Accountable Decryption made Formal and Practical

Rujia Li, IEEE Member, Yuanzhao Li, IEEE Student Member, Qin Wang, IEEE Member, Sisi Duan, IEEE Senior Member, Qi Wang, IEEE Member, and Mark Ryan

Abstract—With the increasing scale and complexity of online activities, accountability, as an after-the-fact mechanism, has become an effective complementary approach to ensure system security. Decades of research have delved into the connotation of accountability. They fail, however, to achieve practical accountability of decryption. This paper seeks to address this gap. We consider the scenario where a client (called encryptor, her) encrypts her data and then chooses a delegate (a.k.a. decryptor, him) that stores data for her. If the decryptor initiates an illegitimate decryption on the encrypted data, there is a non-negligible probability that this behavior will be detected, thereby holding the decryptor accountable for his decryption. We make three contributions. First, we review key definitions of accountability known so far. Based on extensive investigations, we formalize new definitions of accountability specifically targeting the decryption process, denoted as accountable decryption, and discuss the (im)possibilities when capturing this concept. We also define the security goals in correspondence. Secondly, we present a novel Trusted Execution Environment (TEE)-assisted solution aligning with definitions. Instead of fully trusting TEE, we take a further step, making TEE work in the “trust, but verify” model where we trust TEE and use its service, but empower users (i.e., decryptors) to detect the potentially compromised state of TEEs. Thirdly, we implement a full-fledged system and conduct a series of evaluations. The results demonstrate that our solution is efficient. Even in a scenario involving 300,000 log entries, the decryption process concludes in approximately 5.5ms, and malicious decryptors can be identified within 60ms.

Index Terms—Accountability, Decryption, Trusted Hardware

1 INTRODUCTION

Modern cryptographic systems mainly depend on preventive strategies such as passwords, access control mechanisms, and authentication protocols to ensure privacy and security. Prior to gaining access to sensitive data or performing any action that raises privacy or security concerns, individuals must demonstrate their authorization to do so. These preventive strategies can indeed offer a degree of protection against unauthorized users attempting to infiltrate the system. Nonetheless, as the scale and complexity of computer systems increase dramatically, it has become increasingly evident that relying solely on a preventive approach is insufficient. In some break-glass scenarios [1], users have to bypass the preventive strategies to access sensitive information. Consequently, accountability becomes a crucial mechanism to supplement preventive strategies, as it can identify and punish malicious individuals who breach pre-established rules after accessing sensitive data [2].

In this work, we formalize the concept of accountable decryption [3][4], which is an innovative approach that allows users to share the ability to access a specific piece of information, simultaneously providing evidence of whether the information has been accessed or not. We consider a scenario with three roles, as illustrated in Figure 1(a): encryptor, decryptor, and judge. An encryptor is a person who provides access for a decryptor to her encrypted data and defines policies to restrain how the decryption can be conducted. A decryptor decrypts the ciphertext and recovers the original data. Each decryption operation performed by the decryptor unavoidably produces evidence of the decryption which undergoes scrutiny by a judge. The judge verifies whether the conducted decryption complies with the predefined policies. If any policy violation is detected, the judge imposes appropriate punishments on the decryptor. In this way, the decryptor is accountable for his behavior.

Bringing accountability for decryption offers many benefits. For example, in electronic surveillance [5], the law-enforcement agency seeks access to users’ sensitive data from tech companies. Yet, confidential court-ordered inquiries are processed privately to ensure investigation integrity. This curtails oversight of privacy-sensitive government actions. Indeed, there are concerns about government power and privacy, as there is a risk of eavesdropping on legal citizens. Accountable decryption offers a potential solution in this case: a user (encryptor), law-enforcement agency (decryptor), and overseer (judge) work in tandem to strike a balance between investigation requirements and privacy requirements. On the one hand, accountable decryption allows law-enforcement agencies to access sensitive data in adherence to investigative orders. On the other hand, it facilitates the detection of potential abuses of the granted warrant, as overseers can verify whether law-enforcement agencies comply with the court order’s limits.

Beyond electronic surveillance, the practical accountability of decryption offers a range of general benefits for many applications (cf. Section 9.2). We summarize these benefits

as follows.

- **Detection of unauthorized access.** Accountable decryption allows the encryptor to audit the decryption process [3].
- **Deterrents of illegal behaviours** [4]. The decryptor is responsible for its actions, as any violation of the access control to the data can be caught and punished [7].
- **Regulatory compliance.** One can also implement regulatory compliance with the pre-defined policies. The accountability of a decryptor’s behavior demonstrates his compliance with regulations, as a verifiable record of decryption events is provided.
- **Key leakage awareness.** If a decryptor discovers that her ciphertexts have been decrypted without her permission, she will be alerted of a potential leakage of decryption keys.

