† wata@nda.ac.jp

Abstract—QC-MDPC (quasi cyclic moderate density parity check) code-based McEliece cryptosystems are considered to be one of the candidates for post-quantum cryptography. Decreasing DER (decoding error rate) is one of important factor for their security, since recent attacks to these cryptosystems effectively use DER information. In this paper, we pursue the possibility of optimization-base decoding, concretely we examine ADMM (alternating direction method of multipliers), a recent developing method in optimization theory. Further, RSPA (reproducing sum-product algorithm), which efficiently reuse outputs of SPA (sum-product algorithm) is proposed for the reduction of execution time in decoding. By numerical simulations, we show that the proposing scheme shows considerable decrement in DER compared to the conventional decoding methods such as BF (bit-flipping algorithm) variants or SPA.

Index Terms—QC-MDPC code-based cryptosystem, ADMM method, reproducing sum-product algorithm, McEliece cryptosystem.

I. INTRODUCTION

The safety of current cryptosystem (for example, RSA, ECDH) are based on the computation difficulty such as integer factoring or discrete logarithmic problem. These crypto schemes are said to be no longer secure under the presence of quantum computers, which are able to solve these problems in polynomial time [12]. Although current number of qubits are relatively small, algorithms resistant for quantum computers equipped with practical qubits are desirable. Following proposals; lattice-based, code-based, hash-based and multivariate, isogeny-base etc. are considered to be the framework of cryptosystems for post quantum generation and these are continuing to be reviewed in NIST post-quantum cryptography standardization [16].

The present paper is concerned with the reduction of DER (decoding error rate) in code-based cryptosystem. It is known that there is an attack (GJS attack) [7] that effectively uses decoding failure statistics to retrieve the parity check matrix of the code (which is a secret key). Thus, reducing the DER is considered to be one of important factors for preventing such attacks. We note the efforts to reduce DER are seen in recent studies [5] and [9].

The security of code-based schemes is based on the hardness of decoding linear random codes (indeed the problem is known to be NP-hard problem [3]). The first code-based scheme is the McEliece cryptosystem which use Goppa codes. The original McEliece cryptosystem has been withstanding evaluation more than thirty years and still regarded secure. A problem of original McEliece cryptosystem is its large public key size. For the reduction of public key size, various improvements were proposed; see [4], [11], [15]. It should be noted that the usage of LDPC codes directly for this purpose is known to be dangerous, since parity check matrix of LDPC (low-density parity check) codes might be recovered by decoding low Hamming weight codewords, for example using Stern’s method [13], as dual codes of original codes.

On the other hand, QC-MDPC (quasi cyclic moderate density parity check) code is currently regarded as safe and public key size is small, and for such reasons, this scheme is remaining as alternatives of NIST PQC as Public-key Encryption and Key-establishment Algorithms [16]. Standard decoding methods for QC-MDPC codes are variants of BF (bit-flipping algorithm). In this paper, we show DER of QC-MDPC codes can be considerably improved compared to BF algorithm variants by applying ADMM (alternating direction method of multipliers) based decoding, which is a recently developing subject in optimization theory. The ADMM decoding is a method based on IP (integer programming), which achieve MLD (maximum likelihood decoding); see Feldman–Wainwright and Karger [6]. Although IP decoding presents high precision decoding, it costs a considerable amount of execution time and hence the adoption seems to be limited to relatively short code-length problems (about a few hundred bits or so). While the ADMM decoding is reported to be applicable to more than thousands of bits of code-length; see [2], [10]. In this paper, we apply the algorithm of Barman, Liu, Draper and Recht [2] and Liu and Draper [10] as the ADMM decoding method and show even in the case of middle-density parity checks and middle code-length (in cases code-length are 9602 and 10779), it works well.

Here, we have to note that the original projection algorithm (Algorithm 2 of [2]) seems to be including some error (actually, Algorithm 2 of [2] sometimes shows mismatching values compared to the values computed by MIP solver Gurobi optimizer 9.5 [8]); see Figure 1 and 2 in Section III. We present the corrected projection algorithm to the code-polytope in Algorithm 3 and examine its validity in Section VI.

The ADMM method can decode encrypted messages considerably faster than original IP decoding, however, it takes
about 2.8-7.8 times decoding time in average compared to classical BF algorithm; see Table I and II. To fill this gap, we propose yet another decoding method, RSPA (reproducing sum-product algorithm), which efficiently reuse decoding failure of SPA. As a result, combination of RSPA and ADMM decoding show the certain improvement of decoding time in average.

As for the reduction in DER, by numerical examination in Section IV, we observe in the case of \((n, k) = (9602, 4801)\) code, the correctable number of errors increases from \(t = 87\) (BF algorithm) to \(t = 103\) under almost the same DER (less than \(10^{-7}\)). Similarly, in the case of \((n, k) = (10779, 3593)\), correctable number of number of errors increases from \(t = 55\) (BF algorithm) to \(t = 66\) under almost the same DER (less than \(10^{-7}\)). In other words, proposing scheme attains far less DER for fixed error number \(t\) compared to BF algorithm and hence prevents the collection of DER information by adversaries.

II. QC-MDPC McEliece Cryptosystems

A. McEliece cryptosystems

We briefly review McEliece cryptosystems. Throughout this paper, a set of codewords is denoted by \(C\). The variables \(n, k, t\) denote code-length, information bits length and correctable error number respectively. We abbreviate \(m = n - k\). Also, \(k \times n\) binary matrix \(G\), \(m \times n\) binary matrix \(H\), \(n \times n\) matrix \(P\) and \(k \times k\) binary matrix \(S\) represent generator matrix, parity-check matrix, random permutation matrix and scramble matrix respectively. Put

\[
G' = SGP. \tag{1}
\]

Then \((G', t)\) is a public key and \((G, S, P)\) is a private key of Bob. For a message \(m\), using public key, Alice encrypts as

\[
c = mG' + e, \tag{2}
\]

where \(e\) is a correctable error vector whose Hamming weight satisfies \(w(e) = t\). Decoding process of Bob is as follows:

(i) Multiply \(P^{-1}\) to both sides of (2), that is

\[
cP^{-1} = mG'P^{-1} + eP^{-1} = mSG + eP^{-1}. \]

(ii) Since \(w(eP^{-1}) = w(e) = t\), by applying certain decoding scheme, he obtains \(e' = mSG\).

