Abstract

Asynchronous Byzantine fault-tolerant (BFT) protocols assuming no timing assumptions are inherently more robust than their partially synchronous counterparts, but typically have much weaker security guarantees—achieving no information-theoretic security, quantum security, or adaptive security, and using trusted setup.

We design and implement WaterBear, a family of new and efficient asynchronous BFT protocols matching all security guarantees of partially synchronous protocols. To achieve the goal, we have developed the local coin (flipping a coin locally and independently at each replica) based BFT approach—one long deemed as being inefficient—and designed more efficient asynchronous binary agreement (ABA) protocols and their reproposable ABA (RABA) versions from local coins. Our techniques on ABA and RABA are of independent interests and also allow us to build more efficient ABA protocols from common coins (distributively generating the same random coins for all replicas), helping improve various other protocols such as distributed key generation and BFT assuming trusted setup.

We implemented in total five BFT protocols in a new golang library, including four WaterBear protocols and BEAT. Via extensive evaluation, we show that our protocols are efficient under both failure-free and failure scenarios, achieving at least comparable or superior performance to BEAT with much weaker security guarantees. Specifically, the most efficient WaterBear protocol consistently outperforms BEAT in terms of all metrics. For instance, when the number of replicas is 16, the latency of our protocol is about 1/8 of that of BEAT and the throughput of our protocol is 1.23x that of BEAT.

Our work pushes the boundaries of asynchronous BFT, showing the strongest security levels that we know of and high performance can co-exist.

1 Introduction

Byzantine fault-tolerant state machine replication (BFT), a technique traditionally used to build mission-critical systems, has nowadays been the standard model for permissioned blockchains [9, 19, 63] and is used in various ways in hybrid blockchains. Due to their inherent robustness against performance and DoS attacks, asynchronous BFT protocols—relying on no timing assumptions—have been receiving significant attention [11]. While one line of works focuses on performance [28, 43, 44, 54], some other works aim at improving their "security." For instance, BEAT [35] and PACE [64] eliminated the less-established pairing assumption in these protocols; EPIC aimed at providing adaptive security [50]; DAG-Rider strived to achieve quantum safety (though not quantum liveness) [47]; recent works studied how to avoid trusted setup [5, 30, 48].

Table 1 summarizes the security levels that can be achieved for asynchronous BFT protocols implemented. The situation is in sharp contrast to their partially synchronous BFT counterparts (relying on timing assumptions): for example, the classic PBFT protocol [23]—based on authenticated channels only—easily achieves all the properties listed in the table. It is thus our goal to design and implement practical asynchronous BFT protocols achieving all these properties in Table 1—the same security guarantees as in partially synchronous BFT.

1.1 Background

IT security. In computational security, the adversary is restricted to probabilistic polynomial-time. In IT (information-theoretic) security, the adversary is unbounded. Computational protocols assume the hardness of some intractability problems (e.g., RSA, DL). These mathematical problems may, in the future, be proven to be broken or weakened due to newly developed techniques. In contrast, IT security provides everlasting security, typically assuming secure or authenticated channels only (that minimize the attack surface).

No PKC; quantum security. It is an important problem to design Byzantine-resilient protocols relying on no public key cryptography (PKC), considering the efficiency and quantum resilience of symmetric cryptography. For instance, PBFT is known as the first PKC-free partially synchronous BFT [23]. Byzantine-resilient protocols in various other settings are known too [31, 34, 45]. It remains an open problem whether
one could design practical PKC-free asynchronous BFT. Note IT security implies quantum security; the reverse does not hold. Likewise, symmetric cryptography such as blockciphers and hash functions are quantum secure, but quantum secure cryptography may use other PKC primitives (e.g., lattices).

1.2 Why Matching Security Guarantees of Partially Synchronous BFT Hard?

Unlike partially synchronous BFT protocols, asynchronous BFT protocols must be randomized to achieve liveness (due to the celebrated FLP impossibility result [38]). Existing asynchronous BFT protocols rely critically on cryptographic common coin protocols (a distributed object that generates the same random coins to all replicas) which are inefficient if no trusted setup is assumed (see Sec. 2 for detailed discussion). Even if relaxing to quantum security, we currently lack efficient common coin instantiations from quantum secure primitives (e.g., lattices). Note while SodsBC is a quantum-secure BFT protocol, it directly relies on trusted setup to generate the common coins and thus bypasses the core problem of generating common coins efficiently [32].

Meanwhile, achieving stronger security in asynchronous BFT typically comes with a higher cost. For instance, adding adaptive security in [50] makes the original BFT system much slower. We must guarantee that ensuring these properties altogether would not incur too much overhead.

1.3 Our Approach

Reducing the problem to local coin RABA then to ABA. Instead of using common coins, we revisit the local coin based BFT approach that has been long viewed as being inefficient. In the local coin based approach, replicas need to independently and locally flip coins and existing protocols terminate in exponential expected rounds and fail to scale [25, 55].

We thus take a detour and develop the PACE BFT framework [64] in IT and quantum security settings. (Recall existing instantiations in PACE use trusted setup, achieving computational security and static security only.) PACE uses a variant of asynchronous binary Byzantine agreement (ABA) called reproposable ABA (i.e., RABA). It is also shown that some ABA protocols can be efficiently converted to RABA protocols. Crucially, RABA in PACE enables a fast path for consensus. We observe that while PACE was designed with common coin based RABA, the protocol, even with local coin based RABA, can—on average—terminate within a single RABA round with high probability. So the exponential rounds in local coin based ABA is no longer a major efficiency obstacle, and the per-round complexity of ABA protocols becomes critical. Our strategy is to reduce BFT to RABA with local coins and then to ABA with local coins and then improve the per-round complexity of them.

Improving the per-round complexity. As reported in almost all asynchronous BFT systems [35,44,64], ABA is their major performance bottleneck. It is shown that the concrete steps per round of ABA protocols are vital to the performance of asynchronous BFT: even a single step improvement in ABA, the resulting BFT protocol could be improved by, say, 2x [64].

To our knowledge, only two local coin based ABA protocols have been proposed: Ben-Or’s ABA [11] assuming \( n > 5f \), and Bracha’s ABA [13] with \( n > 3f \) (the most efficient protocol for nearly three decades). Bracha’s ABA, unfortunately, has a large number of steps (12 steps) and \( O(n^3) \) messages per round [13]. (The situation is in sharp contrast to ABA assuming common coins which has 3 steps and \( O(n^2) \) messages per round.) Our main technical contributions are indeed efficient local coin based ABA and RABA protocols.

1.4 Our Contributions

1.4.1 Technical Contributions

Efficient local coin based ABA. Table 3 shows two novel local coin based ABA protocols that we introduce in the paper: Cubic-ABA and Quadratic-ABA. Cubic-ABA is easy to understand and implement, and can be viewed as an optimized version of Bracha’s ABA. Cubic-ABA has 7 steps per round in the worst case, while Bracha’s ABA uses 12 steps, almost doubling the number of steps of Cubic-ABA. In contrast, Quadratic-ABA adopts a novel design, having 4 or 5 steps per round only and being the first local coin based ABA with \( O(n^2) \) messages per round.

Tackling a subtle liveness issue for RABA. We go on to design Cubic-RABA and Quadratic-RABA based on Cubic-ABA and Quadratic-ABA, respectively. Unlike prior transformations following a generic approach in [64], we iden-
We compare ABA protocols using common coins in Table 4 weak common coins mean all correct replicas output 0 and 1, The techniques we introduce for Quadratic-ABA are of inde-
Table 5: ABA protocols using perfect common coins.
†
Table 2: WaterBear-QS and WaterBear instantiations. *HMAC is quantum secure but not IT secure; we simply used HMAC in our reference implementation for Waterbear to demonstrate the overhead of Waterbear itself, because all other protocols in this paper and PBFT use MAC for authentication. As in PACE, both WaterBear-QS and WaterBear have a fast path allowing them to terminate in $O((\log n)t)$ As shown in PACE, the probability of triggering fast paths is high. WaterBear-C and WaterBear-QS-C have $O(n^4)$ messages on average due to the usage of Cubic-RABA, while WaterBear-Q and WaterBear-QS-Q have $O(n^3)$ messages on average due to the usage of Quadratic-RABA—matching those of HoneyBadger, BEAT, and PACE.

A new BFT platform. Starting from HoneyBadger, existing asynchronous BFT protocols, including BEAT, Dumbo, and EPIC, use the HoneyBadger programming framework using Python 2.7 (end of life and end of support on January 1, 2020). We instead build a new platform using Golang that is more modular and developer-friendly than existing ones. Our platform currently supports WaterBear-C, WaterBear-Q, WaterBear-QS-C, WaterBear-QS-Q, and BEAT (one of the most efficient open-source asynchronous BFT) [1,35]. Due to its modularity, the library only contains about 11,000 LOC.

Large-scale experiments and robustness evaluation. With deployment in 5 continents, we show our protocols offer comparable performance as the state-of-the-art asynchronous BFT protocols, while achieving much stronger security (IT or quantum security, adaptive security, and no trusted dealer used). We also design and evaluate various failure and attack scenarios, showing all our protocols are highly robust during failures and attacks. Specifically, one of our protocols, WaterBear-QS-Q, consistently outperforms BEAT (with much weaker security guarantees); for instance, when $n = 16$, the latency of
WaterBear-QS-Q is about 1/8 that of BEAT and the throughput of WaterBear-QS-Q is 1.23x that of BEAT. The peak throughput of WaterBear-QS-Q (as \( n \) grows larger) is about 1.47x that of BEAT.

Our system pushes the limits of asynchronous BFT, showing that high performance and the strongest security levels that we know of can co-exist.

2 Related Work

IT BFT in partially synchronous environments. There exist several partially synchronous BFT protocols that are IT secure or can be made IT secure. In particular, PBFT (the journal version) [23], PBFT (in Castro’s PhD thesis) [22], and Cachin’s formulation for PBFT [15] assume authenticated channels but use cryptographic hash functions. These protocols are quantum resistant but not IT secure. They can, however, be modified to achieve IT security if removing the usage of the hash functions. Recently, Stern and Abraham proposed IT HotStuff, an IT secure, partially synchronous BFT protocol that uses \( O(1) \) persistent storage and \( O(n^2) \) messages, each message containing a constant number of words [62].

Adaptive vs. static security for BFT. Most asynchronous BFT protocols implemented, including SINTRA, HoneyBadger, BEAT, and Dumbo, defend against static adversary only. These protocols rely critically on efficient but statically secure threshold cryptography. EPIC is an asynchronous BFT that uses adaptively secure threshold pseudorandom function (PRF) to achieve adaptive security but is not as efficient as its statically secure counterparts. RITAS [55] contains an adaptively secure BFT protocol, but as it relies on inefficient local coin based ABA, it is less efficient than other protocols in large-size networks. DAG-Rider [47] achieves adaptive security if using adaptively secure common coin protocols.

The situation for asynchronous environments is in sharp contrast to that of partially synchronous BFT protocols, most of which attain adaptive security [8, 23, 24, 33, 42, 46, 61]. WaterBear achieves adaptive security and IT security and significantly outperforms EPIC that is not IT secure.

Quantum safety (but no quantum liveness). A BFT protocol is quantum secure if its safety is quantum resistant (quantum safety) and its liveness is quantum resistant (quantum liveness) [47]. DAG-Rider [47] achieves quantum safety, even if when being instantiated using a cryptographic common coin protocol (e.g., [16, 49]). The BKR protocol and their descendants (e.g., HoneyBadger [54], MiB [51], PACE [64]) achieve quantum safety if using techniques from EPIC [50]. All the above-mentioned protocols, however, do not achieve quantum liveness. Tusk [28] and Bullshark [41] are variants of DAG-Rider; they extensively use signatures and hashes and achieve neither quantum safety nor quantum liveness.

SodsBC. SodsBC [32] is a quantum-secure asynchronous protocol relying on trusted setup to build common coins for the first epoch, and each subsequent epoch uses common coins from its previous epoch. Moreover, unlike WaterBear, SodsBC does not achieve adaptive security. While achieving weaker security guarantees, SodsBC appears less efficient than WaterBear-QS-Q: SodsBC outperforms HoneyBadger when \( n \) grows large, but WaterBear-QS-Q significantly and consistently outperforms BEAT, which is more efficient than HoneyBadger. SodsBC also provides a variant without using trusted setup, though the protocol works in partially synchronous environments only and requires running \( n \) parallel PBFT instances. The variant has not yet been implemented.

(II) Byzantine agreement and common coins. Byzantine agreement (BA) is a central tool for both distributed computing and cryptography. The condition \( n \geq 3f + 1 \) is both necessary and sufficient for both synchronous and asynchronous BA protocols [59]. The celebrated impossibility result of Fischer, Lynch, and Paterson [38] implies that a randomized BA protocol must have non-terminating executions. A BA protocol may be \((1 - \epsilon)\)-terminating, where correct replicas terminate the protocol with an overwhelming probability, or almost-surely terminating, where replicas terminate with probability one.

For our purpose, we focus on ABA protocols in the IT setting with a computationally unbounded adversary. For almost-surely ABA, Ben-Or’s ABA requires \( n \geq 5f + 1 \) [11], while Bracha’s ABA [13] achieves optimal resilience. The two protocols use local coins and require an exponential expected running time. Feldman and Micali propose a BA protocol having a constant expected running time in synchronous environments and extend it to build a polynomial-time ABA protocol requiring \( n \geq 4f + 1 \) [37]. Abraham, Dolev, and Halpern [4] provide the first almost-surely ABA with polynomial efficiency (concretely, \( O(n^2) \) expected running time) and optimal resilience. Bangalore, Choudhury, and Patra [10] improve the expected running time of [4] by a factor of \( n \).

For \((1 - \epsilon)\)-terminating ABA, Canetti and Rabin [21] build an expected constant-round ABA protocol with optimal resilience. Patra, Choudhury, and Rangan [58] build a more efficient construction in terms of communication complexity.

Both almost-surely ABA and \((1 - \epsilon)\)-terminating ABA follow the classic framework of Feldman and Micali [37] that reduces ABA to asynchronous verifiable secret sharing (AVSS). The framework uses AVSS to build common coins. The original idea of using common coin for ABA is due to Rabin [60]. Unfortunately, the framework of using AVSS for common coins is prohibitively expensive. For instance, to build AVSS, the approach of Canetti and Rabin [21] needs to begin with an information checking protocol (resembling signatures but working in the IT setting), then asynchronous recoverable sharing, then asynchronous weak secret sharing, and finally AVSS. The improved approach of Patra, Choudhury, and Rangan [58] remains complex, following the route of information-checking protocol, then asynchronous weak commitment, and then AVSS. Moreover, the transformation from AVSS to ABA is equally expensive, requiring running \( n^2 \) AVSS instances to generate a single (weak) coin. Patra,
Choudhury, and Rangan [58] also propose an approach for sharing multiple secrets simultaneously. While such an approach is useful for building more efficient multi-valued BA (MBA), it is unknown if it would yield more efficient ABA protocols. While, for instance, the CNV framework [25] does use MBA, it may run $O(n)$ consecutive MBA instances (which is inefficient).

