal{F}_{\text{OT}} \) denote the 1-out-of-q OT functionality. Let Adv denote an adversary-controlled malicious receiver, which is assumed to corrupt all the servers indexed by some set \( B \subseteq \mathcal{B} \). Let \( A \) denote an honest sender, and let Sim = (Sim1, Sim2, Simout) be a stateful simulator. We define the probabilistic experiments Real\( _{A,\text{Adv}}(\pi) \) and Ideal\( _{A,\text{Adv},\text{Sim}}(\pi) \) as follows:

\[
\text{Real}_{A,\text{Adv}}(\pi) :
\begin{align*}
(m_0, \ldots, m_{q-1}) &\leftarrow A() \\
(u'_i)_{(i,j) \in \mathcal{F}_{\pi,q}} &\leftarrow \pi.\text{Send}(\text{send}, m_0, \ldots, m_{q-1}) \\
(b_i)_{i \in B} &\leftarrow \text{Adv}((u'_i)_{i \in B, j \in \mathcal{F}_q}) \\
\text{output } ((u'_i)_{i \in B, j \in \mathcal{F}_q}, (u'_i)_{i \in B}, (b_i)_{i \in B})
\end{align*}
\]

\[
\text{Ideal}_{A,\text{Adv},\text{Sim}}(\pi) :
\begin{align*}
(m_0, \ldots, m_{q-1}) &\leftarrow A() \\
(u'_i)_{i \in B, j \in \mathcal{F}_q} &\leftarrow \text{Sim}_1() \\
(b_i)_{i \in B} &\leftarrow \text{Adv}((u'_i)_{i \in B, j \in \mathcal{F}_q}) \\
\tilde{b} &\leftarrow \text{Sim}_2((b_i)_{i \in B}) \\
(\text{ready}) &\leftarrow \mathcal{F}_{\text{OT}}(\text{transfer}, \tilde{b}) \\
(m_0, \ldots, m_{q-1}) &\leftarrow A() \\
(\text{sent}, m_b) &\leftarrow \mathcal{F}_{\text{OT}}(\text{send}, m_0, \ldots, m_{q-1}) \\
\text{output } \tilde{b}, m_b, (b_i)_{i \in B}
\end{align*}
\]

We say that \( \pi \) is perfectly secure for the sender against active \( B \)-adversaries if, for every \( B \subseteq \mathcal{B} \), for all adversarial receivers Adv corrupting the set of servers indexed by \( B \), and for all honest senders \( A \), there exists a simulator Sim such that the output values of Real\( _{A,\text{Adv}}(\pi) \) and Ideal\( _{A,\text{Adv},\text{Sim}}(\pi) \) are identically distributed, where the probabilities are taken over the random coins of \( \pi \), \( A \), Adv and Sim.

The two previous definitions, on top of the correctness definition, make up the security definition considered in this work, namely perfect security against active \((A,B)\)-adversaries. We next formally state this.

**Definition 3.4.** Let \( \pi \) be an n-server, 1-out-of-q OT combiner, and let \( A, B \subseteq 2^{2^n} \). We say that \( \pi \) is perfectly secure against active \((A,B)\)-adversaries if it is zero-error, and it is perfectly secure for the sender against active \( B \)-adversaries and for the receiver against active \( A \)-adversaries.

### 4 Single-Use 1-out-of-q OT Combiners

In this section, we present our 1-out-of-q OT combiner in the particular setting where \( \Sigma \) is an ideal \( \mathbb{F}_q \)-LSSS. We achieve a single-use OT combiner with perfect security against active adversaries. In Section 7 we describe our construction for general LSSSs.

The proposed 1-out-of-q OT combiner is shown in Figure 3. It is described according to Definition 2.5 and follows the structure described in Section 1.3.

**Theorem 4.1.** Let \( \Sigma \) be an ideal \( \mathbb{F}_q \)-LSSS with adversary structure \( A \). The OT combiner \( \pi_{\text{OT}} \) defined in Figure 3 is perfectly secure against active \((A,A')\)-adversaries.
Single-use 1-out-of-\(q\) OT Combiner \(\pi_{\OT}\)

\(\pi_{\OT}.\text{Choose}(b)\): Given \(b \in \mathbb{F}_q\), compute a sharing \([b]_\Sigma = (b_1, \ldots, b_n)\) of \(b\) using \(\Sigma\). Note that each \(b_i \in \mathbb{F}_q\) because \(\Sigma\) is ideal.

Output \((b_1, \ldots, b_n)\).

\(\pi_{\OT}.\text{Send}(m_0, \ldots, m_{q-1})\): For each message \(m_k\), independently compute a sharing \([m_k]_\Sigma = (m^{(i,j)}_k)_{(i,j) \in \mathcal{P}_{n,q}}\).

Then, for each \((i, j) \in \mathcal{P}_{n,q}\), compute the values

\[ u^{(i,j)}_j := m^{(i,j)}_0 || m^{(i,j)}_1 || \cdots || m^{(i,j)}_{q-1}. \]

Output \((u^{(i,j)}_j)_{(i,j) \in \mathcal{P}_{n,q}}\), where each tuple \((u^{(i,j)}_0, \ldots, u^{(i,j)}_{q-1})\) is to be sent to server \(S_i\).

\(\pi_{\OT}.\text{Rec}(b, (v_1, \ldots, v_n))\): Parse each \(v_k\), which is received from server \(S_i\), as

\[ v_k = n^{(i)}_0 || n^{(i)}_1 || \cdots || n^{(i)}_{q-1}, \]

where \(n^{(i)}_k \in \mathbb{F}_q\) for each \(k \in \mathbb{F}_q\).

Retrieve \(m_b\) by evaluating

\[ \text{Reconstruct}_{S_b}((n^{(i)}_k)_{i \in \mathcal{P}_n}). \]

If the reconstruction fails at any step, output \(\perp\). Otherwise, output \(m_b\).

When the protocol follows correctly, \(\pi_{\OT}.\text{Rec}\) is executed with \((v_1, \ldots, v_n) = (u^{(1,b)}_1, \ldots, u^{(n,b)}_n)\) and retrieves \(\text{Reconstruct}_{S_b}((m^{(1,b)}_1, \ldots, m^{(n,b)}_n))\).

---

The proof of Theorem 4.1 is split in three blocks: First, in Section 5 we analyze the secret sharing schemes \(S_k\). In Section 6 we prove the correctness of the protocol and then its security. Theorem 4.1 implies Theorem 1.1 for the case that \(\Sigma\) is an ideal LSSS, and the non-ideal case is implied by Theorem 7.1. At the end of Section 6 we prove Corollary 1.2 by combining these results.

Remark 4.2 (Structure). The protocol runs between a sender Alice and a receiver Bob, who communicate through a set of \(n\) servers \(S_1, \ldots, S_n\) that implement the ideal 1-out-of-\(q\) OT functionality \(\pi_{\OT}\) (described in Figure 2).

An ideal \(\mathbb{F}_q\)-LSSS \(\Sigma\) is used by the receiver Bob to request the message with the selected index \(b \in \mathbb{F}_q\): He generates a sharing \([b]_\Sigma = (b_1, \ldots, b_n)\) of \(b\) with \(\Sigma\), and queries each server \(S_i\) with \(b_i \in \mathbb{F}_q\). It corresponds to function \(\pi_{\OT}.\text{Choose}\).