**Reviewing accountability definitions in the literature.**

The concept of accountability has been defined in different contexts. We reviewed accountability definitions in the literature, including those defined for identity authentication [3][9], non-tampering evidence [1][6], and policy violations [7][10]. Our observation is that while these definitions share similarities and follow the general principle of after-the-fact behavior checking and misconduct blaming [1][12], we still need a new notion for accountable decryption.

In particular, prior definitions only provide a rather high-level abstraction of accountability. For instance, they fail to delineate what constitutes legitimate decryption activities. Furthermore, prior definitions often assume the existence of a trusted third party responsible for managing and tracking evidence of actions without addressing scenarios where this intermediary is compromised. Accordingly, we extend prior definitions and propose a new definition for accountable decryption.

**Formalizing definitions and properties for accountable decryption.**

We propose new definitions of accountability that specifically target the decryption process. We emphasize two fundamental pillars for achieving ideal accountability of decryption (cf. Definition [10]). First, our definitions ensure that dishonest decryptors can always be detected and punished (non-repudiation). Second, we ensure that honest decryptors are never wrongly accused and punished (non-frameability). This definition is derived from the synthesis of existing studies with various emphases. It encompasses faithful compliance at every stage, including policy setting, action performance, post-feedback, and punishments with appropriate punishments.

![Diagram](https://example.com/diagram.png)

**Figure 1:** General review on our solution

The above definition, however, might seem sufficient for defining the accountability of decryption. In practice, the decryption is conducted in the decryptor’s local client. A decryptor could decrypt the ciphertext silently and secretly without providing decryption evidence to the judge, and thus, the misbehavior cannot be captured [4]. To achieve the requirement that the decryptor’s actions are visible to the judge, we require another party called *trustee (TS)*, which holds the decryption key. It receives requests from the decryptor and enforces the visibility of the requests to the judge. We show the solution in Figure 1(b). Unfortunately, this reliance on specific roles may raise another concern for our definition, as the TS may become corrupted or untrustworthy. Thus, we propose two practical definitions for accountable decryption, considering a trusted TS (cf. Definition [12]) and an untrusted TS (cf. Definition [15]).

**Building a practical accountable decryption scheme.**

We construct an innovative scheme that achieves accountable decryption, called **PORTEX.** Our solution leverages trusted hardware as the trustee, specifically Trusted Execution Environments (TEEs) [13][14][15]. In particular, by integrating TEEs into the trustees’ infrastructure, the decryptor’s private key and the audit trail of data access are securely protected by trusted hardware. Every time decryption is required, the decryptor must initiate a request to the trusted hardware. In response, the trusted hardware not only supplies the necessary decryption key but also records evidence of the transaction. This process ensures that decryption activities are accountable, thereby fulfilling the criteria outlined in Definition [12].

We have noticed that TEEs are vulnerable to fault attacks [16], software attacks [17], and side-channel attacks [18], et al. While certain countermeasures (e.g., software patches) can mitigate some of these vulnerabilities, achieving a completely secure TEE remains uncertain. Recent research [19][20] has highlighted that a compromised TEE cannot maintain the foundational security properties expected of TEE-based systems. In light of these challenges, our approach deviates from the traditional reliance on the inherent trustworthiness of TEEs. Instead, we introduce two algorithms to cope with TEE failures. The first algorithm inspired by the key management solutions used in [21][22], is designed such that TEE only stores a partial key while the user securely holds another portion. Even if attackers compromise the TEE, they cannot deduce a complete decryption key. The second algorithm adopts a *trust, but verify* model, where we trust TEE and use its service, but empower users (i.e., decryptors) to detect the potentially compromised state of TEEs. This minimizes losses upon detecting a compromised state. By these algorithms, our system is in accordance with Definition [15].

To the best of our knowledge, we proposed the first practical solution that achieves accountability in TEE-based systems without assuming absolute trust in TEEs.

**Providing full-fledged implementation and evaluations.**

We provide a fully functional implementation including encryption module, decryption module, tracing module, and conduct a series of evaluations for our implementation. Experimental results further demonstrate that our system is efficient. Even in an extreme scenario involving 300,000

1 Released at [https://github.com/portex-tee/portex](https://github.com/portex-tee/portex)
2 Public service at [http://ac-dec.com](http://ac-dec.com)
log entries, the decryption process concludes in approximately 5.5ms. Furthermore, a user can identify the malicious decryptor within 69ms, while the compromised TEE is detected in a mere 4.3ms. In addition, we benchmark our proposed system against state-of-the-art studies. The results indicate that our system offers a more practical solution, as it obviates the need for a centralized storage center for ciphertext backups, thereby reducing both the number of participants and the frequency of interactions.