(iii) Multiplying \(G'^{-1}S'\) to \(e'\). Bob retrieves the sent message \(m\).

B. QC-MDPC McEliece cryptosystems with code-rate \(R = (n_0 - 1)/n_0\)

QC-MDPC codes are linear block codes whose binary parity check matrices have moderate density of ‘one’ and are introduced to reduce public key size of original McEliece cryptosystems; see Misoczki, Tillich, Sendier and Barreto. A parity check matrix of QC-MDPC McEliece cryptosystems with code-rate \(R = (n_0 - 1)/n_0\) assumes the following form; see for example [1, Section 3.6],

\[
H = [H_0, H_1, \ldots, H_{n_0 - 1}], \tag{3}
\]

where each \(H_i\), \((0 \leq i \leq n_0 - 1)\) is a binary \(p \times p\) circulant matrix of each row and column weight equals to \(d_c\). Hence it holds that \(n = n_0p\) and \(k = (n_0 - 1)p\) (so \(R = (n_0 - 1)/n_0\)). Without loss of generality, we can assume \(H_{n_0 - 1}\) is non-singular, then the generator matrix of the code is expressed as (see also [1, Section 3.6]),

\[
G = \begin{bmatrix} I_k \mid (H_{n_0 - 1}^{-1} \cdot H_0)^T \\ \vdots \\ (H_{n_0 - 1}^{-1} \cdot H_{n_0 - 2})^T \end{bmatrix}, \tag{4}
\]

where \(I_k\) is the \(k \times k\) identity matrix. Since \((H_{n_0 - 1}^{-1} \cdot H_i)^T, (0 \leq i \leq n_0 - 1)\) are circulant, public key will be only first rows of these matrices, and as a result, reducing the size of the public key.

III. Decoding Methods

A. Bit-flipping decoding algorithm

The basic (classical) bit-flipping decoding algorithm is described as follows:

\begin{algorithm}
\caption{Bit-flipping decoding algorithm}
\begin{algorithmic}
1: \(s \leftarrow Hc^T\).
2: \textbf{while} \(s \neq 0\) \textbf{do}
3: \(i \leftarrow \arg\min_{0 \leq i \leq n - 1} w(s + h_i)\).
4: \textbf{if} \(w(s + h_i) < w(s)\) \textbf{then}
5: \(c_i \leftarrow 1 - c_i\).
6: \(s \leftarrow s + h_i\).
7: \textbf{else}
8: \textbf{return} decoding failure.
9: \textbf{end if}
10: \textbf{end while}
11: \textbf{return} \(c\).
\end{algorithmic}
\end{algorithm}

As shown in the numerical experiments of next section, BF decoding algorithm shows lower DER than SPA, especially in cases \(w(e)\) is relatively small; see Figure 7 and 8.

B. Notations

Next, we introduce ADMM algorithm according to [2]. Although, an algorithm developed in [2] assumes LDPC codes, we show that the algorithm is also effective for decoding of MDPC codes. We define some necessary notations: \(\mathcal{X}\) and \(\mathcal{Y}\) denote: \(\mathcal{X} = \{0, 1\}\) and \(\mathcal{Y} = \{0, 1\}\), since we assume BSC (binary symmetric channel). Thus, sending messages belong to \(k\)-dimensional subspace \(C\) of \(\mathcal{X}^n\) and corresponding received messages belong to \(\mathcal{Y}^n\). The neighborhood of a each “check” \(i\) is denoted by \(N_c(i)\) and the neighborhood of a each “vertex” \(j\) is denoted by \(N_v(j)\), namely:

\[
N_c(i) = \{j \mid H_{i,j} = 1\} \quad \text{and} \quad N_v(j) = \{i \mid H_{i,j} = 1\},
\]

where \(H_{i,j}\) is a \((i, j)\) element of parity check matrix \(H\). In the case, \(H\) is assumed to be as (3), since each row and column of \(H_k, (0 \leq k \leq n_0 - 1)\) has \(d_c\) non-zero element, it holds
that $|N_c(i)| = n_0d_c$, $0 \leq i \leq p$ and $|N_c(j)| = d_c$, $0 \leq j \leq n_0p$.

Let $N_c(i) = \{j_1, j_2, \ldots, j_d\}$ (note that in the case of (3), $d = n_0d_c$), then we define a linear map $P_i : \mathbb{R}^n \rightarrow \mathbb{R}^d$ as

$$(P_i)_{k,l} = \begin{cases} 1, & l = j_k \\ 0, & \text{else.} \end{cases}$$

For example, in the case

$$H = \begin{bmatrix} 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 1 \\ 0 & 0 & 0 & 1 & 1 & 1 \end{bmatrix}$$

we have

$$P_1 = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \end{bmatrix}, \quad P_2 = \begin{bmatrix} 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix},$$

$$P_3 = \begin{bmatrix} 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}.$$  

Define

$$P_d := \{ \mathbf{x} \in \{0,1\}^d \mid \|\mathbf{x}\|_1 \text{ is even} \},$$

where $\| \cdot \|_p$ represents a $l^p$ norm. Then, we can write

$$\mathbf{x} \in \mathcal{C} \Leftrightarrow P_d \mathbf{x} \in \mathbb{P}_d, \quad (1 \leq i \leq m).$$

For $x \in \mathcal{X}$ and $y \in \mathcal{Y}$, $W(y|x)$ represents the conditional probability of BSC, i.e. $W(1|0) = W(0|1) = p$ and $W(0|0) = W(1|1) = 1 - p$ where $p \in [0,1/2]$. Assume a sending message is $x = (x_1, \ldots, x_n) \in \mathcal{X}^n$ and a received message be $y = (y_1, \ldots, y_n) \in \mathcal{Y}^n$. Since we assume memoryless channel, the conditional probability $p(y|x)$ is represented as: $p(y|x) = \prod_{j=1}^n W(y_j|x_j)$. The ML encoding choose $x \in \mathcal{X}^n$ that maximizes $p(x|y)$, thus equivalently maximizes $\sum_{j=1}^n \log W(y_j|x_j)$. We put

$$\gamma_j := \log (W(y_j|0)/W(y_j|1)), \quad (1 \leq j \leq n).$$

Since $\log W(y_j|x_j) = -\gamma_j x_j + \log W(y_j|0)$, ML decoding reduces to determining $x \in \mathcal{C}$ that minimizes $\gamma^T x = \sum_{j=1}^n \gamma_j x_j$. Thus, ML decoding is described as:

Minimize:

$$\sum_{j=1}^n \gamma_j x_j \quad \text{subject to} \quad P_d \mathbf{x} \in \mathbb{P}_d, \quad (1 \leq i \leq m).$$

By the relaxation of each binary variable $x_i (1 \leq i \leq n)$ to the interval $[0,1]$, we obtain LP (linear programming) relaxation of IP (7) (The LP relaxation by Feldman etc. [6] is a kind of this relaxation):

Minimize:

$$\sum_{j=1}^n \gamma_j x_j \quad \text{subject to} \quad P_d \mathbf{x} \in \mathbb{P}_d, \quad (1 \leq i \leq m),$$

where $\mathbb{P}_d$ is a convex hull of $P_d$, i.e. $\mathbb{P}_d = \text{conv}(P_d)$.

C. ADMM formulation

For expressing LP decoding formulation (8) to corresponding ADMM formulation, the “replica” vectors $z_i$, $(1 \leq i \leq m)$ are introduced. Moreover, to accelerate the computation, we also introduce a penalty term. Hence, we consider

Minimize:

$$\sum_{j=1}^n \gamma_j x_j - \alpha \sum_{j=1}^n (x_j - 0.5)^2$$

subject to $P_d \mathbf{x} = z_i, \quad z_i \in \mathbb{P}_d, \quad (1 \leq i \leq m)$,

where $\alpha > 0$ is an acceleration parameter and the second term of objective function is a penalty term. Put $z = (z_1, \ldots, z_m)$ and $\lambda = (\lambda_1, \ldots, \lambda_m)$. The ADMM method optimize the augmented Lagrangian:

$$L_\mu(x, z, \lambda) := \sum_{j=1}^n \gamma_j x_j - \alpha \sum_{j=1}^n (x_j - 0.5)^2$$

$$+ \sum_{i=1}^m \lambda_i^T (P_i x - z_i) + \frac{\mu}{2} \sum_{i=1}^m \|P_i x - z_i\|^2_2,$$

We can write the update steps of ADMM as:

$$x^{q+1} := \arg \min_{x \in [0,1]^n} L_\mu (x, z^q, \lambda^q)$$

$$z_i^{q+1} := \arg \min_{z_i \in \mathbb{P}_d} L_\mu (x^{q+1}, z, \lambda), \quad (1 \leq i \leq m)$$

$$\lambda_i^{q+1} := \lambda_i^q + \mu (P_i x^{q+1} - z_i^{q+1}), \quad (1 \leq i \leq m).$$

Let $\delta x \in \mathbb{R}^n$ be a variation vector of $x$, $\gamma = (\gamma_1, \ldots, \gamma_n)$ and $1 = (1, \ldots, 1)^T$. Then, we obtain

$$L_\mu (x + \delta x, z, \lambda) = L_\mu (x, z, \lambda) + \langle \gamma, \delta x \rangle$$

$$- 2\alpha \langle x - 0.5 \cdot 1, \delta x \rangle + \sum_{i=1}^m \langle \lambda_i, P_i \delta x \rangle$$

$$+ \mu \sum_{i=1}^m \langle P_i x - z_i, P_i \delta x \rangle$$

$$= \langle \gamma, \delta x \rangle - 2\alpha \langle x - 0.5 \cdot 1, \delta x \rangle + \sum_{i=1}^m \langle P_i^T \lambda_i, \delta x \rangle$$

$$+ \mu \sum_{i=1}^m \langle P_i^T P_i \delta x - P_i^T z_i, \delta x \rangle$$

$$= \langle \gamma, \delta x \rangle - 2\alpha \langle x - 0.5 \cdot 1, \delta x \rangle + \sum_{i=1}^m \langle P_i^T \lambda_i, \delta x \rangle$$

$$+ \mu \langle P x - \mu \sum_{i=1}^m P_i^T z_i, \delta x \rangle,$$

where $P = \sum_{i=1}^m P_i^T P_i$. Thus, we obtain,

$$\left( P - \frac{2\alpha}{\mu} I \right) x = \sum_{i=1}^m \left( P_i^T z_i - \frac{1}{\mu} P_i^T \lambda_i \right) - \frac{\alpha}{\mu} x - \frac{\gamma}{\mu}.$$
In the case of (5), we have

\[
P = \sum_{i=1}^{3} P^T_i P_i = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 2 & 0 & 0 \\ 0 & 0 & 0 & 2 & 0 \\ 0 & 0 & 0 & 0 & 2 \end{bmatrix},
\]

and in general, we have \((P)_{i,j} = |N_v(j)| \delta_{i,j}\). For simplicity, we denote by \(z^{(j)}_i\), the \(j\)-th component of \(P^T_i z_i\). Similarly, \(\lambda^{(j)}_i\) denotes the \(j\)-th component of \(P^T_i \lambda_i\). Hence from (12) and the restriction \(x_j \in [0, 1]\) for \(1 \leq j \leq n\), it holds that

\[
x_j = \Pi_{[0,1]} \left( \frac{1}{|N_v(j)|} - \frac{2\alpha}{\mu} \right) \cdot \left\{ \sum_{i=1}^{m} \left( z^{(j)}_i - \frac{\lambda^{(j)}_i}{\mu} \right) - \frac{\alpha + \gamma_j}{\mu} \right\}, \quad (1 \leq j \leq n),
\]

where \(\Pi_{[0,1]}\) is a projection to the interval \([0, 1]\). To obtain the minimizer of the second expression of (11), we rewrite the third and fourth terms of (10) as follows:

\[
\lambda^T_i (P_i x - z_i) + \frac{\mu}{2} \|P_i x - z_i\|^2_2
= \frac{\mu}{2} \left\| P_i x + \frac{\lambda_i}{\mu} - z_i \right\|^2_2 - \frac{\|\lambda_i\|^2_2}{\mu^2}
\]

Hence it holds

\[
z^{q+1}_i = \arg \min_{z_i \in \mathbb{P}_d} \|P_i x^{q+1} + \frac{\lambda_i}{\mu} - z_i\|_2,
\]

which is a metric projection of \(P_i x^{q+1} + \frac{\lambda_i}{\mu}\) onto the closed convex set \(\mathbb{P}_d\) with \(d = N_0d_c\), i.e.

\[
z^{q+1}_i = \Pi_{\mathbb{P}_d} \left( P_i x^{q+1} + \frac{\lambda_i}{\mu} \right).
\]

Summarizing the above argument, the ADMM decoding procedure is described as follows. Recall that \(y = x + e\) is a received message where \(e\) satisfies \(w(e) = t\).