In order for Alice to distribute the messages \(m_0, \ldots, m_{q-1}\), she makes use of \(q\) different secret sharing schemes \(S_0, \ldots, S_{q-1}\), which are related to the affine subspaces \(W_0, \ldots, W_{q-1}\), respectively. It corresponds to function \(\pi_{\OT}.\text{Send}\).

Then, the servers execute the OT functionality with the inputs they received, and send their outputs to Bob. Bob executes \(\pi_{\OT}.\text{Rec}\) and retrieves the message.
The Secret Sharing Scheme $S_k$

Share$_{S_k}$: To share a message $m \in \mathbb{F}_q$, first
- let $k = (k_1, \ldots, k_n) \in \mathbb{F}_q^n$ be a sharing of $k$ using $\Sigma$
- sample $r_1, \ldots, r_{n-1} \in \mathbb{F}_q$ uniformly at random, and let $r_n = m - \sum_{i=1}^{n-1} r_i$
- sample $h = (h_1, \ldots, h_n)$ uniformly at random from $V^*$

For every $i \in \mathcal{P}_n$ and for every $j \in \mathbb{F}_q$, define the $(i,j)$-th share as

$$m^{(i,j)} = r_i + (k_i - j)h_i.$$

Reconstruct$_{S_k}$: In this work we are just interested in reconstructing the message $m$ for subsets $A = \{(1, b_1), \ldots, (n, b_n)\}$ with $(b_1, \ldots, b_n) \in W_k$. In this case, the reconstruction function for $(m^{(i,j)})_{(i,j) \in A}$ is

$$\sum_{i=1}^{n} m^{(i,b_i)}.$$

Fig. 4. The $\mathbb{F}_q$-LSSS $S_k$ related to the secret sharing scheme $\Sigma$, the affine subspace $W_k = [k]_\Sigma$, and $V = [0]_\Sigma$.

Remark 4.3 (Communication complexity). In the choice phase, Bob sends a total of $n \log q$ bits to servers. In the sending phase, Alice sends a total of $q^2 n \log q$ bits to the servers. In the transfer phase, servers send a total of $qn \log q$ bits to Bob. Hence, the communication complexity is $(q^2 + q + 1)n \log q$.

Remark 4.4 (Adversary structure). A protocol is secure against $(\mathcal{A}, \mathcal{A}^*)$-adversaries if and only if it is secure against $(\mathcal{A}, \mathcal{B})$-adversaries for any $\mathcal{R}_2$ pair $(\mathcal{A}, \mathcal{B})$. Also, it is equivalent to saying that it is secure against an adversary corrupting either Alice and a set of servers in $\mathcal{A}$, or Bob and a set of servers $\mathcal{B}$ with $\mathcal{B} \notin \mathcal{A}$, as stated in the abstract. This 1-out-of-$q$ OT combiner is also secure against any $(\mathcal{A}', \mathcal{B}')$-adversary satisfying $\mathcal{A}' \subseteq \mathcal{A}$ and $\mathcal{B}' \subseteq \mathcal{A}^*$.

Remark 4.5 (Variants). The first observation is that the protocol can be run for messages that are shorter than $\log q$. For instance, if the messages are just one bit, the protocol is not affected and the communication complexity is the same.

The second observation is that the protocol can be adapted to run 1-out-of-$q'$ OT combiner for $q' < q$. In this case, Bob will choose $m_b$ among $m_1, \ldots, m_{q'}$. We attain the same level of security, but the communication is reduced. Next, we detail the changes that should be done.

The $\pi_{OT}.\text{Send}$ algorithm does not change. The algorithm $\pi_{OT}.\text{Send}$ has only $q'$ inputs, so the values $u_i^j$ will be shorter, i.e., $u_i^j = m^{(i,j)}_1 || m^{(i,j)}_2 || \cdots || m^{(i,j)}_{q'-1}$.

The servers will perform the 1-out-of-$q$ functionality, and they will send to Bob a shorter $v_i$. The algorithm $\pi_{OT}.\text{Rec}$ is executed analogously. The communication complexity now is $n \log q + q' n \log q + q'n \log q = (qq' + q' + 1)n \log q$.

The flexibility of the construction may be useful for certain adversary structures. It is known that there are adversary structures $(\mathcal{A}, \mathcal{A}^*)$ for which there only exist efficient $\mathbb{F}$-LSSSs $\Sigma$ for fields of a certain characteristic [9].
Remark 4.6 (Multisecret sharing schemes). In the sending phase of our protocol, we share each of the $q$ messages independently. For $q = 2$, this process was improved in \cite{16} by creating sharings of the two messages at the same time, which reduces the number of shares from $4n$ to $2n$. The scheme in \cite{16} can be seen as a multi-secret sharing scheme \cite{12,30}. In such schemes, $n$ shares are generated from a sequence of $k > 1$ secrets, and each secret can be recovered from the shares, but each secret has its own access structure. Observe that we can define our 1-out-of-$q$ constructions from multi-secret sharing schemes. Since our multi-secret sharing scheme is just a combination of independent secret sharing schemes, we decided to simplify the notation. A research line in the direction of this work is to build more efficient 1-out-of-$q$ OT-combiners with multi-secret sharing schemes.

5 Secret Sharing Schemes for OT Combiners

In this section, we introduce a family of secret sharing schemes that are useful to build 1-out-of-$q$ OT combiners. We call them the OT-compatible secret sharing schemes. In Section 5.2, we show that the schemes $S_i$ in Figure 4 are indeed $W_i$-OT-compatible. This fact simplifies the security proof of our 1-out-of-$q$ OT combiners.

5.1 $W$-OT-Compatible Secret Sharing Schemes

Recall the discussion in Section 1.3 about the properties involved in our construction. This section is dedicated to the study of the schemes $S_i$ that guarantee the correctness and security of our protocol. Consider the following definition.

Definition 5.1. Let $F_q$ be a finite field, and let $W \subseteq \mathbb{F}_q^n$. We define $\Gamma_W$ as the access structure on $P_{n,q}$ determined by the minimal access structure

$$\min \Gamma_W = \left\{ \{(1,b_1),(2,b_2),\ldots,(n,b_n)\} : (b_1,b_2,\ldots,b_n) \in W \right\}. $$

The study of the share size of access structures $\Gamma_W$ for general $W$ is of independent interest. If $n = 2$, then $\Gamma_W$ is a bipartite graph access structure, and this case is studied in several works as \cite{0,20}. As a consequence of \cite{31,23}, improvements on the efficiency of schemes for $\Gamma_W$ will result in improvements in the efficiency of CDS protocols, and in the efficiency of secret sharing schemes for general access structures.

Following the discussion in Section 1.3, we are here interested in the construction of secret sharing schemes with access structure $\Gamma_W$ where $W$ is the collection of sharings of $b$ by $\Sigma$. Since we only consider linear schemes, $[b]_\Sigma$ is always a $F_q$ affine space. Hence, from now on, we restrict the study of the access structures $\Gamma_W$ when $W$ is an affine space.