## 2 PRELIMINARIES

**Trusted hardware.** We use the trusted execution environment in this work. TEE is a secure area within the main processor that operates as an isolated kernel. It ensures the confidentiality and integrity of sensitive data and computations. State-of-the-art TEE implementations include Intel Software Guard Extensions (SGX) [13], ARM TrustZone [14], RISC-V Keystone [15]. A TEE typically provides features including: runtime isolation and local/remote attestation. Without loss of generality, we use Intel SGX as the TEE instance to illustrate TEE’s key features. Runtime isolation guarantees that the code execution is isolated from untrusted memory regions. Attestation proves that the application is running within trusted hardware. By following several notions from [23], we define TEE as general trusted hardware HW.

**Definition 1** (Trusted hardware, HW). HW for executing a probabilistic polynomial time (PPT) program \( Q \) consists of algorithms \( \{ \text{HW.Setup, HW.Load, HW.Run, HW.Run&Quote, HW.VerifyQuote} \} \).

- **HW.Setup(\( \lambda \))**: The algorithm inputs the security parameter \( \lambda \), creates a secret key \( \text{sk}_\text{quote} \) for signing remote attestation quotes, and outputs public parameters \( pms_{\text{hw}} \).
- **HW.Load(\( pms_{\text{hw}}, Q \))**: The algorithm creates an enclave and loads the code \( Q \) into the created enclave. It outputs the handle \( hdl \) of an enclave.
- **HW.Run(hdl, in)**: The algorithm executes the program in the enclave with an input \( in \).
- **HW.Run&Quote(hdl, in)**: It takes as input \( hdl \), \( in \), and executes the program in enclaves. After obtaining the result, the enclave signs the output with \( sk_{\text{quote}} \) and creates a quote \( q = (md_{\text{hdl}}, H_Q, in, out, \sigma) \), where \( md_{\text{hdl}} \) is the enclave metadata, \( H_Q \) is a hash of \( Q \), and \( \sigma \) is the signature of previous data.
- **HW.VerifyQuote(pms_{\text{hw}}, q)**: The algorithm verifies the quote. It verifies the signature \( \sigma \) and outputs true if the verification succeeds. Otherwise, it outputs false.

**Integrity of TEE execution.** TEE creates a secure, isolated area that can run the application and handle sensitive data. This area is a self-contained execution environment completely isolated from the rest of the system. The application code cannot be replaced or modified once it is successfully loaded in this area [24]. Thus, the execution of identical loaded code with congruent inputs shall yield consistent outputs. We formalized this property as follows.

**Definition 2** (TEE execution Integrity, Exclnty). Considering that an adversary \( A \) and a challenger \( C \) playing the following game.

\[
\begin{align*}
\text{G}_{\text{Exclnty}}(\lambda) & \quad 1: \quad C \text{ Run } pms_{\text{hw}} \leftarrow \text{HW.Setup}(1^\lambda) \\
& \quad 2: \quad C \text{ and initialize } O := \emptyset. \\
& \quad 3: \quad A \text{ runs } hdl \leftarrow \text{HW.Load}(pms_{\text{hw}}, Q) \\
& \quad 4: \quad A \text{ runs } q \leftarrow \text{HW.Run}(hdl, in) \text{ outputting opt}. \\
& \quad 5: \quad A \text{ adds opt into } O \\
& \quad 6: \quad \text{repeat step 3-5}
\end{align*}
\]

The advantage \( \text{Adv}^\text{G}_{\text{Exclnty}}(\lambda) \) of \( A \) winning the game is

\[
\text{Adv}^\text{G}_{\text{Exclnty}}(\lambda) = P[H.W.\text{Run}(hdl, in) \neq O],
\]

**HW** is Exclnty secure if for all PPT adversary \( A \), there exists a negligible function \( \text{negl}(\lambda) \) such that \( \text{Adv}^\text{G}_{\text{Exclnty}}(\lambda) < \text{negl}(\lambda) \).

**Notes.** In several TEE products (e.g., Intel SGX), to preserve signers’ anonymity, a quote is created using an anonymous group signature [13]. As anonymity is orthogonal to our formalization, we omit it in this work.