**Algorithm 2** The ADMM decoding algorithm

1: Initialize \(\gamma\) as (6), \(q = 0\), set a positive integer \(M\) and \(\epsilon > 0\), a small number.
2: Initialize \(z_i = P_i^y, \lambda_i = 0, (1 \leq i \leq m)\).
3: repeat
   4: for all \(j \ (1 \leq j \leq n)\) do
   5:     Update \(x_j\) according to (13).
   6: end for
   7: for all \(i \ (1 \leq i \leq m)\) do
   8:     set \(v_i = P_i x + \lambda_i / \mu\).
   9:     \(z_i \leftarrow \Pi_{\mathbb{P}_{n_0d_c}} (v_i)\).
   10:    \(\lambda_i \leftarrow \lambda_i + \mu (P_i x - z_i)\).
11: end for
12: \(q \leftarrow q + 1\)
13: until \(\sum_{i=1}^{m} \|P_i x^q - z^q_i\|^2_2 < \epsilon^2 m d_c\) and
   \(\sum_{i=1}^{m} \|z^q_i - z^{q-1}_i\|^2_2 < \epsilon^2 m d_c\) or \(q > M\)
14: return \(x\).

The most time consuming part of the Algorithm 2 is Step 9: \(z_i \leftarrow \Pi_{\mathbb{P}_{n_0d_c}} (v_i)\), a projection of \(v_i\) to code-polytope \(\mathbb{P}_{n_0d_c}\).

Here, we have to note the projection algorithm to the code-polytope \(\mathbb{P}_{n_0d_c}\) (Algorithm 2 of [2]) seems to need some modification, and without such modification, non-negligible degradation in decoding performance arises. Indeed, sometimes mismatching values were observed for the convex-quadratic programming (20) compared to the one obtained by MIP solver Gurobi optimizer 9.5 [8] (we note replacing the projection algorithm for (20) with MIP solver is unrealistic from the time-consuming view point).

We will show these degradations with numerical examples. Figure 1 shows the DER of each decoding method for \((n, k) = (2000, 1000)\) and \(d_c = 5\) LDPC code.

![Fig. 1. DER of each decoding method for \((n, k) = (2000, 1000)\) and \(d_c = 5\) LDPC code.](image)

(2000, 1000) and \(d_c = 5\) LDPC code. In the figure labels “SPA” and “BF” mean sum-product algorithm and bit-flipping algorithm respectively. While labels “PROJ\_O” and “PROJ” mean ADMM decoding with original projection algorithm of [2] (Algorithm 2) and corrected projection algorithm respectively. We can observe that “PROJ” decreases DER about 1/10 times to “PROJ\_O” for each error number \(t\) and even superior to SPA. We note both ADMM decodings use parameters \(\alpha = 10, \mu = 6\) and \(M = 10000\). Figure 2 shows the DER of each decoding method for \((n, k) = (2000, 1000)\) and \(d_c = 25\) MDPC code. In this case SPA deteriorates its performance compared to the of Figure 1 since the low-density property of parity check matrix was lost. Comparing “PROJ\_O” with “PROJ”, we observe that in this case “PROJ” also decreases DER about 1/10 times to “PROJ\_O\_O” for each error number \(t\). We note both ADMM decoding use parameters \(\alpha = 10, \mu = 6\) and \(M = 10000\).

From these observations, we conclude that the correction of projection algorithm is an important factor for the improvement of DER.

**D. Modified projection algorithm**

Following is a correction of projection algorithm to \(\mathbb{P}_{n_0d_c}\). For simplicity, we abbreviate \(d = N_0d_c\) and denote by \([x]_{even}^\text{even}\).
the largest even number integer smaller than $x$. The correctness of the following algorithm is shown in Appendix VI.