If $W \subseteq \mathbb{F}_2^n$ is a binary affine subspace, then the access structure $\Gamma_W$ described above always admits an ideal $\mathbb{F}_2$-LSSS \cite{16}. However, in general, given an affine
subspace \( W \subseteq \mathbb{F}_q^n \), ideal \( \mathbb{F}_q \)-LSSS for the access structure \( \Gamma_W \) are not expected to exist.

Instead of looking for \( \mathbb{F}_q \)-LSSS with access structures of the form \( \Gamma_W \), which will give rise to non-efficient OT combiners, we explore the possibility of relaxing the restrictions on the access structure of \( S_i \) while keeping our security needs.

With the aim of building schemes \( S_i \) for the protocol in Figure 3, we define the notion of \( W \)-OT-compatibility.

**Definition 5.2.** Let \( W \subseteq \mathbb{F}_q^n \). Let \( \Delta \subseteq 2^{P_{n,q}} \) be the family of subsets defined by

\[
\Delta = \{ A_1 \cup \ldots \cup A_n : A_i \subseteq P_i \text{ and } |A_i| = 0, 1 \text{ or } q \text{ for } i = 1, \ldots, n \}.
\]

We say that an access structure \( \Gamma \subseteq 2^{P_{n,q}} \) is \( W \)-OT-compatible if \( \Gamma \cap \Delta = \Gamma_W \cap \Delta \). Similarly, we say that a secret sharing scheme is \( W \)-OT-compatible if its access structure is \( W \)-OT-compatible.

The motivation behind this definition is the following: The secret sharing schemes \( S_0, \ldots, S_{q-1} \) to be used by Alice that we design are built so that an adversary controlling Bob, and possibly some servers, can learn from each server \( S_i \) either

- no shares, e.g. in the case where an active adversary corrupts Alice and \( S_i \),
- one share, e.g. in the case that the server \( S_i \) is not corrupted, or
- all \( q \) shares sent to \( S_i \), in the case that an adversary corrupts Bob and \( S_i \).

Under this assumption, since \( P_i \) corresponds to the shares sent to server \( S_i \), the shares that an adversary controlling Bob is able to see in any execution of the OT combiner are always determined by some subset of \( \Delta \). Therefore, even if the obtained \( \mathbb{F}_q \)-LSSS has an access structure \( \Gamma \) other than \( \Gamma_W \), it serves our security purposes as long as \( \Gamma \) coincides with \( \Gamma_W \) when restricting it to \( \Delta \). That is, as long as \( \Gamma \) is \( W \)-OT-compatible.

We next state some properties of \( W \)-OT-compatible access structures.

**Remark 5.3.** If an access structure \( \Gamma \subseteq 2^{P_{n,q}} \) is \( W \)-OT-compatible, then

- \( \min \Gamma_W \subseteq \min \Gamma \). Hence,

\[
\{(1, b_1), \ldots, (n, b_n)\} \in \Gamma \text{ for every } (b_1, \ldots, b_n) \in W.
\]

- \( \{(1, v_1), \ldots, (n, v_n)\} \notin \Gamma \) for every \( v = (v_1, \ldots, v_n) \in \mathbb{F}_q^n \setminus W \).
- If \( A \in P_{n,q} \) has size \( |A| < n \), then \( A \notin \Gamma \).
- If \( A \in \Gamma \) has size \( |A| = n \), then \( A \in \min \Gamma_W \) and \( A \in \min \Gamma \).
- \( P_{n,q} \setminus P_i \notin \Gamma \) for \( i = 1, \ldots, n \).

See the Appendix A for an example of \( W \)-OT-compatible access structures.
5.2 Analysis of $S_k$

This subsection is dedicated to the analysis of the scheme $S_k$ presented in Figure 4. See the Appendix A for an example for $q = n = 3$. The scheme $S_k$ is an ideal $\mathbb{F}_q$-LSSS defined on the set of $nq$ participants $\mathcal{P}_{n,q}$. It is used by Alice to generate a sharing of the $k$-th message $m_k$, which is distributed among the OT servers. Proposition 5.5 states that $S_k$ is $W_k$-OT-compatible for $W_k = [k]_\Sigma$.

First, we present a technical lemma needed for its proof.

**Lemma 5.4.** Let $\mathbb{F}_q$ be a finite field, and $V \subseteq \mathbb{F}_q^n$ be a vector subspace. Let $t \leq n$ and $y_1, \ldots, y_t \in \mathbb{F}_q$. If $(y_1, \ldots, y_t, x_{t+1}, \ldots, x_n) \notin V$ for every $x_{t+1}, \ldots, x_n \in \mathbb{F}_q$, then there exists $h \in V^\perp$ such that $y_1h_1 + \cdots + y_th_t = 1$ and $h_{t+1} = \cdots = h_n = 0$.

**Proof.** We prove this lemma by backward induction in $t$. The lemma holds for $t = n$ since, given $y = (y_1, \ldots, y_n) \notin V$, there always exists an $h \in V^\perp$ such that $\langle y, h \rangle = 1$.

Assume that $t < n$. Suppose that there exist $y_1, \ldots, y_t \in \mathbb{F}_q$ satisfying $(y_1, \ldots, y_t, x_{t+1}, \ldots, x_n) \notin V$ for all $x_{t+1}, \ldots, x_n \in \mathbb{F}_q$. By induction hypothesis we have that, for every $x \in \mathbb{F}_q$, there exists an $h^x = (h^x_1, \ldots, h^x_n) \in V^\perp$ with

$$\sum_{i=1}^t y_i h^x_i + xh^x_{t+1} = 1 \quad \text{and} \quad h^x_{t+2} = \cdots = h^x_n = 0.$$

If $h^x_{t+1} = 0$ for some $x \in \mathbb{F}_q$, then $h^x$ satisfies the lemma. Otherwise, by the pigeonhole principle, let $x$ and $z$ be two distinct elements of $\mathbb{F}_q$ such that $h^x_{t+1} = h^z_{t+1} \neq 0$. Define

$$h = \frac{h^x - h^z}{h^x_{t+1}(z-x)}.$$

Since $h = (h_1, \ldots, h_n)$ is in $V^\perp$ and satisfies $h_{t+1} = \cdots = h_n = 0$ and

$$y_1h_1 + \cdots + y_th_t = \frac{1}{h^x_{t+1}(z-x)} \left( \sum_{i=1}^t y_i h^x_i - \sum_{i=1}^t y_i h^z_i \right)$$

$$= \frac{1}{h^x_{t+1}(z-x)} ((1 - xh^x_{t+1}) - (1 - zh^z_{t+1})) = 1,$$

we have that $h$ satisfies the lemma. \qed

**Proposition 5.5.** Let $\Sigma$ be an ideal $\mathbb{F}_q$-LSSS. For every $k \in \mathbb{F}_q$, the secret sharing scheme $S_k$ defined in Figure 4 is an ideal $\mathbb{F}_q$-LSSS that is $W_k$-OT-compatible.

**Proof.** In order to prove that $S_k$ is $W_k$-OT-compatible, we prove that $\Gamma$, the access structure of $S_k$, satisfies $I_{W_k} \cap \Delta = \Gamma \cap \Delta$.