3 System Model and Definitions

3.1 System and Threat Model

This section describes the system model for distributed computing protocols, where $f$ out of $n$ replicas may fail arbitrarily (Byzantine failures). Unless specified otherwise, the protocols we consider have the following properties:

- **Optimal resilience**: The protocols in this work assume $f \leq \lfloor \frac{n-1}{3} \rfloor$, which is optimal. A (Byzantine) quorum is a set of $\lceil \frac{n-f+1}{f+1} \rceil$ replicas. For simplicity, we may assume $n = 3f + 1$ and a quorum size of $2f + 1$.
- **Asynchronous network**: We consider completely asynchronous systems making no timing assumptions on message processing or transmission delays. In contrast, partially synchronous systems assume that there exist an upper bound on message processing and transmission delays but the bound may be unknown to anyone [36].
- **No dealer/trusted setup**: We do not assume the existence of a trusted dealer or trusted setup. Neither do we assume there exists an interactive protocol for any public keys, reference strings, or public parameters.
- **Unbounded adversary**: Depending on the capacities of the adversary, a protocol may achieve computational security, where the adversary is bounded and restricted to probabilistic polynomial-time (PPT), or achieve information-theoretic (IT) security, where the adversary is unbounded.
- **Adaptive corruptions**: Depending on how the adversary decides to corrupt parties, there are two types of corruptions: static corruptions and adaptive corruptions. In the static corruption model, the adversary is restricted to choose its set of corrupted replicas at the start of the protocol and cannot change this set later on. An adaptive adversary can choose its set of corrupted replicas at any moment during the execution of the protocol, based on the information it has accumulated thus far (i.e., the messages observed and the states of previously corrupted replicas). There is a strong separation result that statically secure protocols are not necessarily adaptively secure [20,27].

Existing asynchronous BFT protocols implemented assume trusted setup, achieving computational security and static security only. None of them achieve quantum security either.

We may associate a protocol instance with a unique identifier $id$, tagging each message in the instance with $id$. If no ambiguity arises, we may omit the identifiers.

3.2 Definitions and Background

**BFT.** In a BFT protocol, a replica $a$-delivers (atomically deliver) transactions, each submitted by some client. The client computes a final response to its submitted transaction from the responses it receives from replicas. We consider the following properties:

- **Agreement**: If any correct replica $a$-delivers a transaction $tx$, then every correct replica $a$-delivers $tx$.
- **Total order**: If a correct replica $a$-delivers a transaction $tx$ before $a$-delivering $tx'$, then no correct replica $a$-delivers a transaction $tx'$ without first $a$-delivering $tx$.
- **Liveness**: If a transaction $tx$ is submitted to all correct replicas, then all correct replicas eventually $a$-deliver $tx$.

**Asynchronous binary Byzantine agreement (ABA).** An ABA protocol is specified by $propose$ and $decide$. Each replica proposes an initial binary value (called vote) for consensus and replicas will decide on some value. ABA should satisfy the following properties:

- **Validity**: If all correct replicas propose $v$, then any correct replica that terminates decides $v$.
- **Agreement**: If a correct replica decides $v$, then any correct replica that terminates decides $v$.
- **Termination**: Every correct replica eventually decides some value.
- **Integrity**: No correct replica decides twice.

**RABA.** Reproposable ABA (RABA) is a new distributed computing primitive introduced in PACE [64]. In contrast to conventional ABA protocols, where replicas can vote once only, RABA allows replicas to change their votes. Formally, a RABA protocol tagged with a unique identifier $id$ is specified by $propose(id, \cdot)$, $repropose(id, \cdot)$, and $decide(id, \cdot)$, with the input domain being $\{0, 1\}$. For our purpose, RABA is “biased towards 1.” Each replica can propose a vote $v$ at the beginning of the protocol. Each replica can propose a vote only once. A correct replica that proposed 0 is allowed to change its mind and repropose 1. A replica that proposed 1 is not allowed to repropose 0. If a replica reproposes 1, it does so at most once. A replica terminates the protocol identified by $id$ by generating a decide message. RABA (biased toward 1) satisfies the following properties:

- **Validity**: If all correct replicas propose $v$ and never repropose $\bar{v}$, then any correct replica that terminates decides $v$.
- **Unanimous termination**: If all correct replicas propose $v$ and never repropose $\bar{v}$, then all correct replicas eventually terminate.
- **Agreement**: If a correct replica decides $v$, then any correct replica that terminates decides $v$.
- **Biased validity**: If $f+1$ correct replicas propose $1$, then any correct replica that terminates decides 1.
- **Biased termination**: Let $Q$ be the set of correct replicas. Let $Q_1$ be the set of correct replicas that propose 1 and never repropose 0. Let $Q_2$ be correct replicas that propose 0 and later repropose 1. If $Q_2 \neq \emptyset$ and $Q = Q_1 \cup Q_2$, then
each correct replica eventually terminates.

- **Integrity**: No correct replica decides twice.

Validity is slightly different from those for ABA. They are modified to accommodate the RABA syntax. Integrity is defined to ensure RABA decides once and once only.

Unanimous termination and biased termination are carefully introduced to help achieve RABA termination in certain scenarios. External operations would have to force the protocol to meet these termination conditions.

Biased validity in RABA requires that if \( f + 1 \) replicas, not simply all correct replicas, propose 1, then a correct replica that terminates decides 1. The property guarantees the PACE framework to have sufficient transactions delivered.

**RBC**. A Byzantine reliable broadcast (RBC) protocol [7, 14, 18, 29] is specified by \( r\text{-broadcast} \) and \( r\text{-deliver} \) such that the following properties hold:

- **Validity**: If a correct replica \( p \) \( r\text{-broadcasts} \) a message \( m \), then \( p \) eventually \( r\text{-delivers} \) \( m \).
- **Agreement**: If some correct replica \( r\text{-delivers} \) a message \( m \), then every correct replica eventually \( r\text{-delivers} \) \( m \).
- **Integrity**: For any message \( m \), every correct replica \( r\text{-delivers} \) \( m \) at most once. Moreover, if the sender is correct, then \( m \) was previously \( r\text{-broadcast} \) by the sender.

Bracha’s broadcast [13] has a bandwidth of \( O(n^2 |m|) \) and is IT secure, and CT RBC due to Cachin and Tessaro [18] uses hash functions (with output length \( \lambda \)) to reduce the bandwidth to \( O(n |m| + \lambda n^2 \log n) \). Recent works proposed various IT and quantum RBC protocols with lower communication [6, 29].

**PACE framework**. PACE uses RBC and RABA in a black-box manner to construct efficient asynchronous BFT. The framework allows all ABA instances to run in parallel, removing a well-known bottleneck in the original framework of Ben-Or, Kemler, and Rabin [12]. PACE also provides a fast path for consensus, allowing the protocol to terminate using a single RABA round. It is an interesting research problem to improve RABA (and the underlying ABA) protocols in terms of message and communication complexity.

**Steps, phases, and rounds**. In asynchronous environments, the network delay is unbounded. To measure the latency of asynchronous protocols, we use the standard notion of asynchronous steps [21], where a protocol runs in \( x \) asynchronous steps if its running time is at most \( x \) times the maximum message delay between honest replicas during the execution.

We also use the notion of phases for ease of description, where a phase in a protocol consists of a fixed number of steps. When describing some of our protocols, we may divide a protocol into several phases, each of which has several steps.

In this paper, the notion of rounds is restricted to ABA protocols: An ABA protocol proceeds in rounds, where an ABA round consists of a fixed number of steps. For instance, local coin ABA protocols terminate in expected exponential rounds, while ABA assuming common coins (including CC-ABA we introduce in this paper) terminates in expected constant rounds. An ABA round may consist of several phases and each phase consists of several steps.

## 4 ABA from Local Coins and Common Coins

The state-of-the-art local coin based ABA protocol, Bracha’s ABA [13], has \( O(n^3) \) messages and 12 steps in each round. We design two new ABA protocols from local coins, Cubic-ABA and Quadratic-ABA, with two goals in mind—being more efficient than Bracha’s ABA and being compatible with RABA.

We begin with the simpler one, Cubic-ABA, that achieves the same message complexity as Bracha’s ABA but has only 7 steps in each round. Cubic-ABA admits a clean and intuitive proof of correctness. We then present Quadratic-ABA that reduces the number of steps to 5 in each round. The improvement is significant, allowing WaterBear to attain the same average message complexity as PACE—\( O(n^3) \). Both ABA protocols can be modified to efficient RABA protocols.

As an important by-product, extending the idea of Quadratic-ABA and assuming the existence of (weak or perfect) common coins, we can present ABA protocols that have expected constant rounds and outperform the state-of-the-art protocols, as shown in Table 4 and Table 5 in Sec. 1.

### 4.1 Cubic-ABA

Figure 1 describes the pseudocode of Cubic-ABA and Figure 2 illustrates the workflow. Cubic-ABA uses the broadcast primitive of best-effort broadcast and the \( r\text{-broadcast} \) and \( r\text{-deliver} \) primitives of RBC. The protocol proceeds in rounds, beginning with round 0. Each round consists of three phases. In the first phase, a replica \( p_i \) broadcasts a \( \text{pre-vote}_i(iv_r) \) message, where \( iv_r \in \{0, 1\} \) is the input value of \( p_i \), for round \( r \) (In 07). At In 08-09, if \( p_i \) receives \( f + 1 \) \( \text{pre-vote}_i(v) \) for some \( v \in \{0, 1\} \) and has not previously broadcast \( \text{pre-vote}_i(v) \), it also broadcasts \( \text{pre-vote}_i(v) \).

At In 10-14, \( p_i \) enters the second phase. If \( p_i \) receives \( 2f + 1 \) \( \text{pre-vote}_i(v) \), it adds \( v \) to its \( bset_r \), a set consisting only 0 and 1 (In 10-11). Letting \( v \) be the first value added to \( bset_r \) for \( p_i \), \( p_i \) broadcasts a \( \text{main-vote}_i(v) \) message (In 12-14).

In the third phase, a correct replica \( p_i \) accepts a \( \text{main-vote}_i(v) \) message only if \( v \) has already been added locally to \( bset_r \) (In 15). If \( p_i \) has received \( n - f \) \( \text{main-vote}_i(v) \), \( p_i \) \( r\text{-broadcasts} \) a \( \text{final-vote}_i(v) \) message (In 16-17). Otherwise, \( p_i \) \( r\text{-broadcasts} \) \( \text{final-vote}_i(*) \), where * is a distinguished symbol that is neither 0 nor 1 (In 18).

A correct \( p_i \) accepts a \( \text{final-vote}_i(v) \) message, if one of the following two conditions holds (In 23):

- For a \( \text{final-vote}_i(v) \) message with \( v \in \{0, 1\} \), \( v \) has been added to \( bset_r \) for \( p_i \).
- For a \( \text{final-vote}_i(*) \) message, \( bset_r \) contains both 0 and 1.

Upon \( r\text{-deliver} \) \( n - f \) valid \( \text{final-vote}_i(v) \) messages, we distinguish three cases:

- **Ln 20-21**: If \( p_i \) \( r\text{-delivers} \) \( n - f \) valid \( \text{final-vote}_i(v) \) for the
same \( v \in \{0, 1\} \), \( p_i \) decides \( v \) and uses \( v \) as \( iv_{r+1} \) to enter the next round. Each correct replica that decides in round \( r \) continues for one more round (up to the final-vote(\( v \)) step) and terminates the protocol.

- Ln 22-23: If \( p_i \) r-delivers at least \( f + 1 \) valid final-vote(\( v \)) for some \( v \in \{0, 1\} \), \( p_i \) uses \( v \) as input for the next round.
- Ln 24-26: Otherwise, a replica generates a local random coin and uses it as input for the next round.

**Intuition and discussion.**

Our motivation for Cubic-ABA is to reduce the number of parallel RBCs in Bracha’s ABA. We recall Bracha’s ABA in Appendix A. In each round, Bracha’s ABA has three phases, where in each phase, replicas run \( n \) parallel RBCs, with 12 steps and \( O(n^3) \) messages.

In our approach, the first two phases of Cubic-ABA resemble those of common coin based ABA protocols [26, 53, 56, 57, 64], where we ask replicas to broadcast their values. In particular, the first phase ensures that all correct replicas eventually acknowledge the same set of values \( bset_i \); the second phase ensures that no two correct replicas will vote for opposite values in the third phase, though one correct replica may vote for \( b \in \{0, 1\} \) and one may vote for \( * \) (a distinguished vote). Accordingly, we do not have to rely on RBC for the first two phases, as our first two phases already guarantee that correct replicas will not vote for conflicting values for the third phase.

**4.2 Quadratic-ABA**

In Quadratic-ABA, we replace the only parallel RBC phase used in Cubic-ABA using a novel two-step all-to-all broadcast. The goal is to ensure that at the end of each round, if a correct replica receives \( n - f \) matching votes for a value \( v \), any correct replica will receive either \( n - f \) votes for \( v \) or at least \( f + 1 \) matching \( v \). This will guarantee that all correct replicas will vote for \( v \) in the following round.

The pseudocode of Quadratic-ABA is shown in Figure 3. The Quadratic-ABA protocol is round-based, starting from round 0. In each round, there are four phases—pre-vote(\( v \)), main-vote, and final-vote(\( v \)) phases (ln 07-14) are similar to the pre-vote(\( v \)) and main-vote(\( v \)) phases in Cubic-ABA. In the first phase, every replica \( p_i \) broadcasts a pre-vote(\( iv_r \)) message, where \( iv_r \) is the value \( p_i \) votes for in round \( r \) (ln 07). After receiving \( f + 1 \) pre-vote(\( v \)) and \( p_i \) has not previously broadcast pre-vote(\( v \)), \( p_i \) also broadcasts pre-vote(\( v \)) (ln 08-09). At ln 10-11, upon receiving \( n - f \) pre-vote(\( v \)), \( p_i \) adds \( v \) to \( bset_i \). For the first value \( v \) added to \( bset_i \), \( p_i \) broadcasts a main-vote(\( v \)) message (ln 12-14).

For each vote(\( v \)) message, \( p_i \) accepts it only if \( v \) has been added to \( bset_i \). Upon receiving \( n - f \) vote(\( v \)) messages, one of the following two conditions holds.

- Ln 16-17: If \( p_i \) receives \( n - f \) vote(\( v \)) messages, it broadcasts a main-vote(\( v \)) message.
- Ln 18: Otherwise, \( p_i \) broadcasts a main-vote(\( * \)) message. Every correct replica \( p_i \) accepts a main-vote(\( v \)) message only if \( p_i \) has received \( f + 1 \) vote(\( v \)) messages. Every correct replica accepts a main-vote(\( v \)) message only if

07 broadcast pre-vote\(_{r} \) (\( iv_{r} \)) \hspace{1cm} \text{\( \triangleright \) phase 1}
08 upon receiving pre-vote\(_{r} \) (\( v \)) from \( f + 1 \) replicas
09 if pre-vote\(_{r} \) (\( v \)) has not been sent, broadcast pre-vote\(_{r} \) (\( v \))
10 upon receiving pre-vote\(_{r} \) (\( v \)) from \( 2f + 1 \) replicas \hspace{1cm} \text{\( \triangleright \) phase 2}
11 \( bset_{r} \leftarrow bset_{r} \cup \{ v \} \)
12 wait until \( bset_{r} \neq 0 \)
13 if vote\(_{r} \) has not been sent
14 broadcast main-vote\(_{r} \) (\( v \)) where \( v \in bset_{r} \)
15 upon receiving \( n - f \) vote\(_{r} \) (\( v \)) such that for each vote\(_{r} \) (\( v \)), \( v \in bset_{r} \)
16 if there are \( n - f \) vote\(_{r} \) (\( v \))
17 broadcast main-vote\(_{r} \) (\( v \))
18 else broadcast main-vote\(_{r} \) (\( * \))
19 upon receiving \( n - f \) main-vote\(_{r} \) (\( v \)) such that for each main-vote\(_{r} \) (\( v \)), at least \( f + 1 \) vote\(_{r} \) (\( v \)) have been received and for each main-vote\(_{r} \) (\( * \)), \( bset_{r} = \{ 0, 1 \} \) \hspace{1cm} \text{\( \triangleright \) phase 3}
20 if there are \( n - f \) main-vote\(_{r} \) (\( v \))
21 broadcast final-vote\(_{r} \) (\( v \))
22 else broadcast final-vote\(_{r} \) (\( * \))
23 upon receiving \( n - f \) final-vote\(_{r} \) (\( v \)) such that for each final-vote\(_{r} \) (\( v \)), at least \( f + 1 \) main-vote\(_{r} \) (\( v \)) have been received and for each final-vote\(_{r} \) (\( * \)), \( bset_{r} = \{ 0, 1 \} \)
24 if there are \( n - f \) final-vote\(_{r} \) (\( v \))
25 \( iv_{r+1} \leftarrow v \), decide \( v \)
26 else if there are only final-vote\(_{r} \) (\( v \)) and final-vote\(_{r} \) (\( * \))
27 \( iv_{r+1} \leftarrow v \)
28 else
29 \( c \leftarrow \text{Random()} \) \hspace{1cm} \text{obtain local coin}
30 \( iv_{r+1} \leftarrow c \)
31 \( r \leftarrow r + 1 \)

Figure 3: The Quadratic-ABA protocol. The code for \( p_{i} \).