**Algorithm 3** The projection algorithm $\Pi_{PP_d}(u)$

1. Permutate $u$ to $v$ in descending order: $v_1 \geq v_2 \geq \cdots \geq v_d$. Let $Q$ be the corresponding permutation matrix i.e. $v = Qu$.
2. $\hat{z} \leftarrow \Pi_{[0,1]}(v)$. Put $r = ||\hat{z}||_1$ even.
3. Put $f = (f_1, \ldots, f_d)$ and set $f_i = 1$, $(1 \leq i \leq r + 1)$, $f_i = -1$, $(r + 2 \leq i \leq d)$.
4. if $r = d$ or $r = d - 1$ then
   5. return $Q^T \hat{z}$.
    6. end if
7. if $\sum_{i=1}^{d} f_i \hat{z}_i \leq r$ then
6. return $Q^T \hat{z}$.
9. end if
10. set $\beta_{\text{max}} \leftarrow \frac{1}{r} (v_{r+1} - v_{r+2})$.
11. set $\beta = \left\{ \beta_1, \ldots, \beta_{2d} \right\}$ as
   \[
   \beta_i = \begin{cases} 
   v_i - 1, & (1 \leq i \leq r + 1) \\
   -v_i, & (r + 2 \leq i \leq d) \\
   v_i, & (d + 1 \leq i \leq d + r + 1) \\
   1 - v_i, & (d + r + 2 \leq i \leq 2d).
   \end{cases}
   \]
12. set $\tilde{\beta} = \left\{ \tilde{\beta} \in \beta \cup \{0\} \cup \{\beta_{\text{max}}\} \mid 0 \leq \tilde{\beta} \leq \beta_{\text{max}} \right\}$.
13. Sort $\tilde{\beta}$ to $\beta$ in ascending order. Hence $\beta = \{\beta_1, \beta_2, \ldots, \beta_p\}$ satisfies $0 = \beta_0 < \beta_1 < \cdots < \beta_p = \beta_{\text{max}}$.
14. set $L \leftarrow 0, R \leftarrow p, M \leftarrow \lfloor (L + R)/2 \rfloor$.
15. while $R - L > 1$ do
16. set $\hat{z}_i = \begin{cases} 
   v_i - \beta_M, & (1 \leq i \leq r + 1) \\
   v_i + \beta_M, & (r + 2 \leq i \leq d).
   \end{cases}$
17. if $\sum_{i=1}^{d} f_i \cdot (\Pi_{[0,1]}(\hat{z}_i)) < r$ then
18. $R \leftarrow M$.
19. else
20. $L \leftarrow M$.
21. end if
22. $M \leftarrow \lfloor (L + R)/2 \rfloor$.
23. end while
24. set
   \[
   \hat{z}_i = \begin{cases} 
   v_i - \beta_R, & (1 \leq i \leq r + 1) \\
   v_i + \beta_R, & (r + 2 \leq i \leq d).
   \end{cases}
   \]
25. set $f_z \leftarrow \sum_{i=1}^{d} f_i \cdot (\Pi_{[0,1]}(\hat{z}_i))$.
26. set $\beta_{\text{opt}} \leftarrow \max \left\{ \frac{(r - f_z)(\beta_R - \beta_L)}{f_z - f_{z_0}} + \beta_R \right\}$.
27. set $f_{z_0} \leftarrow \sum_{i=1}^{d} f_i \cdot (\Pi_{[0,1]}(\hat{z}_i))$.
28. set $\beta_{\text{opt}} \leftarrow \frac{(r - f_z)(\beta_R - \beta_L)}{f_z - f_{z_0}} + \beta_R$.
29. set $z_i, (1 \leq i \leq d)$ as
   \[
   z_i = \begin{cases} 
   \Pi_{[0,1]}(v_i - \beta_{\text{opt}}), & (1 \leq i \leq r + 1) \\
   \Pi_{[0,1]}(v_i + \beta_{\text{opt}}), & (r + 1 \leq i \leq d).
   \end{cases}
   \]
30. return $Q^T z$.

IV. NUMERICAL EXPERIMENTS

We examine the proposing ADMM based decoding with some parameters of Table II of [11]. Numerical examinations were executed on Intel Core i9-7980XE CPU @ 2.60GHz processor, with no parallelization (except Step 8 in Algorithm 5 where $N_{SPA}$ parallelization were applied) and ANSI C implementation (icc 2021.6.0 with -O3 option). For $(n, k, d_c, n_0) = (9802, 4601, 45, 2)$ code, execution time ratio (execution time of BF was taken as a reference point since in both $t = 100$ and $t = 105$ cases, it was the fastest algorithm) is as Table I. The number of experiments for each method is 100000 times. In SP, maximum iteration number is set as 50 and in ADMM, parameters are set as $(\mu, \alpha, M) = (6, 15, 10000)$. The label “ME” is the “matrix-extension” method proposed in [5]. The maximum extension size of parity matrix is 14403 × 19204. For $(n, k, d_c, n_0) = (10779, 3593, 51, 3)$ code, execution time ratio is as Table II. In SP, maximum iteration number is set as 50 and in ADMM, parameters are set as $(\mu, \alpha, M) = (8, 15, 10000)$. In this case the maximum extension size of parity matrix in “ME” is 14372 × 21588.

Although as we can recognize from Figures 2, 7 and 8, error correction ability of ADMM is outstanding compared to other three methods (BF, SP, ME), average decoding time requires about 2.8 ~ 7.8 times compared to BF decoding. For filling this gap, without using hardware implementation,

</table>
we pursue yet another algorithm RSPA (Reproducing Sum-Product Algorithm) which effectively reuse outputs of SPA. Algorithm of RSPA is as follows:

Algorithm 4 The reproducing sum-product algorithm

1: set $N_{SPA}$ as maximum iteration number, $i = 0$.
2: while $i < N_{SPA}$ do
3: set $c'$ as decoding result of SPA for $c$ (after hard decision is applied to each bits).
4: if $Hc'^T = 0$ then
5: return $c'$.
6: end if
7: $c \leftarrow c'$.
8: $i \leftarrow i + 1$.
9: end while
10: return decoding failure.

We consider the case $He^T \neq 0$. Put the difference between noiseless received information $mG'$ and decoding result of SPA (after hard decision to each bits) as $d_h(c')$: i.e. $d_h(c') = w(mG' - c')$. Thus $d_h(c') - t$ represents decrease (if $d_h(c') - t < 0$) and increase (if $d_h(c') - t > 0$) of error bits number $\|e\|_1$ after hard decision. Figure 3 show the number of observed values of $d_h(c') - t$ when $t = 110$. For example, the number of trials which take $-5 \leq d_h(c') - t \leq -1$ occupies 51, while the number of trials which take $1 \leq d_h(c') - t \leq 5$ is 5, under total 100 decoding errors. Figure 4 shows the number increases. We note that the same effect cannot be expected for BF algorithm. Figure 5 and 6 are results obtained by replacing the decoding method SPA in Algorithm 4 to BF under the circumstance of Figure 3 and 4 respectively. We observe that Figure 5 and 6 show $d_h(c') - t > 0$ almost all cases, and hence we cannot expect the reduction of erroneous bits by successive hard decision of decoding results.

After each iteration of RSPA, in most case, erroneous bits are expected to reduce, so by applying ADMM method to $c$ obtained by hard decision in Step 7, further improvement of DER will be expected. We call this hybrid algorithm RSPA-ADMM method.

Algorithm 5 The RSPA-ADMM method.

1: set $N_{SPA}$ as maximum iteration number, $i = 0$.
2: while $i < N_{SPA}$ do
3: set $c'$ as decoding result of SPA for $c$ (after hard decision is applied to each bits).
4: if $Hc'^T = 0$ then
5: return $c'$.
6: end if
7: $c \leftarrow c'$.

Fig. 3. The barchart of the number of observed values of $w(mG' - h(c'))$ in the case of SPA decoding and $(n, k, d_c, n_0) = (10779, 3593, 51, 3)$ code ($t = 110$).