Let $A = \{(1, b_1), \ldots, (n, b_n)\}$ be a subset in $\min I_{W_k}$, and let $(m^{(i,j)})_{(i,j) \in A}$ be shares by $S_k$. Since $\sum_{i=1}^n r_i = m$, then

$$\sum_{i=1}^n m^{(i,b_i)} = \sum_{i=1}^n (r_i + (k_i - b_i)h_i) = \sum_{i=1}^n r_i + \langle k - b, h \rangle = m.$$
where we used that \( h \in V^\perp \) and \( k - b \in V \) because \( k, b \in W_k \). Hence, \( \Gamma_{W_k} \subseteq \Gamma \) and so \( \Gamma_{W_k} \cap \Delta \subseteq \Gamma \cap \Delta \).

Now, we prove \( \Gamma_{W_k} \cap \Delta \subseteq \Gamma \cap \Delta \) by showing that, for every \( A \in \Delta \), if \( A \notin \Gamma_{W_k} \) then \( A \notin \Gamma \). Let \( A \in \Delta \setminus \Gamma_{W_k} \). If \( A \cap P_i = \emptyset \) for some \( i \), then \( A \) is forbidden for \( S_k \), so \( A \notin \Gamma \). Otherwise assume, without loss of generality, that for some \( i \) we can express

\[
A = \{(1, v_1), \ldots, (t, v_t)\} \cup P_{t+1} \cup \cdots \cup P_n.
\]

We now use Lemma 2.3. More concretely, we show that there exists randomness \( r_1, \ldots, r_n \in \mathbb{F}_q \) and \( h = (h_1, \ldots, h_n) \in V^\perp \) so that the sharing of the message \( m = 1 \) satisfies \( m_{(i,j)} = 0 \) for every \( i, j \in A \).

Since \( A \notin \Gamma_{W_k} \), we have that \((v_1 - k_1, \ldots, v_t - k_t, x_{t+1}, \ldots, x_n) \notin V \) for every \( x_{t+1}, \ldots, x_n \in \mathbb{F}_q \). By Lemma 5.4 there exists an \( h = (h_1, \ldots, h_n) \in V^\perp \) such that \( \sum_{i=1}^{t}(v_i - k_i)h_i = 1 \) and \( h_{t+1} = \cdots = h_n = 0 \). We choose as randomness this \( h \in V^\perp \) and

\[
\begin{align*}
    r_i &= -(k_i - v_i)h_i & \text{for } i = 1, \ldots, t, \\
    r_i &= 0 & \text{for } i = t + 1, \ldots, n - 1.
\end{align*}
\]

Since we want a sharing of the message \( m = 1 \), we take \( r_n = 1 - \sum_{i=1}^{n-1} r_i = 0 \). Then, for \( (i, j) \in A \), the shares \( m_{(i,j)} = r_i + (k_i - j)h_i \) of the message \( m = 1 \) are

\[
\begin{align*}
    m_{(i,v_i)} &= -(k_i - v_i)h_i + (k_i - v_i)h_i = 0 & \text{for } i = 1, \ldots, t, \\
    m_{(i,j)} &= 0 + (k_i - j) \cdot 0 = 0 & \text{for } i = t + 1, \ldots, n.
\end{align*}
\]

For the particular case \( q = 2 \), the proofs of Lemma 5.4 and Proposition 5.5 can be simplified [15]. Indeed, for \( q = 2 \), the access structure of the scheme in Figure 4 is simply \( \Gamma_{W_k} \) [19].

As a consequence of this result, for every affine space \( W \subseteq \mathbb{F}^n_q \) there exists an ideal \( \mathbb{F}_q \)-LSSS that is \( W \)-OT-compatible.

Secret sharing schemes of this kind are connected to Conditional Disclosure of Secrets (CDS) protocols, as can be seen in [34][35][3]. for example. Namely, the shares of this scheme are also the messages of an \( n \)-server CDS protocol for the Boolean function \( f : \{0, \ldots, q-1\}^n \rightarrow \{0,1\} \) defined as follows: \( f(x_1, \ldots, x_n) = 1 \) if and only if \( (x_1, \ldots, x_n) \in W \).

### 6 Correctness and security proofs

We start with the proof of correctness.

**Proposition 6.1.** The OT combiner \( \pi_{OT} \) defined in Figure 3 is zero-error. That is, provided both Alice and Bob are semi-honest, \( \pi_{OT} \) implements the 1-out-of-\( q \) OT functionality correctly.
As a consequence of the next lemma, if the shares proceed with its proof, we first need to establish Lemma 6.2.

**Proof.** Since the sharing of every message is done independently, only the shares do not correspond to any sharing \([b]_\Sigma\) of \(b\), the adversary can not get any information on the message \(m_b\).

The security properties of our constructions are stated in Theorem 4.1. To proceed with its proof, we first need to establish Lemma 6.2.

Suppose that an adversary controlling Bob corrupts a set \(B \subseteq \mathcal{B}\) of servers. As a consequence of the next lemma, if the shares \((b_i)_{i \in B}\) sent to non-corrupted servers in \(B\) do not correspond to any sharing \([b]_\Sigma\) of \(b\), the adversary can not get any information on the message \(m_b\).

**Lemma 6.2.** Let \(m_0, \ldots, m_{q-1} \in \mathbb{F}_q\) be arbitrary messages, and fix independent sharings \([m_k]_{S_b} = (m_k^{(i,j)})_{(i,j) \in \mathcal{P}_{n,q}}\) for every \(k \in \mathbb{F}_q\). Let \(B \subseteq \mathcal{P}_n\) and \((b'_1, \ldots, b'_n) \in \mathbb{F}_q^n\), and define the set \(\mathcal{H} \subseteq \mathcal{P}_{n,q}\) by

\[
\mathcal{H} = \{ (i, b'_i) : i \in B \} \cup \{ (i, j) : i \in B, j \in \mathbb{F}_q \}.
\]

Fix \(b \in \mathbb{F}_q\). Then, if the shares \((b'_i)_{i \in B}\) are not part of any sharing \([b]_\Sigma\), the shares \((m_k^{(i,j)}) : (i, j) \in \mathcal{H}, k \in \mathbb{F}_q\) give no information about \(m_b\).

**Proof.** Since the sharing of every message is done independently, only the shares \((m_k^{(i,j)})_{(i,j) \in \mathcal{H}}\) could potentially give information on \(m_b\). We prove that \(\mathcal{H}\) is forbidden for \(S_b\). Since \(S_b\) is \(W_b\)-OT-compatible and since \(\mathcal{H} \in \Delta\), if \(\mathcal{H}\) were authorized for \(S_b\) then \(\mathcal{H} \in \Gamma_{W_b}\), and thus it would contain a set \(\{(1, b_1), \ldots, (n, b_n)\}\) for some \((b_1, \ldots, b_n) \in W_b\). However, then necessarily \(b_i = b'_i\) for all \(i \in B\), and this would mean that \((b'_i)_{i \in B}\) belongs to a sharing \([b]_\Sigma\), a contradiction.

Now we can complete the proof of Theorem 4.1.