**Cryptographic primitives.** Our construction relies on standard cryptographic primitives, i.e., public key encryption scheme PKE, signature scheme \( S \). Signature scheme \( S \) consists of three PPT algorithms (\( S.\text{Gen}, S.\text{Sign}, S.\text{Verify} \)). \( S.\text{Gen} \) takes as input a key pair \( (vk, sk) \) and outputs a signature \( \sigma \), written as \( (vk, sk) \leftarrow \text{PKE.Gen}(1^\lambda) \).

**Definition 3.** A signature scheme \( S \) is existential unforgeability under chosen message attack (Elu-CMA) secure if for all PPT adversaries \( A \), there exists a negligible function \( \text{negl} \) such that

\[
\text{Pr}[\text{Sig-forg}_{\text{A,S}}(\lambda) = 1] \leq \text{negl}(\lambda),
\]

where \( \text{Sig-forg}_{\text{A,S}}(\lambda) \) is an experiment defined as below:

- Run \( S.\text{Gen}(1^\lambda) \) to obtain a key pair \( (vk, sk) \).
- \( A \) is given \( vk \) and access to a signature oracle \( O^S.\text{Sign}_{vk}(\cdot) \) and \( O^S.\text{Verify}_{vk}(\cdot) \). Then \( A \) outputs a legal message \( m \) with a signature \( \sigma \).
- Let \( Q \) denote the set of messages queried by \( A \) via the oracle \( O^S.\text{Sign}_{vk}(\cdot) \). The experiment’s output is 1 if \( S.\text{Verify}_{vk}(m, \sigma) = 1 \) and \( m \notin Q \), and 0 otherwise.

Due to space limitations, we provide them in our full version.

## 3 DEFINITIONS OF ACCOUNTABILITY

In this section, we review the development of the definitions. Our objectives are twofold: (i) to assess the applicability of the existing definitions to accountable decryption, and (ii) if they are not suitable, to identify commonalities in the current definitions that can serve as a foundation for formulating our new definition.

Nissenzbaum (1996) [25] first proposed the notion of accountability in computer science. It did not provide a clear definition of accountability but strengthened that accountability is crucial for building reliable computer science.
Kailar (1996) [8] and Yumerefendi et al. (2005) [9] extended the definition of accountability by emphasizing its objectivity and establishing its strong connection to real entities. Their work emphasized the importance of binding accountability with a unique identifier, enabling the tracking and linking of actions to specific individuals or entities. This crucial exploration allows the detection of misbehavior.

**Definition 4** (On linkage [8][9]). An accountable system associates states and actions with identities and provides primitives for actors to validate the states and actions of their peers, such that cheating or misbehavior becomes detectable, provable, and undeniable by the perpetrator.

Subsequent endeavors have further enriched the concept of accountability by accentuating the significance of honest behaviors exhibited by participants. To achieve this, Bella et al. (2006) [11] and Haeberlen et al. (2007) [6] embrace accountability as the process of furnishing evidence to a principal, which can subsequently be presented to the judge. Buldas et al. (2006) [26] and Yumerefendi et al. (2007) [27] delved into its application and strengthened the importance of real-time detection of misconduct.

**Definition 5** (On real-time detection of misconduct). Accountability has the following features: (a) reliable evidence [1][6]: The evidence can be validated and achieves fairness (i.e., that one protocol participant gets evidence if and only if the other one does) and non-repudiation; (b) enhanced misbehavior detection [26][27]: A system should provide a means to directly detect and expose misbehavior by its participants, or enable a principal to prove to the judge any detected fraud.

A parallel line of studies, comprising Lampson (2005) [12], and Feigenbaum et al. (2011) [11], further improved the accountability definition by emphasizing that accountability is actually a posteriori behavior. These studies emphasized the significance of consequences and deterrent measures in shaping responsible behavior in various domains. Grant et al. (2005) [10] and Weitzner et al. (2008) [7] underscored the imperative of validating adherence to predefined policies.

**Definition 6** (On punishment, rephrased). Accountability in a computing system implies the following properties: (a) awareness of policy violation [7][10]: Some actors have the right to hold other actors to a set of standards, to judge whether they have fulfilled their responsibilities in light of these standards. (b) posterior penalty [10][11]: An entity is accountable with respect to some policy (or accountable for obeying the policy). Whenever the entity violates the policy, with some non-negligible probability, the entity will be punished.

Subsequent studies such as Haeberlen (2010) [28] have made strides in identifying the key factors that define the connotation of accountability. In addition to that, a few studies, such as Ishai et al. (2014) [29], have delved into establishing formal treatments of accountability.

**Definition 7** (A summary by [28]). A system is accountable if (a) faults can be reliably detected, (b) each fault can be undeniable linked to at least one faulty node, and (c) the faulty entities will be properly sanctioned.