Fig. 4. The bar chart of the number of observed values of $w(mG' - h(c'))$ in the case of SPA decoding and $(n, k, d_c, n_0) = (9602, 4801, 45, 2)$ code ($t = 95$).

Fig. 5. The barchart of the number of observed values of $w(mG' - h(c'))$ in the case of BF decoding and $(n, k, d_c, n_0) = (9602, 4801, 45, 2)$ code ($t = 110$).
We note Step 8 can be done in parallel. As an effect of the introduction of RSPA-ADMM method, it is observed that the average decoding time is reduced to 1.55∼4.02 times compared to BF decoding.

V. DISCUSSION

This paper presented the effectiveness of ADMM based methods in decoding QC-MDPC codes. Since proposing two methods ADMM and RSPA-ADMM have abilities to correct more errors than standard error number assumed for BF algorithm, these ADMM based decoding can detect irregular usage of error numbers that aimed for the collection of DER information by adversaries. Hence, proposing schemes may serve as an audit device which guard the conventional BF algorithm based decoding systems.

Although ADMM based decoding showed certain improvements in DER, following problems remains. First, the systematic methods for the determination of the optimal parameters (μ, α) in ADMM decoding algorithm. Second, an acceleration problem of the ADMM decoding methods. In Algorithm 2, Step 5 can be done in parallel. Thus, the acceleration of parameters μ and α were chosen by heuristic trials, hence these may not be an optimal choice. In spite of this, it would be remarkable that ADMM and RSPA-ADMM attains DFR lower than $10^{-7}$ at $t = 103$ compared to the result that the original BF decoding requires $t = 87$ for attaining almost the same DFR. We note DER of RSPA-ADMM when $t = 103$ might be less than $10^{-7}$, since no decoding error was observed under $10^8$ trials. Figure 8 shows the DER of 6 methods (SPA, BF, ME, RSPA, ADMM, RSPA-ADMM) for $(n, k, d_c, n_0) = (10779, 3593, 51, 3)$ code.

Figure 7 shows the DER of 6 methods (SPA, BF, ME, RSPA, ADMM, RSPA-ADMM) for $(n, k, d_c, n_0) = (9602, 4801, 45, 2)$ code. The maximum iteration number of SP was set to 50. The parameters (μ, α, M) in ADMM and RSPA-ADMM methods were fixed to (6, 15, 10000). We note DER of RSPA-ADMM when $t = 66$ might be less than $10^{-8}$, since no decoding error was observed under $10^8$ trials.

The maximum iteration number of SP was set to 50. The parameters (μ, α, M) in ADMM and RSPA-ADMM methods were fixed to (6, 15, 10000). We note DER of RSPA-ADMM when $t = 66$ might be less than $10^{-8}$, since no decoding error was observed under $10^8$ trials.

This paper presented the effectiveness of ADMM based methods in decoding QC-MDPC codes. Since proposing two methods ADMM and RSPA-ADMM have abilities to correct more errors than standard error number assumed for BF algorithm, these ADMM based decoding can detect irregular usage of error numbers that aimed for the collection of DER information by adversaries. Hence, proposing schemes may serve as an audit device which guard the conventional BF algorithm based decoding systems.

Although ADMM based decoding showed certain improvements in DER, following problems remains. First, the systematic methods for the determination of the optimal parameters (μ, α) in ADMM decoding algorithm. Second, an acceleration problem of the ADMM decoding methods. In Algorithm 2, Step 5 can be done in parallel. Thus, the acceleration of
projection to $\Pi_{PP_d^{min}}$ remains as essential problem. Zhang-Siegel [14] is proposing an alternative projection algorithm that is reported to be effective in the improvement of decoding speed for LDPC codes. The essential improvement of [14] is replacing sorting operation in Step 1 of Algorithm 3 with “cut search algorithm”. Since the numbers of $n_0 d_s$ that should be sorted in Step 1 of Algorithm 3 are rather large number for MDPC codes compared to LDPC codes cases, the “cut search algorithm” might work more effectively than LDPC codes cases in [14].

VI. APPENDIX

A. Preparation

In this section, we show the validity of projection algorithm 3 for the sake of completeness. The main difference with Algorithm 2 of [2] is the set $\hat{\beta}$ in Step 11 of Algorithm 3. In Algorithm 2 of [2], the set $\hat{\beta}$ is defined as:

$$\hat{\beta}_i = \begin{cases} v_i - 1, & (1 \leq i \leq r + 1) \\ -v_i, & (r + 2 \leq i \leq d). \end{cases}$$

This seems to be the main factor which cause non-negligible degradation of DER in Figure 1 and 2.

First, we prepare lemmas necessary for our purpose.

Lemma 6.1 ([2, Proposition 3]): Assume the components of $v \in \mathbb{R}^d$ is sorted in descending (ascending) order, then the components of $\Pi_{PP_d}$ maintain this order.

Definition 6.2: Assume the components of $v, w \in \mathbb{R}^d$ are sorted in descending order, i.e.

$$v_1 \geq v_2 \geq \cdots \geq v_d, \quad w_1 \geq w_2 \geq \cdots \geq w_d.$$

Then the vector $w$ is said to “majorizes” $u$ if

$$\begin{align*}
\sum_{k=1}^{q} u_k &\leq \sum_{k=1}^{q} v_k, & (1 \leq q \leq d - 1) \\
\sum_{k=1}^{d} u_k &\leq \sum_{k=1}^{d} v_k.
\end{align*}$$

Lemma 6.3 ([2, Theorem 1]): Suppose vectors $u$ and $w$ are sorted in descending order. Then $u$ is in the convex hull of all permutations of $w$ if and only if $w$ majorizes $u$.

We define $P^d = \{x \in \{0, 1\}^d \mid \|x\|_1 = s\}$ and $PP^d = \text{conv}(P^d)$. Recall that $PP_d = \text{conv}(P_d)$, so it holds

$$PP_d = \text{conv} \left( \cup_{0 \leq s \leq d, s \text{ even}} PP^d \right).$$

From Lemma 6.3, it holds that $u \in PP_d s$ if and only if

$$\begin{align*}
\sum_{k=1}^{q} u_k &\leq \min(q, s), & (1 \leq q \leq d - 1) \\
\sum_{k=1}^{d} u_k &= s.
\end{align*}$$

Further, following lemma (two-slice lemma) holds:

Lemma 6.4 ([2, Lemma 2]): Suppose the components of $z \in PP_d$ is sorted in descending order. Define $r$ be the minimum even integer greater than or equal to $\|z\|_1 \text{even}$. Then $z$ is expressed by convex combination of $PP_d$ and $PP_d^{r+2}$.