**Proof (Proof of Theorem 4.1).** Correctness is proved in Proposition 6.1. The rest of the proof is split in two parts, corresponding to Definitions 3.2 and 3.3. In each case, we define the simulators and compare the outputs of the ideal and real experiments. Let \(A \in \mathcal{A}\) and \(B \in \mathcal{A}^*\).

**Perfect security for the receiver against active \(\mathcal{A}\)-adversaries:**

\(\text{Sim}_1():\) Generate a sharing of \(0 \in \mathbb{F}_q\),

\([0]_\Sigma = (b^0_1, \ldots, b^0_n)\).

Output \((b^0_i)_{i \in A}\).

\(\text{Sim}_{\text{out}}((u'_i)_{i \in \bar{A}, j \in \mathbb{F}_q}^{}, (z_i)_{i \in A}):\) Retrieve, from the state of \(\text{Sim}\), the sharing \([0]_\Sigma = (b^0_i)_{i \in \mathcal{P}_n}\) that was generated in the previous execution of \(\text{Sim}_1\).

Output \((b^0_i)_{i \in A}, (u'_i)_{i \in \bar{A}, j \in \mathbb{F}_q}, (z_i)_{i \in A}\).
Note that the shares \((b_i)_{i \in A}\) that the adversary \(\text{Adv}\) takes as input correspond to the set \(A \in \mathcal{A}\), which is forbidden for \(\Sigma\). Hence, they are distributed identically to the \(A\)-shares of a sharing of any other \(b' \neq b\) (in particular, of \(0 \in \mathbb{F}_q\)), and so they do not carry any information on \(b\). The messages \(\left((u_i^j)_{i \in A, j \in \mathbb{F}_q}, (z_i)_{i \in A}\right)\) generated by \(\text{Adv}\) are thus identically distributed in both worlds.

Since the shares \((b_i)_{i \in A}\) do not allow to distinguish between the real and the ideal world, we have proved indistinguishability.

**Perfect security for the sender against active \(B\)-adversaries:**

\(\text{Sim}_1()\): For every \(k \in \mathbb{F}_q\), choose \(m'_k \in \mathbb{F}_q\) uniformly at random and generate the sharing \([m'_k]_{\mathcal{S}_k} = (m'^{(i,j)}_k)_{(i,j) \in \mathcal{P}_{n,q}}\). Then, create the values \(u_i^j = m'^{(i,j)}_k \cdots m'^{(i,j)}_{k-1}\) for every \((i, j) \in B \times \mathbb{F}_q\). Output \((u_i^j)_{i \in B, j \in \mathbb{F}_q}\).

\(\text{Sim}_2((b_i)_{i \in B})\): Try to reconstruct the input \(b\) of the adversary \(\text{Adv}\) by executing \(\text{Reconstruct}\) on the input. If the reconstruction succeeds, output the reconstructed message index \(\tilde{b}\). Otherwise, output \(\bot\).

\(\text{Sim}_{\text{out}}(\tilde{b}, m_{\tilde{b}}, (b_i)_{i \in B})\): Retrieve, from the state of \(\text{Sim}\) and for every \(k \in \mathbb{F}_q\), the messages \(m_k\), the sharings \([m'_k]_{\mathcal{S}_k} = (m'^{(i,j)}_k)_{(i,j) \in \mathcal{P}_{n,q}}\) and the messages \((u_i^j)_{i \in B, j \in \mathbb{F}_q}\) that were generated in the previous execution of \(\text{Sim}_1\).

Proceed as follows, depending on whether the reconstruction in \(\text{Sim}_2\) failed or not:

- If \(\tilde{b} \neq \bot\), let \(\tilde{m}_{\tilde{b}} = m_{\tilde{b}}\). Generate a sharing \([\tilde{m}_{\tilde{b}}]_{\mathcal{S}_{\tilde{b}}} = (\tilde{m}'^{(i,j)}_k)_{(i,j) \in \mathcal{P}_{n,q}}\) subject to the restriction that \(\tilde{m}'^{(i,j)}_k = m'^{(i,j)}_{\tilde{b}}\) for every \((i, j) \in B \times \mathbb{F}_q\).

  Note that this is possible, since \(B \times \mathbb{F}_q\) is forbidden for \(S_0, \ldots, S_{q-1}\).

  For every \(k \in \mathbb{F}_q \setminus \{\tilde{b}\}\) and every \((i, j) \in B \times \mathbb{F}_q\), set \(\tilde{m}'^{(i,j)}_k := m'^{(i,j)}_k\).

- If \(\tilde{b} = \bot\), for every \(k \in \mathbb{F}_q\) and \((i, j) \in B \times \mathbb{F}_q\), let

  \(\tilde{m}'^{(i,j)}_k = m'^{(i,j)}_k\).

Create the values \(u_i^{\tilde{b}} = \tilde{m}'^{(i,b_i)}_0 \cdots \tilde{m}'^{(i,b_i)}_{q-1}\) for every \(i \in B\).

Output \((u_i^{\tilde{b}})_{i \in B, j \in \mathbb{F}_q}, (u_i^{b_i})_{i \in B}, (b_i)_{i \in B}\).

In order to prove indistinguishability we first note that, since \(B \in \mathcal{A}'\), the set \(B\) is not in \(\mathcal{A}\) and so it is authorized for \(\Sigma\). By the definition of \(\mathcal{S}_k\), we see that at least one share per server is needed to reconstruct a message. Hence, the set \(B \times \mathbb{F}_q\) is forbidden for \(S_0, \ldots, S_{q-1}\), and so the shares \((u_i^j)_{i \in B, j \in \mathbb{F}_q}\) do not hold any information on the messages \(m_0, \ldots, m_{q-1}\). Therefore, the shares \((b_i)_{i \in B}\) generated by the adversary \(\text{Adv}\) in the real world and in the ideal world are identically distributed.

Since \(B\) is authorized for \(\Sigma\), we have two possibilities as for the shares \((b_i)_{i \in B}\) received by \(\text{Sim}\): either they are part of a sharing \([b]_{\Sigma}\), or they are not part of any sharing for \(\Sigma\) (due to the malicious behavior of \(\text{Adv}\)).

In the first case, \(\text{Sim}_2\) successfully reconstructs \(b\). The set \(\{(i, b_i) : i \in B\} \cup (B \times \mathbb{F}_q)\) is then authorized for \(\mathcal{S}_b\) and, by Lemma 6.2, it is forbidden
for all the other $F_q$-LSSS $S_k$. Since the sharings for $m_k$ generated by $\text{Sim}_{\text{out}}$ are distributed identically to those of the real world, this proves indistinguishability.

In the second case, Lemma 6.2 shows that the shares corresponding to the participants $\{(i, b_i) : i \in \overline{B} \cup (B \times F_q)\}$ give no information about any message in the real world. Therefore, since here $\text{Sim}_{\text{out}}$ generates these shares from random messages in the ideal world, they obey the same distribution as in the real world, as required. $\square$

Finally, we can prove Corollary 1.2.