\( bset_{r} = \{ 0, 1 \} \). Upon receiving \( n - f \) main-vote\(_{r} \) (\( v \)) messages, one of the following two conditions holds.

- Ln 20-21: If \( p_{i} \) receives \( n - f \) main-vote\(_{r} \) (\( v \)) messages, it broadcasts a final-vote\(_{r} \) (\( v \)) message.
- Ln 22: Otherwise, \( p_{i} \) broadcasts final-vote\(_{r} \) (\( * \)) message.

Every correct replica accepts a final-vote\(_{r} \) (\( v \)) message only if it has received \( f + 1 \) main-vote\(_{r} \) (\( v \)) messages. Every correct replica accepts a final-vote\(_{r} \) (\( * \)) message only if \( bset_{r} = \{ 0, 1 \} \).

Upon receiving \( n - f \) final-vote\(_{r} \) (\( v \)) messages, there are three cases:

- Ln 24-25: If \( p_{i} \) receives \( n - f \) final-vote\(_{r} \) (\( v \)), it decides \( v \) and also sets \( iv_{r+1} \) as \( v \). It participates in the protocol for one more round and terminates the protocol.
- Ln 26-27: If \( p_{i} \) receives \( n - f \) final-vote\(_{r} \) (\( v \)) messages that carry only value \( v \) and \( * \), it uses \( v \) for round \( r + 1 \).
- Ln 28-30: Otherwise, \( p_{i} \) generates a local random coin and uses it as input for the next round.

\[ \text{Figure 4: The workflow of Quadratic-ABA.} \]

**Intuition and discussion.** The pre-vote\(_{r} \) (\( v \)) phase and vote\(_{r} \) (\( v \)) phase are similar to the pre-vote\(_{r} \) (\( v \)) phase and the main-vote\(_{r} \) (\( v \)) phase in Cubic-ABA. In Quadratic-ABA, we use the main-vote\(_{r} \) (\( v \)) phase and the final-vote\(_{r} \) (\( v \)) phase to replace the parallel RBC phase of Cubic-ABA. Hence, Quadratic-ABA achieves \( O(n^2) \) messages and \( O(n^2) \) communication.

Our goal is to guarantee that if a correct replica receives \( n - f \) final-vote\(_{r} \) (\( v \)), any correct replica will set \( iv_{r+1} \) as \( v \). First, if a correct replica sends main-vote\(_{r} \) (\( v \)), no correct replica will send main-vote\(_{r} \) (\( \bar{v} \)) (which we prove in Lemma 13 in Appendix E). In particular, if a correct replica sends main-vote\(_{r} \) (\( v \)), at least \( n - f \) replicas have sent vote\(_{r} \) (\( v \)). Therefore, at least one correct replica has sent both vote\(_{r} \) (\( v \)) and vote\(_{r} \) (\( \bar{v} \)), contradicting the fact that each correct replica only sends a single vote\(_{r} \) message in each round. Furthermore, if a correct replica sends final-vote\(_{r} \) (\( v \)), no correct replica will send final-vote\(_{r} \) (\( \bar{v} \)) or even accept final-vote\(_{r} \) (\( \bar{v} \)) from other replicas (Lemma 14 and Lemma 19). This is because if a correct replica accepts final-vote\(_{r} \) (\( \bar{v} \)), at least one correct replica has sent main-vote\(_{r} \) (\( \bar{v} \)). Meanwhile, if a correct replica accepts final-vote\(_{r} \) (\( v \)), at least one correct replica has sent main-vote\(_{r} \) (\( v \)), contradicting Lemma 13. Hence, at the end of each round, if a correct replica receives only final-vote\(_{r} \) (\( v_{1} \)) and final-vote\(_{r} \) (\( * \)), another correct replica receives only final-vote\(_{r} \) (\( v_{2} \)) and final-vote\(_{r} \) (\( * \)), it holds that \( v_{1} = v_{2} \). This result is crucial for agreement and termination.

Furthermore, if a correct replica decides \( v \) in round \( r \), it must have received \( n - f \) final-vote\(_{r} \) (\( v \)). Among them, at least \( f + 1 \) correct replicas have sent final-vote\(_{r} \) (\( v \)). With \( 3f + 1 \) replicas in total, there are at most \( 2f \) final-vote\(_{r} \) (\( \bar{v} \)) or final-vote\(_{r} \) (\( * \)). Hence, every correct replica receives at least one final-vote\(_{r} \) (\( v \)). As no correct replica will accept final-vote\(_{r} \) (\( \bar{v} \)), every correct replica will only have final-vote\(_{r} \) (\( v \)) and final-vote\(_{r} \) (\( * \)). Thus, every correct replica either decides in round \( r \) or enters round \( r + 1 \) and sets \( iv_{r+1} \) to \( v \). Doing so ensures agreement.

### 4.3 CC-ABA

Both Cubic-ABA and Quadratic-ABA can be transformed to ABA from weak common coins [21, 57] and perfect common coins. Here by weak common coins, we mean that all correct replicas output 0 with probability \( 1/d \) and output 1.
with probability $1/d$ where $d$ is a constant and $d \geq 2$, and the probability that correct replicas obtain different values is $(d - 2)/d$. By perfect common coins, we mean that all correct replicas always output the same random coin. Note perfect coins are a special case of weak coins (by setting $d = 2$).

As Quadratic-ABA is more efficient, we here focus on Quadratic-ABA. Our main result is that by replacing local coins of Quadratic-ABA with weak (or perfect) common coins, we immediately obtain CC-ABA terminating in $O(1)$ time. CC-ABA reduces the expected number of steps of prior constructions, as shown in Table 4 and Table 5. Note that ABA is the major bottleneck in asynchronous BFT protocols and has practical implications, as the recent work of PACE has shown that even a single step improvement can lead to a drastic performance improvement (for instance, easily 2x) in BFT protocols [64].

5 RABA from Local Coins

As shown in PACE [64], the PACE framework with RABA significantly outperforms the conventional BKR diagram and enables a fast path for termination. Our goal here is to use local coin based ABA to design RABA without trusted setup. We use Cubic-ABA and Quadratic-ABA to build Cubic-RABA and Quadratic-RABA, respectively. Here, we focus on Quadratic-RABA and present Cubic-RABA in Appendix B.

5.1 The Subtlety of Building Quadratic-RABA

PACE introduced a general approach to converting ABA to RABA [64]. Following their approach, we present Quadratic-RABA in Figure 5. Quadratic-RABA is identical to Quadratic-ABA except for the first round (round 0), where we make the following changes. First, we use a propose() event and a repropose() event (In 03-07). Upon propose($v$), a replica $p_i$ starts round 0 and executes the broadcast-vote($v$) function. Upon repropose($1$) event, regardless of which round a replica is in, $p_i$ still executes the broadcast-vote($v$) function. The propose() and repropose() events are crucial for biased termination. So if a quorum of correct replicas either propose 1 or repropose 1, the protocol will eventually terminate.

Second, in the broadcast-vote($v$) function, replica $p_i$ broadcasts a pre-vote$_0(v)$ message (In 09). At ln 10-14, if $v = 1$, $p_i$ immediately adds 1 to $bset_0$ and broadcasts vote$_0(1)$, main-vote$_0(1)$, and final-vote$_0(1)$.

Third, the coin value in round 0 is set to 1 (In 38). The second and the third modifications guarantee both biased validity property and a fast path of terminating in only one step. Namely, if $f + 1$ correct replicas propose 1, no correct replica will receive $2f + 1$ final-vote$_0(0)$. As we will show in the proof, every correct replica will either directly decide 1 or set $iv_r$ as 1, so all correct replicas decide within two rounds. Furthermore, our protocol has a fast path: if all correct replicas propose 1, they will directly send vote$_0(1)$, main-vote$_0(1)$, final-vote$_0(1)$, allowing correct replicas to decide in one step.

The above modifications largely follow the generic transformation. We find that these modifications are sufficient for a secure Cubic-ABA, just as all known ABA protocols that can be transformed into their secure RABA counterparts (as shown in [64]). Surprisingly and unexpectedly, we find that for Quadratic-ABA, however, there is still a subtle liveness issue for round 0. We illustrate the issue via an example. Suppose $f$ correct replicas propose 1 and $f + 1$ correct replicas propose 0. The $f$ replicas directly broadcast vote$_0(1)$,

01 upon selecting \( m_i \) for \( p_i \) using the technique of EPIC
02 \( \text{r-broadcast}([\{e,j\},m_i]) \) for RBC
03 upon \( r\text{-deliver}([\{e,j\},m_j]) \) for RBC
04 if RABA \( j \) has not been started
05 \( \text{propose}([\{e,j\},1]) \) for RABA
06 else
07 \( \text{repropose}([\{e,j\},1]) \) for RABA
08 upon delivery of \( n-f \) RBC instances
09 for RABA instances that have not been started
10 \( \text{propose}([e,j],0) \)
11 upon \( \text{decide}([e,j],v) \) for any value \( v \) for all RABA instances
12 let \( S \) be set of indexes for RABA instances that decide 1
13 \( \text{wait until} \text{r-deliver}([e,j,m_j]) \) for all RABA where \( j \in S \)
14 \( \text{a-deliver}([\cup_{j \in S} m_j]) \)

Figure 6: The WaterBear family. The code for replica \( p_i \) in epoch \( e \). WaterBear uses the technique of EPIC to select transactions.

main-vote\(_e\)(1), and final-vote\(_e\)(1). Even if the \( f + 1 \) correct replicas that proposed 0 may later repropose 1, they may have already sent vote\(_e\)(0), main-vote\(_e\)(0), and final-vote\(_e\)(0). In this case, no correct replica will accept final-vote\(_e\)(1) as they do not receive \( f + 1 \) main-vote\(_e\)(1). In summary, the issue is, in essence, caused by the fact that each correct replica accepts a main-vote\(_e\)(v) message only if it has previously received \( f + 1 \) vote\(_e\)(v), and each correct replica accepts a final-vote\(_e\)(v) message only if it has previously received \( f + 1 \) main-vote\(_e\)(v).

To resolve the above issue, we introduce another change to round 0 of the protocol. In particular, we relax the conditions for round 0: for each main-vote\(_e\)(v) (In 28) and final-vote\(_e\)(v) (ln 32), a correct replica accepts it as long as \( v \in bse\(_e\) \). With this modification, the set of \( f + 1 \) correct replicas that proposed 0 will repropose 1, so every correct replica will eventually put 1 in pre-vote(0). Hence, every correct replica will eventually accept main-vote\(_e\)(0) and final-vote\(_e\)(0).

Our result underlines the subtlety of constructing RABA from ABA and the importance of a full proof for a new protocol (proof in Appendix H).

## 6 The WaterBear Family

This section describes our asynchronous BFT protocols—WaterBear (WaterBear-C and WaterBear-Q), and WaterBear-QS (WaterBear-QS-C, and WaterBear-QS-Q). All the protocols are quantum secure, and WaterBear-C and WaterBear-Q are additionally information-theoretically secure.

### 6.1 The WaterBear Protocols

WaterBear follows the PACE paradigm but uses the trick in EPIC [50] to avoid the usage of threshold encryption (needed for achieving adaptive security). In particular, WaterBear uses \textit{r-broadcast} and \textit{r-deliver} primitives of Bracha’s broadcast, and \textit{propose}, \textit{repropose} and \textit{decide} primitives of WaterBear RABA. Figure 6 depicts the pseudocode of WaterBear. In terms of transaction selection strategy, we follow EPIC and ask replicas to select random transactions \textit{in plaintext} for most epochs and periodically switch to the FIFO selection, where replicas maintain a log of transactions according to the order transactions are received and replicas select the first group of transactions in the buffer as input. As shown in EPIC, the approach shares similar performance to the random selection approach used in HoneyBadger and BEAT. Following the PACE paradigm, for each epoch \( e \), WaterBear consists of \( n \) parallel RBC instances and \( n \) parallel RABA instances.

In the RBC phase, each replica \( p_i \) \textit{r-broadcasts} a proposal \( m_i \) for RBC. If \( p_i \) \textit{r-delivers} a proposal from RBC, it proposes 1 for RABA. Upon delivery of \( n-f \) RBC instances, instead of waiting for \( n-f \) RABA instances to terminate, \( p_i \) proposes 0 for all RABA instances that have not been started. If \( p_i \) later delivers a proposal from some RBC, it has proposed 0 for RABA, and has not terminated RABA, it reproposes 1 for RABA. We let \( S \) be the set of indexes where RABA \( j \) decides 1. When all RABA instances terminate and all RBC \( (i \in S) \) instances are delivered, \( p_i \) \textit{a-delivers} \( \cup_{j \in S} m_j \). The security of WaterBear directly follows from that of the PACE paradigm. As we propose two RABA protocols Cubic-RABA and Quadratic-RABA. We use Cubic-RABA to build WaterBear-C and Quadratic-RABA to build WaterBear-Q.

### 6.2 The WaterBear-QS Protocols

We now describe WaterBear-QS, also consisting of two asynchronous BFT protocols. We use Cubic-RABA to build WaterBear-QS-C and Quadratic-RABA to build WaterBear-QS-Q. WaterBear-QS does not achieve information-theoretic security but achieves quantum security for both safety and liveness properties. Prior to our work, no such BFT protocol had been implemented. The difference between WaterBear and WaterBear-QS is that WaterBear-QS leverages CT RBC [18] to reduce the communication complexity of RBC. Jumping ahead, we show the modification leads to a dramatic performance improvement compared to WaterBear protocols.

## 7 Implementation and Evaluation

### Implementation

We implemented WaterBear-C, WaterBear-Q, WaterBear-QS-C, and WaterBear-QS-Q in a new Golang library. For comparison, we choose to implement BEAT in our library. BEAT [1, 35] was originally implemented in Python 2.7 using MMR ABA [56]. We implemented a new version of BEAT, replacing MMR ABA with Cobalt-ABA, as Cobalt ABA addressed the liveness issue of MMR. Our implementation involves more than 11,000 LOC for the protocol implementations and about 1,000 LOC for evaluation.

All the protocols use authenticated channels, and WaterBear-QS additionally uses hash functions. We use HMAC to realize the authenticated channel. HMAC is quantum secure but not IT secure; we used HMAC in our reference implementation for WaterBear to demonstrate the overhead of WaterBear itself, because all other protocols introduced
we demonstrate the performance difference between BEAT protocols, but we aim at refuting the conventional wisdom that asynchronous BFT protocols cannot match the security guarantees of partially synchronous protocols while preserving performance.

Overview of evaluation. We evaluate the performance of our protocols on Amazon EC2 utilizing up to 61 virtual machines (VMs) from different regions in five continents. We use both r2.medium and m5.xlarge instances for our evaluation. The r2.medium type has two virtual CPUs and 4GB memory and the m5.xlarge has four virtual CPUs and 16GB memory. Unless otherwise mentioned, we use m5.xlarge instances by default. We deploy our protocols in both LAN and WAN settings. In the LAN setting, the replicas are run in the same region of EC2 (e.g., US Virginia), but these replicas may be located in different physical datacenters. In the WAN setting, the replicas are evenly distributed across different continents.