Suppose $u \in PP_d \cap [0, 1]^d$ and $v \in PP_d^{r+2} \cap [0, 1]^d$. Then, from Lemma 6.4, for $\alpha$ satisfying $0 \leq \alpha \leq 1$, it holds

$$\begin{align*}
\sum_{k=1}^{q} z_k &= \sum_{k=1}^{q} (\alpha u_k + (1 - \alpha) v_k) \\
&= \alpha \sum_{k=1}^{q} u_k + (1 - \alpha) \sum_{k=1}^{q} v_k \\
&\leq \alpha \min(q, r) + (1 - \alpha) \min(q, r + 2), & (1 \leq q \leq d - 1).
\end{align*}$$

and

$$\begin{align*}
\sum_{k=1}^{d} z_k &= \sum_{k=1}^{d} (\alpha u_k + (1 - \alpha) v_k) \\
&= \alpha \sum_{k=1}^{d} u_k + (1 - \alpha) \sum_{k=1}^{d} v_k = \alpha r + (1 - \alpha)(r + 2).
\end{align*}$$

We note in the case $q \leq r$, (17) clearly holds. While in the case $q \geq r + 2$, (since $d - 1 \geq q \geq r + 2$, this case occurs when $r + 3 \leq d$), we can observe (17) holds if(18) is valid. Thus, (17) should be considered only for the case $q = r + 1$. For the case $q = r + 1$, (since $d - 1 \geq q = r + 1$, this case occurs when $r + 2 \leq d$) (17) becomes as follows

$$\sum_{k=1}^{r+1} z_k \leq \alpha r + (1 - \alpha)(r + 1) = r + 1 - \alpha, \quad (r + 2 \leq d).$$

From (18), we have

$$\alpha = 1 - \frac{1}{2} \left( r - \sum_{k=1}^{d} z_k \right),$$

and hence the projection $\Pi_{PP_d}(v)$ for $v \in \mathbb{R}^d$ is described as convex quadratic programming problem:

(P) Minimize $\|v - z\|^2$  

Subject to

$$\begin{align*}
0 &\leq z_i \leq 1, & (1 \leq i \leq d) \\
z_i &\geq z_{i+1}, & (1 \leq i \leq d - 1) \\
r &\leq \sum_{k=1}^{d} z_k \leq r + 2 & \leftrightarrow 0 \leq \alpha \leq 1 \\
\sum_{k=1}^{r+1} z_k - \sum_{k=r+2}^{d} z_k &\leq r, & (r + 2 \leq d) \leftrightarrow (19). \end{align*}$$

We note (24) is valid only in the case $r + 2 \leq d$ and in this case we can express (24)by

$$f^T z \leq r$$

where $f^T = (1, \ldots, 1, -1, \ldots, -1)$.

Following lemma is well-known.

Lemma 6.5: Assume $f, g_i, (1 \leq i \leq m)$ are all convex functions on $\mathbb{R}^d$. Define the minimization problem:

(CP) Minimize $f(x)$  

Subject to $g_i(x) \leq 0, \quad (1 \leq i \leq m), \quad x \in \mathbb{R}^d.$
Suppose \( \bar{x} \) satisfies Karush-Kuhn-Tucker (KKT) conditions. Then \( \bar{x} \) is a (global) minimizer of problem (CP).

In the case of problem (P), \( f \) is a strictly convex function on \( \mathbb{R}^d \), thus we obtain:

**Lemma 6.6:** Assume \( \bar{x} \) satisfies KKT condition for problem (P). Then \( \bar{x} \) is a unique (global) minimizer of problem (P).

### B. Validity of Algorithm 3

Since \( r = \| \| \tilde{x} \| \|_{1, \text{even}} \) (step 2), we have

\[
r \leq d.
\]

(27)

As noted (25) is valid only in the case \( r + 2 \leq d \), we consider the cases \( r = d \) or \( r + 1 = d \) for problem (P). For these cases, from the definition of \( r \) it holds

\[
r \leq \sum_{k=1}^{d} \tilde{z}_k \leq r + 2.
\]

Since \( v_1 \geq v_2 \geq \cdots \geq v_d \), \( \hat{z}_k (1 \leq k \leq d) \) keeps this order. Thus

\[
\hat{z}_{k+1} - \hat{z}_k \geq 0, \quad (1 \leq k \leq d - 1).
\]

From the definition \( 0 \leq \hat{z}_k \leq 1, \quad (1 \leq k \leq d) \). Hence \( \hat{z} \) is a minimizer of problem (P) under constraint conditions (21), (22) and (23); (see steps 4 and 5).

Hereafter, we fix \( r + 2 \leq d \). First we consider the case \( f_T^T \hat{z} \leq r \). As in the case \( r = d \) or \( r + 1 = d \), \( \hat{z} \) satisfies conditions (21), (22) and (23). Moreover, form the assumption (24) is satisfied. Hence \( \hat{z} \) is a minimizer of problem (P); (see step 7 and 8).

Hence we can assume

\[
f_T^T \hat{z} > r.
\]

(28)

The KKT condition for the problem (P) is described as: there exists \( \beta, \nu, \eta, \xi, \theta \) and \( \zeta \) such that following conditions are satisfied.

\[
z = v - f_T \beta - \nu - \eta (\xi - \zeta) 1 + S^T \theta,
\]

(29)

\[
0 \leq \beta \perp f_T^T z - r \leq 0,
\]

(30)

\[
0 \leq \nu \perp z \leq 1,
\]

(31)

\[
0 \leq \eta \perp z \geq 0,
\]

(32)

\[
\theta \perp Sz \geq 0,
\]

(33)

\[
0 \leq \xi \perp 1^T z - r - 2 \leq 0,
\]

(34)

\[
0 \leq \zeta \perp 1^T z - r \geq 0,
\]

(35)

then \( z \) is a unique minimizer of (P). Here \( \perp \) means for example for (31) \( \nu_i (1 - \xi_i) = 0, \quad (1 \leq i \leq d) \) and

\[
S = \begin{bmatrix}
1 & -1 & 0 & 0 & \cdots & 0 & 0 \\
0 & 1 & -1 & 0 & \cdots & 0 & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\
0 & 0 & 0 & 0 & \cdots & 1 & -1
\end{bmatrix}.
\]

We note the uniqueness of the minimizer follows from Lemma 6.5.