Proof (Corollary 1.2). For $q > n$, we choose $\Sigma$ to be the Shamir secret sharing scheme [43] over $F_q$ with adversary structure $\mathcal{A} = \{A \subseteq P_n : |A| < n/2\}$. If $n$ is odd, then $\mathcal{A} = \mathcal{A}^*$; else $\mathcal{A}^* = \{A \subseteq P_n : |A| \leq n/2\}$. For $q = n$, we choose the canonical one-participant-extension of the the Shamir secret sharing scheme with adversary structure $\mathcal{A}$. In both cases, $\Sigma$ is ideal and $F_q$-linear. Then the result follows from and Theorem 4.1 and Remark 4.3. $\square$

7 Our Multi-Use, One-out-of-$q$ OT Combiner

In this section, we show how our protocol $\pi_{\text{OT}}$ from Section 4 extends to the general case where the adversary structure $\mathcal{A}$ does not necessarily admit an ideal $F_q$-LSSS. Theorems 4.1 and 7.1 imply Theorem 1.1.

7.1 OT-Compatible Secret Sharing Schemes

Let $\Sigma$ be an $F_q$-LSSS for $n$ participants with adversary structure $\mathcal{A}$. Since $\Sigma$ is now not necessarily ideal, if $[b]_\Sigma = (\tilde{b}_1, \ldots, \tilde{b}_n)$ is a sharing of $b$ using $\Sigma$, we note that each share $\tilde{b}_i$ belongs to some vector space $E_i = F_{\ell_i}^q$ for some integer $\ell_i \geq 1$.

Hence, unlike in the ideal case, $\tilde{b}_i$ may not correspond to a single message index but a sequence of them.

Denote by $\ell = \sum_{i=1}^n \ell_i$ the normalized share size of $\Sigma$. Rather than looking at the sharings $(\tilde{b}_1, \ldots, \tilde{b}_n)$ as elements of $F_{\ell_1}^q \times \cdots \times F_{\ell_n}^q$, we concatenate their components and we see them as elements of the vector space $F_\ell^q$. Denote the corresponding vector space isomorphism by

$$\varphi : F_{\ell_1}^q \times \cdots \times F_{\ell_n}^q \rightarrow F_\ell^q.$$ 

According to this, given $\Sigma$ with the $\text{Share}_\Sigma$ function, we can define the ideal scheme $\Sigma'$ on $P_\ell = \{1, \ldots, \ell\}$ with share spaces $E'_i = F_q$ for every $i$, satisfying that $[b]_{\Sigma'} = \varphi([b]_\Sigma) = (b_1, \ldots, b_\ell)$ for every $b \in F_q$, where each $b_i \in F_q$.

As in the previous section, let $V \subseteq F_\ell^q$ denote the vector space consisting of all the sharings of 0 under the scheme $\Sigma'$. Given any $b \in F_q$, let $W_b \subseteq F_\ell^q$ be the affine subspace of sharings of $b$ for $\Sigma'$.

Given the $F_q$-LSSS $\Sigma'$ and $k \in F_q$, we instantiate the $F_q$-LSSS $S'_k$ associated to the affine subspace $W_{b_k}$ in Figure 5. The scheme $S'_k$ is now defined on the set of $\ell q$ participants $P_{\ell q}$ and it is $F_q$-linear and ideal.
The Secret Sharing Scheme $S'_k$

Share$_{S'_k}$: To share a message $m \in \mathbb{F}_q$, first
- let $k = (k_1, \ldots, k_\ell) \in \mathbb{F}_q^\ell$ be a sharing of $k$ using $\Sigma'$
- sample $r_1, \ldots, r_{\ell-1} \in \mathbb{F}_q$ uniformly at random, and let $r_\ell = m - \sum_{i=1}^{\ell-1} r_i$
- sample $h = (h_1, \ldots, h_\ell)$ uniformly at random from $V^\perp$

For every $i \in \mathcal{P}_\ell$ and for every $j \in \mathbb{F}_q$, define the $(i,j)$-th share as
\[
m^{(i,j)} = r_i + (k_i - j)h_i.
\]

Reconstruct$_{S'_k}$: Analogously to $S_k$ (Figure 4), it is enough to define the reconstruction function for subsets $A = \{(1,b_1), \ldots, (\ell,b_\ell)\}$ in $\min W_k$. The reconstruction function for $(m^{(i,j)})_{(i,j) \in A}$ is
\[
\sum_{i=1}^{\ell} m^{(i,b_i)}.
\]

The reconstruction function of $S'_k$ in Figure 5 is analogous to the one in Figure 5. Note that it effectively retrieves $m_k$ because
\[
\sum_{i=1}^{\ell} m^{(i,b_i)} = \sum_{i=1}^{\ell} (r_i + (k_i - b_i)h_i) = \sum_{i=1}^{\ell} r_i + \langle k - b, h \rangle = m_k.
\]

As a direct consequence of Proposition 5.5 we have that, for every $k \in \mathbb{F}_q$, the secret sharing schemes $S'_k$ are $\mathbb{F}_q$-linear, perfect, ideal and $W_k$-OT-compatible.

7.2 The Protocol

We now generalize the 1-out-of-$q$ OT combiner presented previously to the case where $\Sigma$ is not ideal. The obtained OT combiner is still black-box and $n$-server, but it is no longer single-use, because we assume that each of the $n$ OT candidate servers $S_i$ are called a total of $\ell_i$ times. To this end, for $i \in \mathcal{P}_n$, denote by $I_i = \left\{ \sum_{j=1}^{i-1} \ell_i + 1, \ldots, \sum_{j=1}^i \ell_i \right\}$ the set of participants of $\mathcal{P}_\ell$ whose shares are associated to the same server $S_i$. We describe our multi-use OT combiner in Figure 6.

The next theorem states the correctness and security properties of our construction.

**Theorem 7.1.** Let $\Sigma$ be an $\mathbb{F}_q$-LSSS with adversary structure $\mathcal{A} \subseteq 2^{\mathcal{P}_n}$. The OT combiner $\pi_{OT}'$ defined in Figure 6 is perfectly secure against active $(\mathcal{A},\mathcal{A}')$-adversaries.

**Proof.** Consider the ideal $\mathbb{F}_q$-LSSS $\Sigma'$ over $\mathcal{P}_\ell$ defined in Figure 6 and let $\mathcal{A}' \subseteq 2^{\mathcal{P}_\ell}$ be its adversary structure. By Theorem 4.1, this construction is perfectly
Our 1-out-of-\(q\) OT Combiner Protocol \(\pi'_{\text{OT}}\)

\(\pi'_{\text{OT}}.\text{Choose}(b)\): Given \(b \in \mathbb{F}_q\), compute a sharing \([b]_{\Sigma'} = (b'_1, \ldots, b'_\ell)\) of \(b\) using \(\Sigma'\).
Note that each \(b'_i \in \mathbb{F}_q\) because \(\Sigma'\) is ideal.
Output \((b_1, \ldots, b_n)\), where \(b_i = (b'_j)_{j \in I_i}\).

\(\pi'_{\text{OT}}.\text{Send}(m_0, \ldots, m_{q-1})\): For each message \(m_k\), independently compute a sharing
\([m_k]_{\Sigma'} = (m_k^{(i,j)}))_{(i,j) \in \mathcal{P}_{\ell,q}}.\)

Then, for every \((i, j) \in \mathcal{P}_{\ell,q}\), compute the values
\(w_i^j := m_0^{(i,j)}||m_1^{(i,j)}||\cdots||m_{q-1}^{(i,j)}\).