We conduct the experiments under different network sizes and contention levels (batch size). We use $f$ to denote the network size; in each experiment, we use 3$f+1$ replicas in total. We let $b$ denote the contention level; in particular, each replica proposes $b$ transactions in each epoch. For each experiment, we vary the batch size $b$ from 1 to 25,000. For each experiment, we report the average performance (for both throughput and latency). We use two different transaction sizes. We evaluate the performance for transactions with 100 bytes by default and also evaluate it with 250 bytes.

We assess the performance of the protocols under failure-free and failure scenarios. While our failure-case evaluation is not the first such evaluation for asynchronous BFT protocols, the testbed we built aims to be comprehensive, encompassing realistic failure and attack scenarios we can envision. We roughly summarize our main results in the following:

- The WaterBear protocols using Quadratic-RABA (WaterBear-QS-Q and WaterBear-Q) are much more efficient than the protocols using Cubic-RABA (WaterBear-QS-C and WaterBear-C), as Quadratic-RABA has $O(n^2)$ messages and much fewer steps than Cubic-RABA (with $O(n^3)$ messages). The result justifies the importance of designing Quadratic-RABA and Quadratic-ABA.

- The quantum secure WaterBear protocols (WaterBear-QS-C and WaterBear-QS-Q) drastically outperform their IT counterparts (WaterBear-C and WaterBear-Q), as the RBC used for WaterBear-QS-C and WaterBear-QS-Q is more bandwidth-efficient than that for WaterBear-C and WaterBear-Q. The finding highlights the cost of achieving IT security from quantum security for our protocols.

- Regarding latency, all WaterBear protocols have lower latency (under no contention) than BEAT. Regarding throughput, all our protocols, except WaterBear-QS-Q (our most efficient protocol), share similar performance as BEAT.

- WaterBear-QS-Q consistently and significantly outpaces BEAT. For instance, when $n = 16$, WaterBear-QS-Q has
about 1/8 the latency that of BEAT and 1.23x the throughput of BEAT. As \( n \) grows larger, the peak throughput of WaterBear-QS-Q is about 1.47x that of BEAT. The peak throughput of WaterBear-QS-Q (as \( n \) grows larger) is about 1.47x that of BEAT.

- All four protocols we propose are highly robust against various crash and Byzantine failures, just as BEAT.

### 7.1 Performance in Failure-Free Cases

**Latency.** We report the latency of the protocols in both LAN and WAN settings for \( f = 1, 2, \) and 5 in Figure 7 with for \( b = 1 \) and 100. All WaterBear protocols consistently achieve lower latency than BEAT in both LAN and WAN environments, mainly because our protocols have a coin-free fast path. Among the protocols, WaterBear-QS-Q has consistently lower latency than all other protocols, as WaterBear-QS-Q has the lowest communication complexity among the WaterBear protocols. As \( f \) increases, the latency difference between WaterBear-QS-Q and other protocols becomes more visible. For instance, when \( f = 5 \) in the WAN setting, BEAT achieves 3.47x latency of that for WaterBear-QS-Q; in the LAN setting, the latency for BEAT is 8.78x of that for WaterBear-QS-Q.

**Throughput and scalability.** We report throughput and throughput vs. latency in Figure 8 by varying the network size \( f \) from 1 to 20.

First, we find that the throughput of WaterBear-C and WaterBear-Q are consistently lower than the other protocols. As WaterBear-C (resp. WaterBear-Q) and WaterBear-QS-C (resp. WaterBear-QS-Q) differ in RBC only, RBC is clearly one performance bottleneck. The result highlights the cost of achieving IT security.

We assess the throughput of all five protocols for \( f = 1 \) in WAN as depicted in Figure 8b: the peak throughput of WaterBear-QS-Q is slightly higher in most experiments. We also conduct a separate experiment in LANs, as shown in Figure 8a. Unlike the results in WANs, the throughput of BEAT in LANs is marginally higher than WaterBear-QS-C, and the throughput of WaterBear-QS-Q is marginally higher than BEAT: the peak throughput of BEAT is 2.3% higher than WaterBear-QS-C, and the peak throughput of WaterBear-QS-Q is 3.9% higher than BEAT. The peak throughput of WaterBear-QS-C is 65.7 ktx/sec in LANs and 37.8 ktx/sec in WANs, and the peak throughput of WaterBear-QS-Q is 69.9 ktx/sec in LANs and 38.4 ktx/sec in WANs.

When \( f \) increases, in general, WaterBear-QS-Q and WaterBear-QS-C outpace all the other protocols. The peak throughput of WaterBear-QS-C is higher than BEAT when \( f = 5 \) and \( f = 10 \) but lower when \( f = 20 \) only. Meanwhile, WaterBear-QS-Q is consistently more efficient than all other protocols (higher throughput and lower latency). For instance, when \( f = 10 \), the peak throughput of WaterBear-QS-Q is 47.4% higher than BEAT. The reason why WaterBear-QS-Q is more efficient than WaterBear-QS-C is that WaterBear-QS-Q uses a more communication-efficient RABA protocol.

### Additional evaluation results

We show in Appendix Sec. C additional evaluation results, including performance on different types of VMs, performance with different transaction sizes, and memory and CPU usage for the protocols implemented.

### 7.2 Performance under Failures

To assess the protocol performance under failures and attacks, we carefully design various experiments as follows.

- **\( S_0 \): (failure-free)** In this scenario, all replicas are correct. \( S_0 \) is the baseline scenario used to compare with failure scenarios.

- **\( S_1 \): (crash)** In this scenario, we let \( f \) replicas crash by not participating in the protocols.

- **\( S_2 \): (Byzantine; keep voting 0)** In this scenario, we control all \( f \) faulty replicas to keep voting for 0 in each step of (R)ABA. For all the five protocols, doing so would intuitively make fewer ABA and RABA instances decide 1 and would likely decrease the throughput of the protocols. We aim to observe the throughput reduction in this scenario compared to the failure-free scenario.

- **\( S_3 \): (Byzantine; flipping the (R)ABA input)** In this scenario, we let \( f \) replicas exhibit Byzantine behavior in the (R)ABA phase. The strategy is to vote for a flipped value in (R)ABA. In other words, in each (R)ABA step, each Byzantine replica inputs \( b \) when it should have input \( b \). Doing so could potentially force each (R)ABA instance to experience more steps to terminate for all five protocols. For WaterBear and WaterBear-QS, the strategy would, at first glance, likely be more fruitful. For both protocols, a RABA instance may terminate in round 0, thanks to the biased validity property of RABA. The flipping strategy illustrated above may make them not decide in round 0 and force them to enter the second round of RABA, where the two protocols start to query the local coins.

We assess the performance of the five protocols implemented under failures for \( f = 1 \) (Figure 9a), \( f = 2 \) (Figure 9b), and \( f = 5 \) (Figure 9c).

**Performance under crash failures (\( S_1 \)).** The throughput of all the five protocols implemented under crash failures is higher than that in the failure-free case, except for \( f = 1 \), where all protocols share similar performance between the two scenarios. Our result echoes those of previous works. The reason is that under crash failures, the network bandwidth consumption is much lower (about 33% lower) than in the failure-free case. Note that when \( f = 1 \), the network bandwidth consumption is not as dominating as in other cases; hence, the performance difference among the protocols for \( f = 1 \) is less visible.

**Performance under Byzantine failures (\( S_2 \) and \( S_3 \)).** The performance of all the protocols under Byzantine failures is slightly lower than that in the failure-free scenario and the crash failure scenario. WaterBear-QS-C and WaterBear-QS-Q suffer from slightly higher performance degradation under
Byzantine failures compared to BEAT. The higher performance degradation is due to the use of local coins. As replicas start to use local coins in round \( r > 0 \), the RABA protocol may decide in more rounds. In all cases, WaterBear-QS-C and WaterBear-QS-Q remain more efficient than BEAT.

The difference between \( S_2 \) and \( S_3 \) is that faulty replicas broadcast 0 in \( S_2 \) but broadcast the flipped value in \( S_3 \). For BEAT, the performance in \( S_3 \) is higher for \( f = 1 \) and \( f = 5 \) but lower for \( f = 2 \); the difference in all the cases is not significant though. In contrast, for WaterBear-QS-C and WaterBear-QS-Q, the performance in \( S_3 \) is consistently lower than \( S_2 \), showing that the flipping strategy in \( S_3 \) works slightly better than that in \( S_2 \).

8 Conclusion

This paper designs and implements a family of practical asynchronous BFT protocols matching the security guarantees of their partially synchronous counterparts. Our experiments demonstrate that our protocols are efficient in both failure and failure-free scenarios. In particular, one of our protocols, WaterBear-QC-Q, consistently outperforms the state-of-the-art asynchronous protocols with much weaker security guarantees. We also build in different settings more efficient ABA and RABA protocols that can be used to improve various high-level Byzantine-resilient protocols. Our work, for the first time, shows that the strongest security models and high performance can co-exist for asynchronous BFT.

[34] Sisi Duan, Michael K Reiter, and Haibin Zhang. Secure causal atomic broadcast, revisited. In *DSN*.

We present Bracha’s ABA [13]. The pseudocode is shown in Figure 10. Bracha’s ABA has three phases. In each phase, each replica broadcasts its value via a RBC instance, i.e., there are parallel RBC instances in each of the three phases. As the underlying RBC has \( O(n^2) \) messages and 4 steps, Bracha’s ABA has \( O(n^3) \) messages and 12 steps in each round.

In Bracha’s ABA, every replica maintains a set \( vset \) containing valid values. In each phase, every replica only accepts messages that carry valid values. The valid values \( vset \) must be congruent with the values each replica receives from the previous phase (or the last phase of the previous round). In the first phase of round 0, both 0 and 1 are considered valid. In the second and third phases, a value is added to \( vset \) only if the replica receives the value from enough replicas.

In the first phase, every replica \( p_i \) r-broadcasts a \( \text{pre-vote}_{r}(iv_r) \) message (ln 08), where \( iv_r \) is the input value of \( p_i \) for round \( r \).

In the second phase, \( p_i \) waits for \( n - f \) \( \text{pre-vote}_r() \) messages such that for each \( \text{pre-vote}_r(v), v \in vset \). There are two cases:

- Ln 10-13: If \( p_i \) has received \( n - f \) \( \text{pre-vote}_r(v) \) for some \( v \in \{0, 1\}, p_i \) decides \( v \) and sets both \( vset \) and \( iv_{r + 1} \) as \( v \). Replica \( p_i \) continues for one more round and terminates the protocol (up to either ln 10 or ln 25 before \( p_i \) decides some value again).

- Ln 14-15: Otherwise, \( p_i \) sets \( v \) as the majority value in the set of \( \text{pre-vote}_r() \) messages it receives. The set \( vset \) is not changed, i.e., \( vset = \{0, 1\} \).

In both cases, \( p_i \) r-broadcasts a \( \text{main-vote}_r(v) \) message (ln 16).

In the third phase, every replica \( p_i \) waits for \( n - f \) valid \( \text{main-vote}_r() \) messages (ln 17). There are two cases:

- Ln 18-19: If \( p_i \) receives at least \( n/2 \) \( \text{main-vote}_r(v) \), it sets \( vset \) as \( \{v\} \).

- Ln 20-22: Otherwise, \( p_i \) sets \( v \) as \( * \) and \( vset \) as \( \{0, 1\} \).

In both cases, \( p_i \) r-broadcasts a \( \text{final-vote}_r(v) \) message (ln 23). Then every replica waits for \( n - f \) valid \( \text{final-vote}_r() \)
messages (In 24). Note that final-vote$_r(*)$ is considered valid only if vset = \{0, 1\}. There are three cases:

- **ln 25-28:** If $p_i$ receives at least $2f + 1$ final-vote$_r(v)$, it decides $v$ and sets iv$_{r+1}$ as $v$. Replica $p_i$ continues for one more round (up to either ln 10 or ln 25) and terminates the protocol.

- **ln 29-31:** If $p_i$ receives at least $f + 1$ final-vote$_r(v)$, it sets iv$_{r+1}$ as $v$ and vset as \{v\}.

- **ln 32-35:** Otherwise, $p_i$ uses the local coin value as iv$_{r+1}$ and vset as \{0, 1\}, i.e., $p_i$ accepts both 0 and 1 in the first phase of the following round.

**B Cubic-RABA**

The pseudocode of Cubic-RABA protocol is shown in Figure 11. Cubic-RABA is identical to Cubic-ABA, except for round 0 (the first round). We have made the following changes for round 0. First, both propose() and repropose() events are allowed. Upon the propose(v) event (In 03), a replica $p_i$ executes the broadcast-vote(v) function and starts round 0. Upon the repropose(v) function (In 06), $p_i$ executes broadcast-vote(v). Note that upon a repropose() event, $p_i$ must have already started the protocol and may even proceed to a round greater than 0. In this case, regardless of which round the replica is in, it executes the broadcast-vote(v) function and broadcasts a pre-vote$_0(v)$ message.

Second, in the broadcast-vote(v) function (In 08-13), $p_i$ broadcasts a pre-vote$_0(v)$ message. If $v = 1$, $p_i$ adds 1 to bset$_0$ (In 11). If $p_i$ has not previously broadcast main-vote$_0()$, it broadcasts main-vote$_0(1)$ (In 12). If $p_i$ has not r-broadcast final-vote$_0()$, it r-broadcasts final-vote$_0(1)$ (In 13). Furthermore, in round 0, if $p_i$ receives $f + 1$ pre-vote$_0(1)$ messages and has not broadcast main-vote$_0()$ or final-vote$_0()$ (In 18), it also broadcasts main-vote$_0(1)$ (In 20-21) and r-broadcasts final-vote$_0(1)$ (In 22-23).

Finally, the coin value for round 0 is set to 1 (In 39). In round $r \geq 1$, Cubic-RABA is identical to Cubic-ABA.

**Analysis.** The proof of Cubic-RABA is shown in Appendix G. We show that the changes we have made on top of Cubic-ABA can transform Cubic-ABA into a RABA protocol. In particular, it guarantees that if a quorum of correct replicas either directly propose 1 or propose 0 and later on repropose 1, the protocol will terminate. The second and third changes ensure the biased validity property. If $f + 1$ correct replicas propose 1, they will directly add 1 to bset$_0$, broadcast pre-vote$_0(1)$, main-vote$_0(1)$, and r-broadcast final-vote$_0(1)$. Namely, no correct replica can receive $n - f$ main-vote$_0(0)$ or r-broadcast final-vote$_0(0)$. Furthermore, no correct replica can receive $n - f$ final-vote$_0(0)$ or $f + 1$ final-vote$_0(0)$. Furthermore, for the case where a correct replica uses the local coin to enter the next round, the coin value is also 1. Accordingly, Cubic-RABA achieves biased validity. Other properties of Cubic-RABA follow from Cubic-ABA, as we only modify round 0 of the protocol.

**C Additional Evaluation Results**

**Performance on different types of VMs.** Different from prior protocols (HoneyBadger, BEAT, Dumbo, EPIC) that all evaluate the performance on t2.medium instances, we evaluate the performance of the protocols using both t2.medium (t2 in the figures) and m5.xlarge (m5 in the figures) instances. In particular, we evaluate the throughput with $b = 15,000$ for $f = 1, f = 2$, and $f = 5$, the results of which are shown in Figure 12a. For all the protocols, the peak throughput on m5.xlarge instances is about 2× that on t2.medium.
**Performance with different transaction sizes.** We also report the throughput of the protocols by fixing \( b \) to 15,000 but using different sizes of transactions (100 bytes and 250 bytes), the results of which are shown in Figure 12b. For all five protocols, the performance using transaction size of 100 bytes is consistently higher, being at least twice as efficient as that with 250 bytes. The finding highlights the main bottleneck for the protocols for large transaction sizes is RBC.