In the following we see that such \( \beta, \nu, \eta, \xi, \theta \) and \( \zeta \) exists. For fixed \( \beta > 0 \) we decide \( \nu_i, \quad (1 \leq i \leq d) \) as follows:

\[
\nu_i = \begin{cases}
0, & v_i - \beta (f_T) \leq 1 \\
v_i - \beta (f_T), & 1 < v_i - \beta (f_T) \leq 1
\end{cases}
\]

(36)

Similarly, \( \eta_i \) is decided as follows:

\[
\eta_i = \begin{cases}
0, & v_i - (f_T) \geq 0 \\
v_i + \beta (f_T), & 1 < v_i - (f_T) \leq 0
\end{cases}
\]

(37)

Moreover, we fix \( \xi = \zeta = 0 \) and \( \theta = 0 \). From these \( z \), which is the LHS of (29) is regarded as a function of \( \beta \) and expressed as

\[
z(\beta) = \Pi_{[0,1]}^d (v - \beta f_T).
\]

(38)

Hence, from (36), condition (31) is satisfied, also form (37), condition (32) is satisfied. As Step 10, range of \( \beta \) is defined as

\[
0 \leq \beta \leq \beta_{\text{max}} = \frac{1}{2} (v_{r+1} - v_{r+2}).
\]

(39)

We note following holds:

\[
\beta \leq \beta_{\text{max}} \iff v_{r+2} + \beta \leq v_{r+1} - \beta.
\]

From

\[
(z(\beta_{\text{max}}))_{r+1} = \Pi_{[0,1]}^d (v_{r+1} - \beta_{\text{max}})
\]

(40)

and

\[
(z(\beta_{\text{max}}))_{r+2} = \Pi_{[0,1]}^d (v_{r+2} + \beta_{\text{max}})
\]

(41)

we have

\[
f_T z(\beta_{\text{max}}) = \sum_{i=1}^{r} (z(\beta_{\text{max}}))_i + (z(\beta_{\text{max}}))_{r+1}
\]

(42)

Since from (28)

\[
f_T z(0) = f_T \hat{z} > r,
\]

there exists \( \beta_{\text{max}} \quad (0 < \beta_{\text{opt}} \leq \beta_{\text{max}}) \) such that

\[
f_T z(\beta_{\text{opt}}) = r.
\]

(43)

We will show that \( z(\beta_{\text{opt}}) \) satisfies KKT condition (recall that conditions (31) and (32) are already satisfied). From (40), the condition (30) is satisfied.
To see (33), $Sz(β_{opt}) > 0$ is enough (since $θ = 0$, $\perp$ relation is satisfied). From the assumption (Step 1), for non-negative $β$ it holds

$$v_1 − β ≥ v_2 − β ≥ \cdots ≥ v_{r+1} − β$$

and

$$v_{r+2} + β ≥ v_{r+3} + β ≥ \cdots ≥ v_d + β.$$

Since $v_{r+1} − β ≥ v_{r+2} + β$ we have

$$β ≤ \frac{1}{2} (v_{r+1} − v_{r+2}) = β_{max}.$$

Thus, we have shown (33).

To see (34) and (35)

$$r ≤ \sum_{i=1}^{d} (z(β_{opt}))_i ≤ r + 2$$

is enough. From (28),

$$r ≤ r + 2 \sum_{i=r+2}^{d} (z(β_{opt}))_i = \sum_{i=1}^{d} (z(β_{opt}))_i.$$

Also from (28),

$$\sum_{i=r+2}^{d} (z(β_{opt}))_i = \sum_{i=1}^{r+1} (z(β_{opt}))_i − r ≤ r + 1 − r = 1,$$

we obtain

$$\sum_{i=1}^{d} (z(β_{opt}))_i = \sum_{i=1}^{r+1} (z(β_{opt}))_i + \sum_{i=r+2}^{d} (z(β_{opt}))_i ≤ r + 1 + 1 = r + 2.$$

Hence, we have shown conditions (34) and (35). Moreover, from Lemma 6.5, $β_{opt}$ is unique. Summarizing the argument, we have shown that $z(β_{opt})$ is the unique minimizer of the problem (P).

### C. Searching method for $β_{opt}$

Since $β_{opt}$ is unique, bi-section method is effective. Define

$$\varphi(β) = fr(β).$$

We can observe that $φ$ is continuous and piecewise linear function. The possible non-differentiable points are such $β$, satisfying $v_i − β = 1$ or $v_i − β = 0$ or $v_i + β = 1$ or $v_i + β = 0$.

We divide set of these possible non-differentiable points in to four sets:

$$E_1 = \{v_i − 1 \mid 1 ≤ i ≤ r + 1\},$$

$$L_1 = \{v_i \mid 1 ≤ i ≤ r + 1\},$$

$$E_3 = \{1 − v_i \mid r + 2 ≤ i ≤ d\},$$

$$L_2 = \{v_i \mid 1 ≤ r + 2 ≤ d\}$$

and put

$$\hat{β} = E_1 \cup L_1 \cup E_2 \cup L_2.$$

We set

$$\hat{β} \leftarrow \{β ∈ \hat{β} \cup \{0\} \mid 0 ≤ \hat{β} ≤ β_{max}\}$$

and sort $β$ to $β$ in ascending order. Hence $β = \{β_1, β_2, \ldots, β_p\}$ satisfies $0 ≤ β_0 < β_1 < \cdots < β_p = β_{max}$ (Step 12 and 13). We can find $β_{opt}$ effectively with bi-section method by finding points $β_j$ and $β_{j+1}$ satisfying $\sum_{i=1}^{j} (f_r)_i (z(β_j))_i > r$ and $\sum_{i=j+1}^{p} (f_r)_i (z(β_{j+1}))_i > r$ ($0 ≤ j ≤ p − 1$).