Output \((w_i^j)_{(i,j) \in \mathcal{P}_{\ell,q}}, \) where \(w_i^j = (w_i^k)_{k \in I_i}\).

\(\pi'_{\text{OT}}.\text{Rec}(b, (v_1, \ldots, v_\ell))\): Parse each \(v_i\) as \(v_i = (v_i^k)_{k \in I_i}\), where
\(v_i^k = n_0^{(k)}||n_1^{(k)}||\cdots||n_{q-1}^{(k)}\),
and where \(n_j^{(k)} \in \mathbb{F}_q\) for each \((k, j) \in \mathcal{P}_{\ell,q}\).
Retrieve \(m_b\) by evaluating \(\text{Reconstruct}_{\Sigma'}((n_b^{(k)})_{k \in I_i}).\)
If the reconstruction fails at any step, output \(\perp\).
Otherwise, output the reconstructed message \(m_b\).

Fig. 6. Our 1-out-of-\(q\) OT combiner \(\pi'_{\text{OT}}\) for a general access structure \(\mathcal{A}\).

secure against active \((\mathcal{A}', (\mathcal{A}')^*)\)-adversaries. The correctness of the protocol in Figure 6 follows from the correctness of the construction in Figure 3 proved in Section 6.

We next prove security against \((\mathcal{A}, \mathcal{A}^*)\)-adversaries. Note that each server \(S_i\) indexed by \(i \in \mathcal{P}_n\) corresponds to the participants \(I_i \subseteq \mathcal{P}_\ell\) of the scheme \(\Sigma'\).

First note that, by construction of \(\Sigma'\), we have \(A \in \mathcal{A}\) if and only if \(A' = \bigcup_{i \in A} I_i \in \mathcal{A}'\). Hence, any adversary that corrupts Alice and a set \(A \in \mathcal{A}\) in the extended multi-use construction, will have as many capabilities as an adversary corrupting Alice and the servers corresponding to \(A'\) in the single-use construction, since the interaction with a particular OT implementation can be thought of as the concatenation of the interactions of the different calls to it.

Next, suppose that an adversary corrupts Bob and a set \(B \subseteq \mathcal{P}_n\) of servers. Analogously to the previous case, the adversary will have as many capabilities as an adversary corrupting Bob and the servers \(B' = \bigcup_{i \in B} I_i\). Then \(B'\) is in \((\mathcal{A}')^*\), and so the protocol is secure against the active corruption of this adversary. \(\square\)

Remark 7.2. If the normalized total share size of \(\Sigma\) is \(\ell\), Bob sends a total of \(\ell \log q\) bits to servers in the choice phase. In the sending phase, Alice sends a total of \(q^2\ell \log q\) bits to the servers. In the transfer phase, servers send a total of \(q^{\ell} \log q\) bits to Bob. Hence, the communication complexity is \((q^2 + q + 1)\ell \log q\). As in the ideal case, this protocol can be adapted as an 1-out-of-\(q'\) OT combiner for \(q' < q\), in which case the communication complexity is \((qq' + q' + 1)\ell \log q\).
Now we state a result from [16] that characterizes the pairs \((A, B)\) of adversary structures for which perfectly secure 1-out-of-2 OT combiners are known to be impossible to attain. It is used in 7.4.

**Proposition 7.3 ([16]).** If \((A, B)\) is not an \(R_2\) pair of adversary structures, then perfectly secure 1-out-of-2 OT combiners against active \((A, B)\)-adversaries cannot exist.

**Corollary 7.4.** Let \((A, B)\) be a pair adversary structures. There exist perfectly secure 1-out-of-\(q\) OT combiners against active \((A, B)\)-adversaries if and only if \((A, B)\) is \(R_2\).

**Proof.** Suppose that \((A, B)\) is \(R_2\). By [29], \(A\) admits an \(F_q\)-LSSS \(\Sigma\). By Theorem 7.1, \(\Sigma\) provides a secure OT combiner for \((A, B)\). Now suppose, for the sake of contradiction, that \((A, B)\) is not \(R_2\). If there exists a secure 1-out-of-\(q\) combiner for \((A, B)\), then there exists a secure 1-out-of-2 combiner for \((A, B)\), which contradicts Proposition 7.3. \(\Box\)

8 One-out-of-\(q\) OT-combiners from 1-out-of-2 OT-combiners

We dedicate this section to construct 1-out-of-\(q\) OT combiners from 1-out-of-2 OT combiners. For this purpose, we adapt a technique to construct a 1-out-of-\(q\) OT instance from 1-out-of-2 OT instances that presented by Crépeau, Brassard and Robert [18]. As far as we know, this approach has not been studied in any previous works. As we will see, for certain adversary structures, it is possible to get better communication complexity than using the protocols described above. Moreover, the construction does not restrict the number of messages \(q\) to a prime power, and it allows for arbitrary \(q \geq 2\). However, the construction is inherently multi-use, as it requires multiple calls to 1-out-of-2 OT instances. The suitability of this construction with respect the ones presented above will depend on the efficiency of \(\mathbb{F}_2\)-linear secret sharing schemes for the adversary structure with respect \(\mathbb{F}_q\)-linear secret sharing schemes, the efficiency of the OT instances involved, and the length of the messages.

We describe the 1-out-of-\(q\) OT combiner \(\pi_{OT}\) for bit messages in Figure 7. For messages of larger bitsize \(s > 1\), we can extend this construction using zigzag functions [18], which requires \(3^\lceil \log_2 s \rceil\) executions of this bit-OT protocol. In the figure, we call \(\pi_{OT}\) the 1-out-of-2 \(n\)-server bit-OT combiner. For this construction, we can instantiate \(\pi_{OT}\) with the general 1-out-of-\(q\) OT combiner presented in Figure 6 for the case \(q = 2\), which is equivalent to the one presented in [15] for non-ideal schemes. We can also use the combiner in [16] to reduce the size of messages taken as input by OT candidates.

One advantage of this construction is that it only uses 1-out-of-2 OT protocols. As mentioned above, it results in a highly multi-use solution, as in general it requires a multi-use combiner for each of the 1-out-of-2 OT combiners, and the multiple calls to it required by the 1-out-of-\(q\) combiner technique of [18].
1-out-of-\( q \) OT Combiner \( \pi_{OT} \) from a 1-out-of-2 OT Combiner \( \pi_{OT} \)

\( \pi_{OT} \).Choose(\( b \)): Given \( b \in F_q \), let \( (b_0, \ldots, b_{q-2}) \) be a sequence of bits defined as

\[
 b_k = \begin{cases} 
 1 & \text{if } k < b \\
 0, & \text{otherwise}.
\end{cases}
\]

For \( k = 0, \ldots, q-2 \), let \( (b^{(k)}_1, \ldots, b^{(k)}_n) = \pi_{OT} \).Choose(\( b_k \)).

Output \( (b^{(0)}_1, \ldots, b^{(q-2)}_1) \in \mathcal{P}_n \).