**Memory and CPU usage.** We present in Figure 13 memory and CPU usage for \( n = 16 \) and varying batch sizes. The results are obtained by using the *top* Linux monitoring tool. For the memory usage, all protocols consume higher memory when \( b \) increases. This is expected, since replicas need to process more transactions as the batch size grows. Meanwhile, WaterBear-C and WaterBear-Q consistently consume slightly higher memory than the other protocols, because the RBC for both protocols require more bandwidth. For the CPU usage, WaterBear-QS-C and WaterBear-QS-Q have lower CPU usage than other protocols, as these two protocols are PKC-free and only use symmetric key cryptography.

![Figure 12: Performance of the protocols for \( f = 1, 2, \) and 5.](image1)

![Figure 13: Memory and CPU usage.](image2)

**D Proof of Cubic-ABA**

We show that Cubic-ABA achieves validity, agreement, termination, and integrity.

**Lemma 1.** If all correct replicas propose \( iv_r = v \) in round \( r \), then any correct replica that enters round \( r + 1 \) sets \( iv_{r+1} = v \).

**Proof.** If all correct replicas propose \( v \) in round \( r \), every correct replica broadcasts \( \text{pre-vote}_r(v) \). No correct replica will forward \( \text{pre-vote}_r(v) \), as there are no more than \( f + 1 \) \( \text{pre-vote}_r(\bar{v}) \) messages. Hence, no correct replica will add \( \bar{v} \) to \( \text{bset}_r \). Furthermore, all correct replicas will eventually send \( \text{main-vote}_r(v) \) and \( r\text{-broadcast} \) \( \text{final-vote}_r(v) \). No correct replica accepts \( \text{final-vote}_r(\bar{v}) \) or \( \text{final-vote}_r(\bar{v}) \), since they only have \( v \) in their \( \text{bset}_r \). Hence, any correct replica that enters round \( r + 1 \) sets \( iv_{r+1} = v \).

Note that the lemma above holds for the case where a correct replica decides \( v \) in round \( r \).

**Lemma 2.** If all correct replicas propose \( v \) in round \( r \), then for any \( r' > r \), any correct replica that enters round \( r' \) sets \( iv_{r'} = v \).

**Proof.** The proof is by induction on the round number. The base case holds for \( r \) according to Lemma 1. For the induction step, we show that the lemma holds for round \( r' + 1 \). In other words, if all correct replicas propose \( iv_{r'} = v \) in round \( r' \), then in round \( r' + 1 \), any correct replica sets \( iv_{r'+1} = v \).

In round \( r' \), as no correct replica sends \( \text{pre-vote}_{r'}(\bar{v}) \), no correct replica can receive \( f + 1 \) \( \text{pre-vote}_{r'}(\bar{v}) \) messages. In other words, no correct replica will forward \( \text{pre-vote}_{r'}(\bar{v}) \). Meanwhile, no correct replica will accept \( \text{final-vote}_{r'}(\bar{v}) \) or \( \text{final-vote}_{r'}(\bar{v}) \) since correct replicas only have \( v \) in their \( \text{bset}_{r'} \). Furthermore, every correct replica will \( r\text{-broadcast} \).
We already know that at least with Lemma 2 since any correct replica that enters round $r$ (Agreement) Theorem 5. Theorem 3 with $r$-broadcasts $S$ $p$ final messages (let the set of replicas be $S$). Among the $S$ and fewer than $f + 1$ replicas. In other words, at least one correct replica has set $\bar{v}$ and broadcast pre-vote, ($\bar{v}$). This is a contradiction with Lemma 2 since any correct replica that enters round $r$ sets $iv_r$ as $v$. This completes the proof of the theorem.

Lemma 4. If a correct replica $p_i$ decides $v$ in round $r$, any correct replica that enters round $r + 1$ sets $iv_{r+1}$ as $v$.

Proof. If $p_i$ decides $v$ in round $r$, it $r$-delivers $n - f$ final-vote, ($v$). In other words, at least $f + 1$ correct replicas $r$-broadcast $\bar{v}$ and $r$-delivers $p_k$ final-vote, ($v$). We assume that a correct replica $p_k$ enters round $r + 1$ using value $iv_{r+1} = \bar{v}$ and prove the lemma by contradiction. If $p_k$ sets $iv_{r+1}$ as $v$, there are three conditions: A) $p_k$ $r$-delivers at least $n - f$ final-vote, ($\bar{v}$); B) $p_k$ $r$-delivers $f + 1$ final-vote, ($\bar{v}$); C) none of the conditions holds. In other words, $p_k$ has received fewer than $f + 1$ final-vote, ($v$) and fewer than $f + 1$ final-vote, ($\bar{v}$). We now show that none of the three conditions is possible.

Condition A): Replica $p_k$ $r$-delivers $n - f$ final-vote, ($\bar{v}$). We already know that at least $n - f$ replicas $r$-broadcast final-vote, ($v$). Therefore, at least one correct replica $r$-broadcast both final-vote, ($v$) and final-vote, ($\bar{v}$), a contradiction.

Condition B): Replica $p_k$ $r$-delivers $f + 1$ final-vote, ($\bar{v}$). We already know that $p_k$ $r$-delivers $n - f$ final-vote, ($v$). Therefore, at least one replica (correct or Byzantine) $r$-broadcast both final-vote, ($v$) and final-vote, ($\bar{v}$) such that $p_k$ $r$-delivers final-vote, ($\bar{v}$) and $p_r$ $r$-delivers final-vote, ($v$). This is a violation of the agreement property or RBC.

Condition C): Replica $p_k$ $r$-delivers $n - f$ final-vote, ($v$) messages (let the set of replicas be $S_1$). Among the messages from $S_1$, fewer than $f + 1$ are final-vote, ($\bar{v}$) and fewer than $f + 1$ are final-vote, ($v$). Other messages can only be final-vote, ($\star$). We already know that $p_k$ $r$-delivers $n - f$ final-vote, ($v$) (let the set of replicas be $S_2$). $S_1$ and $S_2$ have at least $n - 2f + 1$ replicas in common. Therefore, at least one replica $r$-broadcasts both $v$ and $\star$ (or $\bar{v}$) such that $p_k$ $r$-delivers final-vote, ($v$) and $p_k$ has $r$-delivers final-vote, ($\bar{v}$) (or final-vote, ($\bar{v}$)), a violation of agreement of property RBC.

Theorem 5 (Agreement). If a correct replica decides $v$, then any correct replica that terminates decides $v$.

Proof. We assume that a correct replica $p_i$ decides $v$ and another correct replica $p_j$ decides $\bar{v}$ and prove the theorem by contradiction. There are two cases: 1) $p_i$ and $p_j$ decide in the same round $r$; 2) $p_i$ and $p_j$ decide in different rounds.

We first prove case 1). If replica $p_i$ decides $v$ in round $r$, it $r$-delivers $n - f$ final-vote, ($v$). If $p_j$ decides $\bar{v}$, it $r$-delivers $n - f$ final-vote, ($\bar{v}$). The two sets of $n - f$ replicas have at least $f + 1$ replicas in common. Among the $f + 1$ replicas, at least one is correct. Therefore, at least one correct replica must have $r$-broadcast both final-vote, ($v$) and final-vote, ($\bar{v}$), a contradiction.

We now prove case 2) by assuming that $p_i$ decides value $v$ in round $r$ and $p_j$ decides $\bar{v}$ in round $r'$ where $r' > r$.

According to Lemma 4, any correct replica enters round $r + 1$ sets $iv_{r+1}$ as $v$. Furthermore, according to Lemma 2, for any round $r^{th}$, any correct replica sets enters round $r^{th}$ sets $iv_r$ as $v$. If replica $p_j$ decides value $\bar{v}$ in round $r'$, at least one correct replica has set $iv_r$ as $v$ and pre-vote, ($\bar{v}$), a contradiction with Lemma 2.

Lemma 5. Let $v_1 \in \{0, 1\}$ and $v_2 \in \{0, 1\}$. If a correct replica $p_i$ $r$-delivers $f + 1$ final-vote, ($v_1$) and enters round $r + 1$, another correct replica $p_j$ $r$-delivers $f + 1$ final-vote, ($v_2$) and enters round $r + 1$, then it holds that $v_1 = v_2$.

Proof. If $p_i$ $r$-delivers $f + 1$ final-vote, ($v_1$), at least one correct replica $r$-broadcasts final-vote, ($v_1$). According to the protocol, the correct replica has received $n - f$ main-vote, ($v_1$). Therefore, for any other correct replicas, among the $n - f$ main-vote, ($\star$) messages, at least one must be main-vote, ($v_1$). They either receive $n - f$ main-vote, ($v_1$) and $r$-broadcast final-vote, ($v_1$), or receive both main-vote, ($v_1$) and main-vote, ($v_1$) and $r$-broadcast final-vote, ($\star$). No correct replica will $r$-broadcast final-vote, ($\bar{v}$). For replica $p_j$, if it $r$-delivers $f + 1$ final-vote, ($v_2$), at least one correct replica $r$-broadcasts final-vote, ($v_2$). Therefore, it must hold that $v_1 = v_2$.

Theorem 7 (Termination). Every correct replica eventually decides some value.

Proof. The proof consists of two parts. First, in each round $r$, correct replicas will enter the next round. Second, the value $iv_r$ used by any correct replica cannot be manipulated by the adversary.

We first show that in round $r$, correct replicas will enter the next round. In each round, every replica sets $iv_r$ as either 0 or 1 in Cubic-ABA. Accordingly, at least $f + 1$ correct replicas have the same $iv_r = v$. Therefore, all correct replicas will eventually receive $2f + 1$ pre-vote, ($v$) for some $v$ and send main-vote, ($\star$) message. Correct replicas will have at least $v$ in their set, and $r$-broadcast either final-vote, ($v$) for some $v$ or final-vote, ($\star$). Similarly, any correct replica will eventually $r$-deliver $n - f$ final-vote, ($\star$) messages and enter the next round.

We then show that if a correct replica $p_i$ does not decide in round $r$, the value $iv_{r+1} = \bar{v}$ cannot be manipulated by a
malicious network scheduler such that correct replicas always enter the next round with inconsistent values. If \( p_i \) does not decide in round \( r \), there are two conditions: A) \( p_i \) r-delivers \( f + 1 \) final-vote,\((v)\); B) \( p_i \) r-delivers \( n - f \) final-vote,\((v)\) messages. In the final-vote,\((v)\) messages, fewer than \( f + 1 \) are final-vote,\((v)\) and fewer than \( f + 1 \) are final-vote,\((\bar{v})\). For condition B, a correct replica enters the next round with its local coin \( c \). The \( c \) value is independent with the value chosen by any correct replica. We now prove that the value \( v \) in condition A cannot be manipulated.

According to Lemma 6, if a correct replica receives \( f + 1 \) final-vote,\((v_1)\) and another correct replica receives \( f + 1 \) final-vote,\((v_2)\), then it holds that \( v_1 = v_2 \). If correct replicas use local coins to enter the next round, with a probability of \( \frac{1}{2^{n-1}} \), replicas will enter the next round with the same value. The protocol will reach a state where agreement can be reached in \( 2^{n-f} \) expected rounds. After that, it takes another round for each replica to terminate, i.e., the protocol terminates in \( 2^{n-f} + 1 \) expected rounds.

Theorem 8 (Integrity). No correct replica decides twice.

Proof. According to the protocol, after a correct replica decides some value, it participates in one more round of the protocol. However, it terminates the protocol after it r-broadcasts a final-vote,\((v)\) message. Thus, the replica does not decide again in the following round. This completes the proof of the theorem.

E Proof of Quadratic-ABA

We show that Quadratic-ABA achieves validity, agreement, termination, and integrity.

Lemma 9. If all correct replicas propose \( iv_r = v \) in round \( r \), then any correct replica that enters round \( r + 1 \) sets \( iv_{r+1} \) as \( v \).

Proof. If all correct replicas propose \( iv_r = v \) in round \( r \), every correct replica broadcasts pre-vote,\((v)\). No correct replica will receive more than \( f + 1 \) pre-vote,\((\bar{v})\) messages. Hence, no correct replica will add \( \bar{v} \) to bset,\(r \). Furthermore, all correct replicas will eventually send vote,\((v)\) and receive \( n - f \) vote,\((v)\). As no correct replica ever has \( \bar{v} \) in bset,\(r \), all correct replica will not accept vote,\((v)\). Therefore, all correct replicas will send main-vote,\((v)\). No correct replica will accept main-vote,\((\bar{v})\) or main-vote,\((\ast)\) as \( \bar{v} \notin \text{bset}, \) and it cannot receive more than \( f + 1 \) vote,\((\bar{v})\). Accordingly, every correct replica will send final-vote,\((v)\) and receive \( n - f \) final-vote,\((v)\). No correct replica accepts final-vote,\((\bar{v})\) as they only have \( v \) in their bset,\(r \). Hence, any correct replica that enters round \( r + 1 \) sets \( iv_{r+1} \) as \( v \).

Note that the lemma above holds for the case where a correct replica decides \( v \) in round \( r \).

Lemma 10. If all correct replicas propose \( iv_r = v \) in round \( r \), then for any \( r' > r \), any correct replica that enters round \( r' \) sets \( iv_{r'} \) as \( v \).

Proof. The proof is by induction on the round number. The base case holds for \( r \) according to Lemma 9. For the induction step, we show that the lemma holds for round \( r'+1 \). In other words, if all correct replicas propose \( iv_{r'} = v \) in round \( r' \), then in round \( r'+1 \), any correct replica sets \( iv_{r'+1} \) as \( v \).

In round \( r' \), as no correct replica sends pre-vote,\((v)\), no correct replica can receive \( f + 1 \) pre-vote,\((\bar{v})\) messages. In other words, no correct replica will put \( \bar{v} \) to bset,\(r \). Therefore, all correct replicas will send vote,\((v)\) and no correct replicas will receive \( f + 1 \) vote,\((v)\). Accordingly, all correct replicas will send main-vote,\((v)\) and will not accept main-vote,\((\bar{v})\). Any correct replica then only sends final-vote,\((v)\). Meanwhile, no correct replica will accept final-vote,\((v)\) or final-vote,\((\ast)\) since correct replicas only have \( v \) in their bset,\( r \) and no correct replica can receive \( f + 1 \) main-vote,\((v)\). Furthermore, every correct replica will receive \( n - f \) final-vote,\((v)\). It is now clear that any correct replica that enters round \( r'+1 \) sets \( iv_{r'+1} \) as \( v \).

Lemma 11. If a correct replica \( p_i \) sends final-vote,\((v)\), at least one correct replica has proposed \( iv_r = \bar{v} \) and broadcast pre-vote,\((\bar{v})\).

Proof. If \( p_i \) sends final-vote,\((v)\), it must have received \( n - f \) main-vote,\((\bar{v})\). Among the replicas that sent main-vote,\((\bar{v})\), at least \( f + 1 \) are correct. The correct replicas must have sent vote,\((\bar{v})\) and put \( \bar{v} \) to bset,\(r \). Each replica puts \( \bar{v} \) to bset,\(r \) only if it receives \( n - f \) pre-vote,\((\bar{v})\). Therefore, at least one correct replica has proposed \( iv_r = \bar{v} \) and broadcast pre-vote,\((\bar{v})\).

Theorem 12 (Validity). If all correct replicas propose \( v \), then any correct replica that terminates decides \( v \).

Proof. We assume that a correct replica \( p_i \) terminates and decides \( \bar{v} \) and prove the correctness by contradiction.

If \( p_i \) terminates and decides \( \bar{v} \) in round \( 0 \), it will enter round \( 1 \) with \( iv_1 = \bar{v} \). This is a contradiction with Lemma 9. If \( p_i \) terminates and decides \( \bar{v} \) in round \( r > 0 \), it receives \( n - f \) final-vote,\((\bar{v})\). Among the replicas that sent final-vote,\((\bar{v})\), at least \( f + 1 \) are correct. According to Lemma 11, at least one correct replica has broadcast pre-vote,\((\bar{v})\). This is a contradiction with Lemma 10 since any correct replica that enters round \( r \) sets \( iv_r \) as \( v \).