\( \pi_{OT} \).Send(\( m_0, \ldots, m_{q-1} \)): Sample \( q-2 \) bits \( r_1, \ldots, r_{q-2} \) uniformly at random.

Then, compute the values \( (w_0, \ldots, w_{q-2}) \) as

\[
 w_k = \begin{cases} 
 \pi_{OT} \).Send(\( m_0, r_1 \)) & \text{if } k = 0, \\
 \pi_{OT} \).Send(\( m_k \oplus r_k, r_{k+1} \oplus r_k \)) & \text{if } 1 \leq k < q-2, \\
 \pi_{OT} \).Send(\( m_{q-2} \oplus r_{q-2}, m_{q-1} \oplus r_{q-2} \)) & \text{if } k = q-2.
\end{cases}
\]

Parse \( w_k = (w^{(i)}_k)_{(i,j) \in \mathcal{P}_{q-2}} \).

For every \( i = 1, \ldots, n \), let \( u_i = (u^{(i)}_k)_{(k,j) \in \mathcal{P}_{q-1,2}} \).

Output \( (u_1, \ldots, u_n) \).

\( \pi_{OT} \).Rec(\( b, (v_1, \ldots, v_n) \)): For every \( i = 1, \ldots, n \), parse \( v_i = (v_i^0, \ldots, v_i^{q-2}) \).

For every \( k < b \), let \( y_k = \pi_{OT} \).Rec(\( 1, (v_i^1, \ldots, v_i^k) \)).

If \( b < q-1 \), let \( y_b = \pi_{OT} \).Rec(\( 0, (v_i^1, \ldots, v_i^{b}) \)).

If the reconstruction fails at any step, output \( \perp \).

Otherwise, if \( b < q-1 \), output \( \bigoplus_{k=0}^{q-2} y_k \). Else, if \( b = q-1 \), output \( \bigoplus_{k=0}^{q-2} y_k \).

---

Fig. 7. 1-out-of-\( q \) OT combiner \( \pi_{OT} \) from an 1-out-of-2 OT combiner \( \pi_{OT} \).

Next, we evaluate the communication cost of this protocol for messages of one bit and general adversary structures. We instantiate it with the 1-out-of-2 OT combiner from Figure 6. Suppose that the pair \( (A,B) \) requires a \( F_2 \)-LSSS \( \Sigma \) with normalized share size \( \ell \). In the Choice phase, the output of each \( \pi_{OT} \).Choose has \( \ell \) bits, and the total is \( (q-1)\ell \) bits. In the Sending phase, the output of each \( \pi_{OT} \).Send is \( 4\ell \) bits, so it outputs \( 4(q-1)\ell \) bits in total. In the Transfer phase, servers send \( 2\ell \) bits, in total. Therefore, the communication cost is \( (5q-3)\ell \) bits.

If the 1-out-of-2 combiner in [16] is used instead of [14], this communication complexity can be reduced to \( (3q-2)\ell \).

In order to compare it with the other construction of this work, we consider the threshold \( t \) adversary structure \( A_t \), for \( 1 < t < n \), and the pair \( (A_t, A^t) \). This adversary pair requires a scheme with normalized share size \( \ell = n \log n \). The resulting protocol exchanges \( (3q-1)n \log n \) bits, and it uses each of the \( n \) 1-out-of-2 bit-OT candidates \( q \log n \) times. For messages in \( F_q \), the use of zigzag
functions implies increasing the communication cost and the OT calls by a factor of the order of $\log q$.

In this 1-out-of-$q$ OT combiner, information is only exchanged through a 1-out-of-2 combiner, and its security properties rest exclusively on this 1-out-of-2 combiner. The corresponding result is summarized in Theorem 1.3 for the case of threshold adversary structures.

A An Example of $\Sigma$ and $\mathcal{S}_0$ for $q = n = 3$

Consider the case $q = n = 3$ and let $\mathcal{A}$ and $\mathcal{B}$ be adversary structures of threshold $t = 1$. Let $\Sigma$ be a Shamir secret sharing over $\mathbb{F}_3$ with $n$ participants and adversary structure of threshold 1. The secret is $b \in \mathbb{F}_3$. Bob chooses $r$ at random, and the shares are $b + r$, $b + 2r$ and $r$, corresponding to the points 1, 2, and the point at infinity. The sharings of $b = 0$ are the following ones:

$$W_0 = V = \{(0, 0, 0), (1, 2, 1), (2, 1, 2)\}$$

Hence, we have that

$$\min F_{W_0} = \{(1, 0), (2, 0), (3, 0)\}, \{(1, 1), (2, 2), (3, 1)\}, \{(1, 2), (2, 1), (3, 2)\}$$

Now we analyze the scheme $\mathcal{S}_0$, used by Alice and described in [4] which is run by Bob to share $m_0$. The share of the server $(i, j)$ for $i \in \mathcal{P}_3$ and $j \in \mathbb{F}_3$ is $r_i + jh_i$, where $r_i$ are additive shares of the secret $m_0$, and $(h_1, h_2, h_3)$ is an element of $V^\perp$ chosen at random. Note that $V^\perp = \langle (1, 1, 0), (0, 1, 1) \rangle$.

Let $\Gamma$ be the access structure of $\mathcal{S}_0$. Observe that subsets of $\min F_{W_0}$ are in $\Gamma$, because the sum of the shares corresponding to these subsets equals the
secret. Hence, $I_{W_0} \subseteq \Gamma$. Indeed, $\Gamma$ is strictly greater than $I_{W_0}$: For example, the subset

$$\{(1,0), (2,0), (3,1), (3,2)\}$$

is in $\Gamma$ because the sum of the shares corresponding to $(1,0)$ and $(2,0)$, plus the double of the shares corresponding to $(3,1)$ and $(3,2)$, equals the secret, and this subset it is not in $I_{W_0}$. We will see now that $\Gamma$ is $W_0$-OT compatible.

It can be seen to check that the minimal sets of $\Gamma$ are

$$\{(1,c_1),(2,c_2),(3,c_3)\}, \{(i_1,c_{i_1}),(i_2,c_{i_2})\} \cup P_{i_3} \setminus \{(i_3,c_{i_3})\}, \text{ and}$$

$$\{(i_1,c_{i_1})\} \cup P_{i_2} \cup P_{i_3} \setminus \{(i_2,c_{i_2}),(i_3,c_{i_3})\}$$

for every $(c_1,c_2,c_3) \in W_0$ and every permutation $(i_1,i_2,i_3)$ of $(1,2,3)$. It can be checked that $\Gamma \cap \Delta$ are the subsets

$$\{(1,c_1),(2,c_2),(3,c_3)\}, \{(1,c_1),(2,c_2),(3,c_3)\} \cup P_i \text{ for } i \in \{1,2,3\},$$

$$\{(1,c_1),(2,c_2),(3,c_3)\} \cup P_i \cup P_j \text{ for } i,j \in \{1,2,3\}, \text{ and } P_1 \cup P_2 \cup P_3$$

for every $(c_1,c_2,c_3) \in W_0$. Since $\Gamma \cap \Delta = I_{W_0} \cap \Delta$, $\Gamma$ is $W_0$-OT compatible.