Lemma 13. If a correct replica \( p_i \) sends main-vote,\((v)\), any correct replica \( p_j \) only sends main-vote,\((v)\) or main-vote,\((\ast)\).

Proof. If \( p_i \) sends main-vote,\((v)\), it has received \( n - f \) vote,\((v)\). We assume that \( p_j \) sends main-vote,\((\bar{v})\) and prove the lemma by contradiction. If \( p_j \) sends main-vote,\((\bar{v})\), it has received \( n - f \) vote,\((\bar{v})\). According to the protocol, every correct replica only sends vote,\((\ast)\) message once and each replica
only sends either $\text{vote}_i(v)$ or $\text{vote}_i(\bar{v})$. Therefore, at least one correct replica has sent $\text{vote}_i(v)$ to $p_i$ and sent $\text{vote}_i(\bar{v})$ to $p_j$, a contradiction.

**Lemma 14.** If a correct replica $p_i$ sends final-vote$(v)$, any correct replica $p_j$ only sends final-vote$(v)$ or final-vote$(\bar{v})$.

**Proof.** If $p_i$ sends final-vote$(v)$, it has received $n-f$ main-vote$(v)$. We assume that $p_j$ sends final-vote$(\bar{v})$ and prove the lemma by contradiction. If $p_j$ sends final-vote$(\bar{v})$, it has received $n-f$ main-vote$(\bar{v})$. According to the protocol, every correct replica only sends main-vote$(v)$ message once. Therefore, at least one correct replica has sent main-vote$(v)$ to $p_i$ and sent main-vote$(\bar{v})$ to $p_j$, a contradiction.

**Lemma 15.** If a correct replica $p_i$ decides $v$ in round $r$, any correct replica that enters round $r+1$ sets $i_{v+1}$ as $v$.

**Proof.** If $p_i$ decides $v$ in round $r$, it receives $n-f$ final-vote$(v)$. In other words, at least $f+1$ correct replicas have broadcast final-vote$(v)$. We assume that a correct replica $p_k$ enters round $r+1$ sets $i_{v+1}$ as $v$ and prove the lemma by contradiction. If $p_k$ sets $i_{v+1}$ as $v$, there are three conditions: A) $p_k$ receives at least $n-f$ final-vote$(v)$; B) $p_k$ only receives final-vote$(v)$ and final-vote$(\bar{v})$; C) none of the above holds. In other words, $p_k$ receives only final-vote$(v)$ or receives both final-vote$(v)$ and final-vote$(\bar{v})$. We now show that none of the three conditions is possible.

Condition A): Replica $p_k$ receives $n-f$ final-vote$(v)$. We already know that at least $n-f$ replicas have sent final-vote$(v)$ as $p_i$ receives $n-f$ final-vote$(v)$. Therefore, at least one correct replica has sent both final-vote$(v)$ and final-vote$(\bar{v})$, a contradiction.

Condition B): Replica $p_k$ receives $n-f$ final-vote$(v)$ and final-vote$(\bar{v})$ and has not received final-vote$(v)$. We already know that $p_i$ receives $n-f$ final-vote$(v)$. Therefore, at least one correct replica has sent final-vote$(v)$ to $p_i$ and either final-vote$(v)$ or final-vote$(\bar{v})$ to $p_j$, a contradiction.

Condition C): Replica $p_k$ receives only final-vote$(v)$ or receives both final-vote$(v)$ and final-vote$(\bar{v})$. We know that $p_i$ receives $n-f$ final-vote$(v)$. Therefore, at least $f+1$ correct replicas have sent final-vote$(v)$. If $p_k$ receives $n-f$ final-vote$(v)$ messages, at least one of them must be final-vote$(v)$. In this case, if $p_k$ enters round $r+1$ with $i_{v+1}$ as $v$, $p_k$ must have received at least one final-vote$(v)$, as if $p_k$ only receives final-vote$(v)$ and final-vote$(\bar{v})$, it will set $i_{v+1}$ as $v$. If $p_k$ accepts final-vote$(v)$, it has received $f+1$ main-vote$(v)$, among which at least one is sent by a correct replica. If $p_k$ accepts final-vote$(\bar{v})$, it has received $f+1$ main-vote$(\bar{v})$, among which at least one is sent by a correct replica. This is a contradiction with Lemma 13.

**Theorem 16** (Agreement). If a correct replica decides $v$, then any correct replica that terminates decides $v$.

**Proof.** We assume that a correct replica $p_i$ decides $v$ and another correct replica $p_j$ decides $\bar{v}$ and prove the theorem by contradiction. There are two cases: 1) $p_i$ and $p_j$ decide in the same round $r$; 2) $p_i$ and $p_j$ decide in different rounds.

We first prove case 1). If replica $p_i$ decides $v$ in round $r$, it receives $n-f$ final-vote$(v)$. If $p_j$ decides $\bar{v}$, it receives $n-f$ final-vote$(\bar{v})$. The two sets of $n-f$ replicas have at least $f+1$ replicas in common. Among the $f+1$ replicas, at least one is correct. Therefore, at least one correct replica must have sent both final-vote$(v)$ and final-vote$(\bar{v})$, a contradiction.

We now prove case 2) by assuming that $p_i$ decides value $v$ in round $r$ and $p_j$ decides $v$ in round $r'$ where $r' > r$.

According to Lemma 15, if $p_i$ decides $v$, any correct replica enters round $r+1$ sets $i_{v+1}$ as $v$. Furthermore, according to Lemma 10, for any round $r'' \geq r+1$, any correct replica that enters round $r''$ sets $i_{v'}$ as $v$. If replica $p_j$ decides value $v$ in round $r'$, it has received $n-f$ final-vote$(v)$ so at least $f+1$ correct replicas have sent final-vote$(v)$. According to Lemma 11, at least one correct replica has set $i_{v'}$ as $v$ and sent pre-vote$(v)$, a contradiction with Lemma 10.

**Lemma 17.** If a correct replica $p_i$ sends vote$(v)$ for $v \in \{0, 1\}$, any correct replica eventually accepts vote$(v)$.

**Proof.** If $p_i$ sends vote$(v)$ message, it has received $n-f$ pre-vote$(v)$, among which at least $f+1$ are sent by correct replicas. Accordingly to the protocol, any correct replica that has not sent pre-vote$(v)$ will also send pre-vote$(v)$ upon receiving $f+1$ pre-vote$(v)$. Therefore, every correct replica eventually sends pre-vote$(v)$, receives $n-f$ pre-vote$(v)$, and then adds $v$ to $\text{bset}_r$. Hence, every correct replica eventually accepts vote$(v)$.

**Lemma 18.** If a correct replica $p_i$ broadcasts a main-vote$(v)$ or a main-vote$(v)$ message given that $v \in \{0, 1\}$, any correct replica accepts the main-vote$(v)$ message.

**Proof.** If $p_i$ sends main-vote$(v)$ message, it has received and accepted $n-f$ vote$(v)$, among which at least $f+1$ are sent by correct replicas. Therefore, any correct replica eventually receives $f+1$ vote$(v)$ and accept vote$(v)$.

If $p_i$ sends a main-vote$(v)$ message, it must have received and accepted both vote$(v)$ and vote$(\bar{v})$, or it has received at least one vote$(v)$. In any of the cases, $p_i$ has put both 0 and 1 to $\text{bset}_r$. If $p_i$ puts $v$ to $\text{bset}_r$, it has received 2$f+1$ pre-vote$(v)$, among which at least $f+1$ are sent by correct replicas. Then any correct replica eventually receives $f+1$ pre-vote$(v)$ and sends pre-vote$(v)$. Every correct replica eventually receives $n-f$ pre-vote$(v)$ and adds $v$ to $\text{bset}_r$. Therefore, every correct replica eventually accepts main-vote$(v)$.

**Lemma 19.** If a correct replica $p_i$ broadcasts a final-vote$(v)$ or a final-vote$(v)$ message given that $v \in \{0, 1\}$, any correct replica accepts the final-vote$(v)$ message.

**Proof.** The lemma can be proved similarly as in Lemma 18.
Lemma 20. Let \( v_1 \in \{0, 1\} \) and \( v_2 \in \{0, 1\} \). If a correct replica \( p_r \) receives only \( n - f \) final-vote\(_c(v)\) and final-vote\(_e(v_1)\) messages, another correct replica \( p_j \) only receives \( n - f \) final-vote\(_c(v_2)\) and final-vote\(_e(v)\) messages, \( v_1 = v_2 \).

Proof. If \( p_r \) accepts final-vote\(_e(v_1)\), it has previously received \( f + 1 \) main-vote\(_e(v_1)\), among which at least one is sent by a correct replica. If \( p_j \) accepts final-vote\(_e(v_1)\), it has previously received \( f + 1 \) main-vote\(_e(v_2)\), among which at least one is sent by a correct replica. According to Lemma 13, it holds that \( v_1 = v_2 \).

Theorem 21 (Termination). Every correct replica eventually decides some value.

Proof. The proof consists of two parts. First, in each round \( r \), correct replicas will enter the next round. Second, the value \( iv_r \) used by any correct replica cannot be manipulated by the adversary.

We first show that in round \( r \), correct replicas will enter the next round. In each round, every replica sets \( iv_r \) to either 0 or 1 in Quadratic-ABA. Accordingly, at least \( f + 1 \) correct replicas have the same \( iv_r = v \). All correct replicas will eventually receive \( 2f + 1 \) pre-vote\(_e(v)\) for some \( v \) and send a vote\(_c()\) message. Correct replicas will send either vote\(_e(0)\) or vote\(_e(1)\) and receive at least \( n - f \) main-vote\(_e()\) messages. For any correct replica, if it sends vote\(_e(v)\) for \( v \in \{0, 1\} \), any correct replica will eventually accept vote\(_e(v)\), according to Lemma 17. All correct replicas will then send either main-vote\(_e(v)\) for \( v \in \{0, 1\} \) or main-vote\(_e(\cdot)\). According to Lemma 18, every correct replica eventually accepts any main-vote\(_e()\) message sent by a correct replica. Then every correct replica either sends final-vote\(_e(v)\) or final-vote\(_e()\). According to Lemma 19, every correct replica accepts any final-vote\(_e()\) message from a correct replica. Therefore, any correct replica will eventually receive \( n - f \) final-vote\(_e()\) messages and enter the next round.

We then show that if a correct replica \( p_i \) does not decide in round \( r \), the value \( iv_{r+1} = v \) cannot be manipulated by a malicious network scheduler such that correct replicas always enter the next round with inconsistent values. If \( p_i \) does not decide in round \( r \), there are two conditions: A) \( p_i \) receives \( n - f \) final-vote\(_e(v)\) and final-vote\(_e(\cdot)\); B) \( p_i \) receives both final-vote\(_e(v)\) and final-vote\(_e(\bar{v})\) messages, or receives \( n - f \) final-vote\(_e(\cdot)\). For condition B, a correct replica enters the next round with its local coin \( c \). The \( c \) value is independent with the value chosen by any correct replica. We now prove that the value \( v \) in condition A cannot be manipulated.

According to Lemma 20, if \( p_j \) receives \( n - f \) final-vote\(_e(v_1)\) and final-vote\(_e(\cdot)\) and \( p_j \) receives \( n - f \) final-vote\(_e(v_1)\) and final-vote\(_e(\cdot)\), \( v_1 = v_2 \). In other words, the value \( v \) used by any correct replica cannot be manipulated by the network scheduler.

If correct replicas use local coins to enter the next round, with a probability of \( 1 - \frac{1}{2^{n/2}} \), replicas will enter the next round with the same value. Replicas will reach a state where agreement can be reached in \( 2^{n/2} \) expected rounds and execute the protocol for another round before terminating the protocol. Therefore, the protocol will terminate in \( 2^{n/2} + 1 \) expected rounds.

Theorem 22 (Integrity). No correct replica decides twice.

Proof. According to the protocol, after a correct replica decides some value, it participates in one more round of the protocol. However, it terminates the protocol after it receives a final-vote\(_e(\cdot)\) message. Hence, the replica does not decide again in the following round.

F Proof of CC-ABA

We prove the correctness of CC-ABA that simply replaces the local coins of Quadratic-ABA with weak common coins (or perfect common coins). According to the proofs of Quadratic-ABA, the validity, agreement, and integrity properties do not depend on the values of the coins. Therefore, validity, agreement and integrity follow those of Quadratic-ABA. We now present the following lemma and prove termination.

Lemma 23. If a correct replica receives and accepts both final-vote\(_e(v_1)\) and final-vote\(_e(v_2)\) such that \( v_1, v_2 \in \{0, 1\} \).

Proof. If a correct replica accepts final-vote\(_e(v_1)\), it has previously received at least \( f + 1 \) main-vote\(_e(v_1)\). If the replica accepts final-vote\(_e(v_2)\), it has previously received at least \( f + 1 \) main-vote\(_e(v_2)\). Therefore, at least one correct replica has sent main-vote\(_e(v_1)\) and at least one correct replica has sent main-vote\(_e(v_2)\). According to Lemma 13, if a correct replica sends main-vote\(_e(v_1)\), any correct replica will only send main-vote\(_e(v_1)\) or main-vote\(_e(\cdot)\). Therefore, we conclude that \( v_1 = v_2 \).

The proof consists of two parts. First, in each round \( r \), correct replicas will enter the next round. Second, the value \( iv_r \), used by any correct replica cannot be manipulated by the adversary.

We first show that in round \( r \), correct replicas will enter the next round. In each round, every replica sets \( iv_r \) as either 0 or 1. Accordingly, at least \( f + 1 \) correct replicas have the same \( iv_r = v \). All correct replicas will eventually receive \( 2f + 1 \) pre-vote\(_e(v)\) for some \( v \) and send vote\(_c()\) message. Correct replicas will send either vote\(_e(0)\) or vote\(_e(1)\) and receive at least \( n - f \) main-vote\(_e()\) messages. For any correct replica, if it sends vote\(_e(v)\) for \( v \in \{0, 1\} \), any correct replica will eventually accept vote\(_e(v)\), according to Lemma 17. All correct replicas will then send either main-vote\(_e(v)\) for \( v \in \{0, 1\} \) or main-vote\(_e(\cdot)\). According to Lemma 18, every correct replica eventually accepts any main-vote\(_e()\) message sent by a correct replica. Then every correct replica either sends final-vote\(_e(v)\) or final-vote\(_e(\cdot)\). According to Lemma 19, every correct replica accepts any final-vote\(_e()\) message from a correct replica. Therefore, any correct replica will eventually receive \( n - f \) final-vote\(_e()\) messages and enter the next round.

In other words, the value \( v \) used by any correct replica cannot be manipulated by the network scheduler.

If correct replicas use local coins to enter the next round, with a probability of \( 1 - \frac{1}{2^{n/2}} \), replicas will enter the next round
a correct replica. Therefore, any correct replica will eventually receive \(n - f\) final-vote_\(r\) messages and enter the next round.

We then show that if a correct replica \(p_i\) does not decide in round \(r\), the value \(iv_{r+1} = v\) cannot be manipulated by a malicious network scheduler such that correct replicas always enter the next round with inconsistent values. If \(p_i\) does not decide in round \(r\), there are two conditions: A) \(p_i\) receives \(n - f\) final-vote_\(r\) messages with only final-vote_\(0\)(\(v\)) and final-vote_\(r\)(\(v\)), B) \(p_i\) receives both final-vote_\(r\)(\(v\)) and final-vote_\(r\)(\(\bar{v}\)) messages, or receives \(n - f\) final-vote_\(r\)(\(\ast\)).

If condition A applies to at least two correct replicas, according to Lemma 20, if \(p_i\) receives \(n - f\) final-vote_\(r\)(\(v_1\)) and final-vote_\(r\)(\(\ast\)) and \(p_j\) receives \(n - f\) final-vote_\(r\)(\(v_1\)) and final-vote_\(r\)(\(\bar{v}\)), \(v_1 = v_2\). In other words, the value \(v\) used by any correct replica cannot be manipulated by an adversary.

If condition B applies to at least two correct replicas, the correct replicas enter the next round with the weak common coin. With a probability of \(2/d\), all correct replicas will have the same \(iv_{r+1}\) value. This value cannot be manipulated by an adversary.

We now show that if condition A applies to a correct replica \(p_i\) and condition B applies to a correct replica \(p_j\), the value \(v\) cannot be manipulated by an adversary. If \(p_j\) sets \(iv_{r+1}\) as the weak common coin value, it has either received \(n - f\) final-vote_\(r\)(\(\ast\)) or both final-vote_\(r\)(\(v\)) and final-vote_\(r\)(\(\bar{v}\)). According to Lemma 23, the latter case is impossible. Therefore, \(p_j\) receives \(n - f\) final-vote_\(r\)(\(\ast\)). Accordingly, at least \(f + 1\) correct replicas have sent final-vote_\(r\)(\(\ast\)). The correct replicas have previously sent either main-vote_\(r\)(\(v\)) or main-vote_\(r\)(\(\ast\)) for some \(v \in \{0, 1\}\) according to Lemma 13. No correct replica will send main-vote_\(r\)(\(\bar{v}\)). If condition A applies to \(p_i\) and \(p_j\) sets \(iv_{r+1}\) as \(v_1 (v_1 \in \{0, 1\})\), \(p_i\) has received at least \(f + 1\) main-vote_\(r\)(\(v_1\)). Since at least one correct replica has sent main-vote_\(r\)(\(v_1\)), this value \(v_1\) can only be \(v\) as we already know that no correct replica will send main-vote_\(r\)(\(\bar{v}\)). In other words, the value \(iv_{r+1}\) cannot be manipulated by an adversary.

CC-ABA uses weak common coins. If correct replicas begin the protocol with different input values, replicas will reach a state where decisions can be made in expected \(1 - \Sigma_{r=1}^d \frac{1}{2}(1 - \frac{1}{2})^{r-1} = d\) rounds. After that, it takes another round for replicas to terminate the protocol, so the expected number of rounds is \(d + 1\). For the special case that uses perfect common coins, the expected number of rounds is 3.

\section{Proof of Cubic-RABA}

We now show that Cubic-RABA achieves validity, unanimous termination, agreement, biased validity, biased termination, and integrity.

\begin{lemma}
If all correct replicas propose \(v\) in round 0 and never repropose \(\bar{v}\), then any correct replica enters the round 1 sets \(iv_1\) as \(v\).
\end{lemma}

\begin{proof}
In round 0, all replicas send pre-vote_\(0\)(\(v\)). No correct replica will receive \(f + 1\) pre-vote_\(0\)(\(\bar{v}\)) and send pre-vote_\(0\)(\(v\)). Similarly, all correct replicas will send main-vote_\(0\)(\(v\)) and will never accept main-vote_\(0\)(\(\bar{v}\)). All correct replicas will \(r\)-broadcast final-vote_\(0\)(\(v\)) and will never accept final-vote_\(0\)(\(\bar{v}\)). Therefore, any correct replica that enters round 1 sets \(iv_1\) as \(v\).
\end{proof}

\begin{theorem}[Validity]
If all correct replicas propose \(v\) and never repropose \(\bar{v}\), then any correct replica that terminates decides \(v\).
\end{theorem}

\begin{proof}
We assume that a correct replica \(p_i\) terminates and decides \(\bar{v}\) and prove the correctness by contradiction. If \(p_i\) terminates and decides \(\bar{v}\) in round 0, correctness follows from Lemma 24. We now prove the case where \(p_i\) decides in round \(r > 0\).

Since Cubic-RABA follows Cubic-ABA starting from round 1, Lemma 2 holds for \(r > 0\). If \(p_i\) terminates and decides \(\bar{v}\) in round \(r > 0\), it \(r\)-delivers \(n - f\) final-vote_\(r\)(\(\bar{v}\)). Additionally, \(p_i\) has added \(\bar{v}\) to its bset_\(r\). Therefore, at least one correct replica has set \(iv_r\) as \(\bar{v}\) and broadcast pre-vote_\(r\)(\(\bar{v}\)). This is a contradiction with Lemma 2 since any correct replica that enters round \(r\) sets \(iv_r\) as \(v\). This completes the proof of the theorem.
\end{proof}

\begin{theorem}[Unanimous termination]
If all correct replicas propose \(v\) and never repropose \(\bar{v}\), then all correct replicas eventually terminate.
\end{theorem}

\begin{proof}
If all correct replicas propose \(v\) and never repropose \(\bar{v}\), all correct replicas only send pre-vote_\(0\)(\(v\)). No correct replica will add \(\bar{v}\) to bset_\(0\). Furthermore, no correct replica will accept main-vote_\(0\)(\(\bar{v}\)) or final-vote_\(0\)(\(\bar{v}\)). Eventually all correct replicas will receive \(2f + 1\) pre-vote_\(0\)(\(v\)), add \(v\) to bset_\(0\), and broadcast main-vote_\(0\)(\(v\)). Similarly, all correct replicas will eventually receive \(n - f\) main-vote_\(0\)(\(v\)) and \(r\)-broadcast final-vote_\(0\)(\(v\)). All correct replicas will \(r\)-deliver \(n - f\) final-vote_\(0\)(\(v\)). In other words, all correct replicas will terminate and decide \(v\).
\end{proof}

\begin{lemma}
If \(p_i\) decides \(v\) in round 0, any correct replica that enters round 1 sets \(iv_1\) as \(v\).
\end{lemma}

\begin{proof}
If \(p_i\) decides \(v\) in round 1, it \(r\)-delivers \(n - f\) final-vote_\(0\)(\(v\)), among which at least \(f + 1\) replicas are correct. We assume that a correct replica \(p_k\) enters round 1 with \(iv_1 = \bar{v}\) and prove the correctness by contradiction. If \(p_k\) enters round \(r + 1\) and sets \(iv_1\) as \(\bar{v}\), there are three conditions: A) \(p_k\) \(r\)-delivers at least \(n - f\) final-vote_\(r\)(\(\bar{v}\)); B) \(p_k\) \(r\)-delivers \(f + 1\) final-vote_\(0\)(\(\bar{v}\)); C) \(p_k\) has not received more than \(f + 1\) final-vote_\(0\)(\(v\)) and \(p_k\) has not received more than \(f + 1\) final-vote_\(0\)(\(\bar{v}\)). We now show that none of the three conditions is possible.

Condition A): Replica \(p_k\) \(r\)-delivers \(n - f\) final-vote_\(0\)(\(\bar{v}\)). We already know that at least \(f + 1\) correct replicas \(r\)-broadcast
We already know that at least one correct replica $r$-broadcasts both final-vote$_0(v)$ and final-vote$_0(\bar{v})$, a contradiction.

Condition B): Replica $p_i$ $r$-delivers $f + 1$ final-vote$_0(\bar{v})$. We already know that $p_i$ $r$-delivers $n - f$ final-vote$_0(v)$. Therefore, at least one replica (correct or Byzantine) $r$-broadcasts both final-vote$_0(\bar{v})$ and final-vote$_0(v)$ such that $p_i$ $r$-delivers final-vote$_0(\bar{v})$ and $p_i$ $r$-delivers final-vote$_0(v)$, a violation of the agreement property of RBC.

Condition C): Replica $p_k$ $r$-delivers $n - f$ final-vote$_0(\bar{v})$ messages (let the set of replicas be $S_1$). In the messages, fewer than $f + 1$ are final-vote$_0(\bar{v})$ and fewer than $f + 1$ are final-vote$_0(v)$. Other messages must be final-vote$_0(\ast)$. We already know that $p_i$ $r$-delivers $n - f$ final-vote$_0(\bar{v})$ (let the set of replicas be $S_2$). $S_1$ and $S_2$ have at least $n - 2f \geq f + 1$ replicas in common. In other words, at least one replica $r$-broadcasts a final-vote$_0(\bar{v})$ message such that $p_i$ $r$-delivers final-vote$_0(\bar{v})$ and $p_k$ $r$-delivers final-vote$_0(\bar{v})$ (or final-vote$_0(\ast)$), a violation of the agreement property of RBC.

**Theorem 28** (Agreement). *If a correct replica decides $v$, then any correct replica that terminates decides $v*.

*Proof.* We assume that a correct replica $p_i$ decides $v$ and a correct replica $p_j$ decides $\bar{v}$ and prove the theorem by contradiction. Since Cubic-RABA follows Cubic-ABA starting from round $r > 0$, if both $p_i$ and $p_j$ decide in round $r > 0$, correctness follows from the agreement property of Cubic-ABA. We now show the correctness in the following cases: 1) both $p_i$ and $p_j$ decide in round 0; 2) $p_i$ decides in round 0 and $p_j$ decides in round $r > 0$.

Case 1): If $p_i$ decides $v$, it $r$-delivers $n - f$ final-vote$_0(v)$. If $p_j$ decides $\bar{v}$, it $r$-delivers $n - f$ final-vote$_0(\bar{v})$. The two quorum of replicas have at least $n - 2f$ replicas in common. Among the $n - 2f$ replicas, at least one is correct since $n - 2f \geq f + 1$. Therefore, at least one correct replica $r$-broadcasts both final-vote$_0(v)$ and final-vote$_0(\bar{v})$, a contradiction since each replica only $r$-broadcasts a final-vote$_0(\ast)$ message once in each round.

Case 2): If $p_j$ decides $\bar{v}$ in round $r = 1$, it has received at least $2f + 1$ pre-vote$_1(\bar{v})$, where at least one correct replica has sent pre-vote$_1(\bar{v})$, a contradiction with Lemma 27. Starting from round 1, Cubic-RABA follows Cubic-ABA so that Lemma 2 holds. If $p_j$ decides $\bar{v}$ in round $r > 1$, at least one correct replica must have sent pre-vote$_k(\bar{v})$, a contradiction with Lemma 2 since any correct replica sets $iv_1$ as $v$.

This completes the proof of the theorem.

**Lemma 29.** *If $f + 1$ correct replicas propose 1 in round 0, every replica either directly decides 1 in round 0 or/and enters round 1 with $iv_1 = 1$.*

*Proof.* If a correct replica $p_i$ enters round 1, there are three conditions: A) $p_i$ $r$-delivers $n - f$ final-vote$_0(v)$ with the same $v$; B) $p_i$ $r$-delivers at least $f + 1$ final-vote$_0(v)$ for some $v$; C) none of condition A or B holds. We show that $v = 1$ for all three conditions and replicas will set $iv_1 = v = 1$.

For condition A, we already know that at least $f + 1$ correct replicas have broadcast final-vote$_0(1)$. Therefore, $p_i$ must have received $n - f$ final-vote$_0(1)$. This is because if $p_i$ receives $n - f$ final-vote$_0(0)$, at least one correct replica $r$-broadcasts both final-vote$_0(1)$ and final-vote$_0(0)$, a contradiction. In other words, $p_i$ decides 1.

For condition B, we assume $p_i$ $r$-delivers $f + 1$ final-vote$_0(0)$ and prove the correctness by contradiction. If $p_i$ $r$-delivers $f + 1$ final-vote$_0(0)$, at least one correct replica $r$-broadcasts final-vote$_0(0)$. If the correct replica $r$-broadcasts final-vote$_0(0)$, the replica must have received $n - f$ main-vote$_0(0)$. We already know that at least $f + 1$ correct replicas have sent main-vote$_0(1)$. Any correct replica broadcasts main-vote$_0(1)$ message once. In other words, at least one correct replica has broadcast both main-vote$_0(0)$ and main-vote$_0(1)$, a contradiction. Therefore, in this condition, $p_i$ must have $r$-delivered $f + 1$ final-vote$_0(1)$. It is now clear that any correct replica uses $iv_1 = 1$ to enter round 1.

For condition C, any correct replica will use 1 as $iv_1$ since the local coin value is set as 1 in round 0. This completes the proof of the lemma.

**Theorem 30** (Biased validity). *If $f + 1$ correct replicas propose 1, then any correct replica that terminates decides 1.*

*Proof.* We assume that a correct replica $p_i$ decides 0 and prove the correctness by contradiction. If $p_i$ decides in round 0, correctness follows from Lemma 29. If $p_i$ decides 0 in round $r > 0$, at least one correct replica has set $iv_0$ as 0 and broadcast pre-vote$_0(0)$. Since Cubic-RABA follows Cubic-ABA starting from round 1, Lemma 2 holds. Therefore, the claim that at least one correct replica has set $iv_0$ as 0 is a contradiction with Lemma 2. This completes the proof of the theorem.

**Theorem 31** (Biased termination). *Let $Q$ be the set of correct replicas. Let $Q_1$ be the set of correct replicas that propose 1 and never repropose 0. Let $Q_2$ be correct replicas that propose 0 and later repose 1. If $Q_2 \neq \emptyset$ and $Q = Q_1 \cup Q_2$, then each correct replica eventually terminates.*

*Proof.* The proof consists of two parts. First, every replica correct eventually enters the next round. Second, if a correct replica enters the next round with input $v$, $v$ cannot be manipulated by the adversary.

We first prove that every replica eventually enters the next round. Since Cubic-RABA follows Cubic-ABA starting from round 1, this part follows from termination of Cubic-ABA. We only need to prove that every correct replica eventually enters round 1. For replicas in $Q_1$, they broadcast pre-vote$_0(1)$ and add 1 to bset$_0$. For replicas in $Q_2$, they broadcast pre-vote$_0(0)$ upon the propose(0) function, broadcast pre-vote$_0(1)$ upon the repropose(1) function, and eventually add 1 to bset$_0$. 24
There are two cases: 1) the size of $Q_1$ is greater than $f + 1$; 2) the size of $Q_1$ is smaller than $f + 1$.

For the first case, at least $f + 1$ replicas in $Q_1$ will directly broadcast main-vote$_0(1)$ and r-broadcast final-vote$_0(1)$. For any correct replica $p_i$ in $Q_2$, it may send main-vote$_0(1)$ or main-vote$_0(0)$. There are two sub-cases: none of the correct replicas send main-vote$_0(0)$; at least one correct replica has sent main-vote$_0(0)$. For the first sub-case, it is clear that every correct replica eventually receives and accepts $n - f$ main-vote$_0(1)$, as every correct replica has $1$ in its bset$_0$. Similarly, every correct replica will r-broadcast final-vote$_0(1)$ and accept $n - f$ final-vote$_0(1)$. For the second sub-case, if a correct replica $p_i$ sends main-vote$_0(0)$, it receives $2f + 1$ pre-vote$_0(0)$, among which at least $f + 1$ are sent by correct replicas. Therefore, every correct replica will eventually receive $f + 1$ pre-vote$_0(0)$ and broadcast pre-vote$_0(0)$. Every replica eventually adds $0$ to bset$_0$. Since every correct replica has both $1$ and $0$ in bset$_0$, every correct replica accepts both main-vote$_0(0)$ and main-vote$_0(1)$. Similarly, every correct replica accepts both final-vote$_0(0)$ and final-vote$_0(1)$. In other words, every correct replica eventually enters the next round.

For the second case, replicas in $Q_2$ will send pre-vote$_0(0)$ upon propose($0$). They will send pre-vote$_0(1)$ upon repropose($1$) and add $1$ to bset$_0$. Since the size of $Q_2$ is greater than $f + 1$ (the size of $Q_1$ is smaller than $f + 1$ and $Q = Q_1 \cup Q_2$), every replica will receive $f + 1$ pre-vote$_0(0)$, send pre-vote$_0(0)$, and add $0$ to bset$_0$. Furthermore, every correct replica in $Q_2$ broadcasts pre-vote$_0(0)$ upon repropose($1$). Since the size of $Q_2$ is greater than $f + 1$, it holds that every correct replica eventually adds $1$ to bset$_0$. Therefore, every replica will accept main-vote$_0(0)$ and main-vote$_0(1)$, final-vote$_0(0)$, and final-vote$_0(1)$. In other words, every correct replica eventually enters the next round.

We now prove the second part that the value $iv$ used by any correct replica cannot be manipulated by the adversary. Since Cubic-RABA follows Cubic-ABA starting from round 1, correctness follows from Lemma 6 and termination of Cubic-ABA.

**Theorem 32** (Integrity). No correct replica decides twice.

**Proof.** In each round, every replica only sends a main-vote$_r(1)$ message and a final-vote$_r(0)$ message once. Hence, only one value will be decided and integrity thus follows.

**H** Proof of Quadratic-RABA

We now show that Quadratic-RABA achieves validity, unanimous termination, agreement, biased validity, biased termination, and integrity.

**Lemma 33.** If all correct replicas propose $v$ in round 0 and never repropose $\bar{v}$, then any correct replica enters the round 1 sets $iv_1$ as $v$.

**Proof.** If all correct replicas propose $v$ in round 0, every correct replica broadcasts pre-vote$_0(v)$. No correct replica will receive more than $f + 1$ pre-vote$_0(\bar{v})$ messages. Hence, no correct replica will add $\bar{v}$ to bset$_0$. Furthermore, all correct replicas will eventually send vote$_0(v)$ and receive $n - f$ vote$_0(\bar{v})$. As no correct replica ever has $\bar{v}$ in bset$_0$, all correct replicas will not accept vote$_0(\bar{v})$. Therefore, all correct replicas will send main-vote$_0(v)$. No correct replica will accept main-vote$_0(\bar{v})$ or main-vote$_0(\bar{v})$ as $\bar{v} \not\in$ bset$_0$ and there are no more than $f + 1$ vote$_0(v)$. Accordingly, every correct replicas will send final-vote$_0(v)$ and receive $n - f$ final-vote$_0(v)$. No correct replica accepts final-vote$_0(\bar{v})$ as they only have $v$ in their bset, and no correct replica can receive more than $f + 1$ final-vote$_0(\bar{v})$. Hence, any correct replica that enters round $r + 1$ sets $iv_{r+1}$ as $v$.

**Theorem 34** (Validity). If all correct replicas propose $v$ and never repropose $\bar{v}$, then any correct replica that terminates decides $v$.

**Proof.** We assume that a correct replica $p_i$ terminates and decides $\bar{v}$ and prove the correctness by contradiction. If $p_i$ terminates and decides $\bar{v}$ in round 0, correctness follows from Lemma 33. We now prove the case where $p_i$ decides in round $r > 0$.

Since Quadratic-RABA follows Quadratic-ABA starting from round 1, Lemma 10 holds for $r > 0$. If $p_i$ terminates and decides $\bar{v}$ in round $r > 0$, it receives $n - f$ final-vote$_r(\bar{v})$. Among the replicas that send final-vote$_r(\bar{v})$, at least $f + 1$ are correct. According to Lemma 11, at least one correct replica has broadcast pre-vote$_r(\bar{v})$. This is a contradiction with Lemma 10 since any correct replica that enters round $r$ sets $iv_r$ as $v$. This completes the proof of the theorem.

**Theorem 35** (Unanimous termination). If all correct replicas propose $v$ and never repropose $\bar{v}$, then all correct replicas eventually terminate.

**Proof.** If all correct replicas propose $v$ and never repropose $\bar{v}$, all correct replicas only send pre-vote$_0(v)$. No correct replica will add $\bar{v}$ to bset$_0$. Furthermore, no correct replica will accept vote$_0(\bar{v})$, main-vote$_0(\bar{v})$, or final-vote$_0(\bar{v})$. Eventually all correct replicas will receive $n - f$ pre-vote$_0(v)$, add $\bar{v}$ to bset$_0$, and broadcast vote$_0(v)$. Similarly, all correct replicas will eventually receive $n - f$ vote$_0(v)$ and broadcast main-vote$_0(v)$. All correct replicas will receive $n - f$ main-vote$_0(v)$ and broadcast final-vote$_0(v)$. In other words, all correct replicas will eventually receive $n - f$ final-vote$_0(v)$ and decide $v$.

**Lemma 36.** If $p_i$ decides $v$ in round 0, any correct replica that enters round 1 sets $iv_1$ as $v$.

**Proof.** If $p_i$ decides $v$ in round 1, it receives $n - f$ final-vote$_0(v)$, among which at least $f + 1$ are sent by correct replicas. We assume that a correct replica $p_k$ enters round
1 with \( iv_1 = \bar{v} \) and prove the correctness by contradiction. If \( p_k \) enters round \( r + 1 \) and sets \( iv_1 \) as \( \bar{v} \), there are three conditions: A) \( p_j \) receives at least \( n - f \) final-vote, \( \bar{v} \); B) \( p_k \) receive only final-vote\( \bar{v}(v) \) and final-vote\( v(\ast) \); C) none of the above applies. In case C), as \( p_j \) will use the common coin value 1 as \( iv_1 \), the case is impossible. We now show that none of the first two conditions is possible.

Condition A): Replica \( p_i \) receives \( n - f \) final-vote\( \bar{v}(v) \). We already know that at least \( f + 1 \) correct replicas have sent final-vote\( (v) \). Therefore, at least one correct replica sends both final-vote\( (v) \) and final-vote\( \bar{v}(v) \), a contradiction.

Condition B): Replica \( p_k \) receives final-vote\( \bar{v}(v) \) and final-vote\( v(\ast) \). We already know that \( p_i \) receives \( n - f \) final-vote\( \bar{v}(v) \). Therefore, at least one replica has sent final-vote\( (v) \) to \( p_i \) and a final-vote\( \bar{v}(v) \) (or final-vote\( v(\ast) \) message) to \( p_j \), a contradiction.

Theorem 37 (Agreement). If a correct replica decides \( v \), then any correct replica that terminates decides \( v \).

Proof. We assume that a correct replica \( p_i \) decides \( v \) and a correct replica \( p_j \) decides \( \bar{v} \) and prove the theorem by contradiction. Since Quadratic-RABA follows Quadratic-ABA starting from round \( r > 0 \), if both \( p_i \) and \( p_j \) decide in round \( r > 0 \), correctness follows from the agreement property of Quadratic-ABA. We now show the correctness in the following cases: 1) both \( p_i \) and \( p_j \) decide in round 0; 2) \( p_i \) decides in round 0 and \( p_j \) decides in round \( r > 0 \).

Case 1): If \( p_i \) decides \( v \), it receives \( n - f \) final-vote\( \bar{v}(v) \). If \( p_j \) decides \( \bar{v} \), it receives \( n - f \) final-vote\( \bar{v}(v) \). The two quorum of replicas have at least \( n - 2f \) replicas in common. Among the \( n - 2f \) replicas, at least one is correct since \( n - 2f \geq f + 1 \). Therefore, at least one correct replica sends both final-vote\( (v) \) and final-vote\( \bar{v}(v) \), a contradiction since each replica only sends a final-vote\( (v) \) message once in each round.

Case 2): If \( p_j \) decides \( \bar{v} \) in round \( r = 1 \), it has received at least \( n - f \) pre-vote\( v(\bar{v}) \), where at least one correct replica has sent pre-vote\( v(\bar{v}) \), a contradiction with Lemma 36. Starting from round 0, Quadratic-RABA follows Quadratic-ABA so that both \( p_j \) decides \( \bar{v} \) in round \( r > 1 \), at least one correct replica must have sent pre-vote\( v(\bar{v}) \), a contradiction with Lemma 10 since any correct replica sets \( iv_r \) as \( v \).

Lemma 38. If \( f + 1 \) correct replicas propose 1 in round 0, every replica either directly decides 1 in round 0 or land enters round 1 with \( iv_1 = 1 \).

Proof. If a correct replica \( p_i \) enters round 1, there are three conditions: A) \( p_i \) receives \( n - f \) final-vote\( v(v) \) with the same \( v \); B) \( p_i \) receives at least a final-vote\( \bar{v}(v) \) message for some \( v \); C) none of condition A or B holds. We show that \( v = 1 \) for all three conditions and replicas will set \( iv_1 \) as \( v = 1 \).

For condition A, we already know that at least \( f + 1 \) correct replicas have broadcast final-vote\( \bar{v}(v) \). If \( p_i \) receives \( n - f \) final-vote\( \bar{v}(v) \), at least one correct replica has sent both final-vote\( \bar{v}(v) \) and final-vote\( v(v) \), a contradiction. In other words, in this condition \( p_i \) decides 1.

For condition B, we \( p_i \) receives only final-vote\( \bar{v}(v) \) and final-vote\( v(v) \). We already know that at least \( f + 1 \) correct replicas have sent final-vote\( \bar{v}(v) \). Therefore, at least one correct replica must have sent both final-vote\( \bar{v}(v) \) and final-vote\( v(v) \) (or final-vote\( v(v) \)), a contradiction.

For condition C, any correct replica will use 1 as input for round 1 since the local coin value is set as 1 in round 0.

Theorem 39 (Biased validity). If \( f + 1 \) correct replicas propose 1 in round 0, then any correct replica that terminates decides 1.

Proof. If \( p_i \) decides in round 0, correctness follows from Lemma 38. If \( p_i \) decides 0 in round \( r > 0 \), at least one correct replica has set \( iv_r \) as 0 and broadcast pre-vote\( v(0) \). Since Quadratic-RABA follows Quadratic-ABA starting from round 1, Lemma 10 holds. Therefore, the claim that at least one correct replica has set \( iv_r \) as 0 is a contradiction with Lemma 10. This completes the proof of the theorem.

Lemma 40. If \( f + 1 \) correct replicas propose 1 in round 0, every correct replica eventually accepts final-vote\( \bar{v}(v) \).

Proof. If \( f + 1 \) correct replicas propose 1, they will directly broadcast pre-vote\( v(0) \), pre-vote\( v(1) \), main-vote\( v(1) \), and final-vote\( v(1) \) every correct replica will eventually receive pre-vote\( v(1) \). For those correct replicas that have not sent pre-vote\( v(0) \), they will also broadcast pre-vote\( v(0) \). Therefore, every correct replica eventually adds 1 to bset, As \( f + 1 \) correct replicas broadcast main-vote\( v(1) \), every correct replica eventually accepts main-vote\( v(1) \). Similarly, as \( f + 1 \) correct replicas broadcast main-vote\( v(1) \), every correct replica eventually accepts final-vote\( v(1) \).

Lemma 41. If a correct replica sends final-vote\( v(0) \) or final-vote\( v(\ast) \), every correct replica eventually accepts the final-vote\( v(\ast) \) message.

Proof. Case 1: If a correct replica sends final-vote\( v(0) \), it has received \( n - f \) main-vote\( v(0) \), among which at least \( f + 1 \) are sent by correct replicas. Furthermore, the correct replica has put 0 in its bset, so it receives \( n - f \) pre-vote\( v(0) \). As \( f + 1 \) correct replicas have sent pre-vote\( v(0) \), every correct replica eventually receives \( f + 1 \) pre-vote\( v(0) \) and send pre-vote\( v(0) \). Accordingly, every correct replica puts 0 in bset, As every correct replica also eventually receives \( f + 1 \) main-vote\( v(0) \), every correct replica will accept final-vote\( v(0) \).

Case 2: If a correct replica sends final-vote\( v(\ast) \), its bset, is \{0, 1\}, i.e., it has received both \( n - f \) pre-vote\( v(0) \) and \( n - f \) pre-vote\( v(1) \). Following the prior case, every correct replica eventually has bset, = \{0, 1\}, so every correct replica accepts final-vote\( v(\ast) \).

Theorem 42 (Biased termination). Let \( Q \) be the set of correct replicas. Let \( Q_1 \) be the set of correct replicas that propose 1
and never repropose 0. Let $Q_2$ be correct replicas that propose 0 and later repropose 1. If $Q_2 \neq \emptyset$ and $Q = Q_1 \cup Q_2$, then each correct replica eventually terminates.

**Proof.** The proof consists of two parts. First, every replica correct eventually enters the next round. Second, if a correct replica enters the next round with input $v$, $v$ cannot be manipulated by the adversary.

We first prove that every replica eventually enters the next round. Since Quadratic-RABA follows Quadratic-ABA starting from round 1, this part follows from termination of Cubic-ABA. We only need to prove that every correct replica eventually moves to round 1. For replicas in $Q_1$, they broadcast pre-vote$_0(1)$ and add 1 to bset$_0$. For replicas in $Q_2$, they broadcast pre-vote$_0(0)$ upon the propose(0) event, broadcast pre-vote$_0(1)$ upon the repropose(1) event, and eventually add 1 to bset$_0$. There are two cases: 1) the size of $Q_1$ is greater than $f + 1$; 2) the size of $Q_1$ is smaller than $f + 1$.

For the first case, at least $f + 1$ replicas in $Q_1$ will directly broadcast vote$_0(1)$, main-vote$_0(1)$, and final-vote$_0(1)$. For any correct replica $p_i$ in $Q_2$, it may send vote$_0(1)$ or vote$_0(0)$. There are two sub-cases: none of the correct replicas send vote$_0(0)$; at least one correct replica has sent vote$_0(0)$. For the first sub-case, it is straightforward to see that every correct replica eventually receives and accepts $n - f$ vote$_0(1)$, as every correct replica has 1 in its bset$_0$. Similarly, every correct replica will send main-vote$_0(1)$ and accept $n - f$ main-vote$_0(1)$. Similarly, every correct replica will send final-vote$_0(1)$. According to Lemma 40, every correct replica eventually accepts final-vote$_0(1)$ so correct replicas will enter the next round. For the second sub-case, if a correct replica $p_i$ sends vote$_0(0)$, it receives $n - f$ pre-vote$_0(0)$, among which at least $f + 1$ are sent by correct replicas. Therefore, every correct replica will eventually receive $f + 1$ pre-vote$_0(0)$ and broadcast pre-vote$_0(0)$. Every replica eventually adds 0 to bset$_0$. Since every correct replica has both 1 and 0 in bset$_0$, every correct replica accepts both vote$_0(0)$ and vote$_0(1)$. Similarly, every correct replica accepts both main-vote$_0(0)$ and main-vote$_0(1)$. In other words, every correct replica may send a final-vote$_0(1)$ message with any value, i.e., 1, 0, or *. According to Lemma 40, every correct replica eventually accepts final-vote$_0(1)$. According to Lemma 41, any correct replica accepts the final-vote$_0(1)$ message sent by any correct replica. Therefore, every correct replica eventually enters the next round.

For the second case, replicas in $Q_2$ will send pre-vote$_0(0)$ upon propose(0). They will send pre-vote$_0(1)$ upon repropose(1) and add 1 to bset$_0$. Since the size of $Q_2$ is greater than $f + 1$ (the size of $Q_1$ is smaller than $f + 1$ and $Q = Q_1 \cup Q_2$), every replica will receive $f + 1$ pre-vote$_0(0)$, send pre-vote$_0(0)$, and add 0 to bset$_0$. Furthermore, every correct replica in $Q_2$ broadcasts pre-vote$_0(1)$ upon repropose(1). Since the size of $Q_2$ is greater than $f + 1$, every correct replica eventually adds 1 to bset$_0$. According to the protocol, in round 0, every correct replica accepts main-vote$_0(v)$ and final-vote$_0(v)$ if $v$ is added to bset$_0$. Therefore, every replica will accept both vote$_0(0)$ and vote$_0(1)$, and main-vote$_0(1)$ and final-vote$_0(1)$ with any value. Accordingly, every correct replica eventually enters the next round.

We now prove the second part where the value $iv$ used by any correct replica cannot be manipulated by the adversary. Since Quadratic-RABA follows Quadratic-ABA starting from round 1, correctness follows from Lemma 20 and termination of Quadratic-ABA.

**Theorem 43** (Integrity). No correct replica decides twice.

**Proof.** In each round, every replica only sends a final-vote$_r(1)$ message once. Hence, only one value will be decided and integrity thus follows.