The above review shows that decades of research have thoroughly studied the concept of accountability with different focuses. However, they fail to fully capture the entities, components, and algorithms involved in accountable encryption. For example, none of the definitions explicitly define the actions of encryption operations or what constitutes legitimate decryption activities. This finding highlights the need for an accountable decryption definition.

**General principle of accountability.** We summarize the general principle of accountability in the above definitions. It holds the following features: (1) linkage identities: each action is linked to an entity that performed it; (2) reliable evidence: the system maintains a record of past actions such that entities cannot secretly omit, falsely, or tamper; (3) policy compliance: the evidence can be inspected for signs of faults; (4) detection: when a judge detects a fault, it can obtain an alert of the fault that can be verified independently by a third party; (5) punishment: a proper sanction can be applied to misconduct entities.

## 4 Accountable Decryption

In this section, we formally define the accountability of encryption. Our definition fits in the scenario where users choose a delegate to store their encrypted data and are aware of any subsequent decryption actions of the encrypted data. The process involves multiple roles: encryptor (E), decryptor (D), and judge (J). E and D are entities that create ciphertexts and perform the decryption of ciphertexts. J is responsible for detecting the misbehavior and imposes penalties against D who conduct such misbehavior. Accountable decryption requires five protocols.

- **Setup.** $\params \leftarrow \setup(1^\sec)$: The system takes security parameters $\sec$ and outputs the public parameters $\params$. Here, $\params$ is the default input for the rest of the algorithms and is thus ignored for simplicity.

- **Encryption.** $(\ct, \P) \leftarrow \encrypt(\aux, m)$: An encryptor $E$ executes this algorithm to generate a ciphertext $\ct$ by using a message $m$ and decryptor’s auxiliary data $\aux$, and policies $\P$. Here, $\P$ dictates what are legal actions. Notably, $\params$ is a public parameter for all algorithms. In contrast, $\aux$ consists of auxiliary parameters for certain encryption tasks.

- **Decryption.** $(m, \pi) \leftarrow \encoding(\key, \ct)$: A decryptor $D$ executes this algorithm within a designated environment, denoted as $\encoding$. It takes as input a private key $\key$, a ciphertext $\ct$, and the encapsulated environment variables of $\encoding$. If the decryption is successful, it outputs a plaintext $m$ and a piece of evidence $\pi$, which serves as substantiation for validating the decryption process. Otherwise, it outputs ⊥, indicating an abort. Notably, $\encoding$ captures critical aspects of the event, including precise timing, the unfolding sequence, and the identities of participating entities. The symbol $\encoding \equiv \encoding$ denotes a bidirectional relationship. Specifically, $\pi \equiv \encoding$ signifies that $\pi$ captures all occurrences of $\encoding$, and simultaneously, every state of $\encoding$ is accurately represented and recorded in $\pi$.

- **Check violation.** $\tag \leftarrow \check\violation(\pi, \ct, \P)$: A judge $J$ executes this algorithm to scrutinize the actions of the decryptor, ensuring compliance with the
predefined policies. It takes as input the evidence of decryption π, the policy P and outputs a result tag ∈ \{true, false\}. Here, false indicates the decryptor’s action is aligned with policies, and we define it as legitimate decryption.

- **Punishment.** true/false ← Punish(tag, P); J imposes penalties against D in case of non-compliance. Here, true indicates penalties are imposed successfully.

Our definition follows the general principle summarized in Section 3. It has the ability to trace, identify, and punish malicious decryptors. In particular, if D maliciously accesses the plaintext, J provides feedback on D’s actions by checking evidence π, and then imposes penalties upon D for its misbehaved decryption.

### 4.1 Ideal Accountable Decryption

We formalize the ideal notion of accountable decryption in terms of two properties: non-repudiation which says that decryptors who did illegal decryption can be identified and penalized, and non-frameability, which says that decryptors who performed legal decryption should not be blamed or subjected to false accusations.

To formalize non-repudiation, we consider a game in which the adversary takes on the role of the decryptor and is allowed to interact with other honest roles. The adversary wins if it illegally decrypts a ciphertext (i.e., e is allowed to interact with other honest roles. The adversary which the adversary takes on the role of the decryptor and who performed legal decryption should not be blamed or penalized, and decryptors who did illegal decryption can be identified and punished.

### 4.2 Practical Accountable Decryption

To address this challenge, we introduce a new role to manage key and π, and we call this role trustee (TS). Accordingly, we introduce one protocol (called, EvidenceKeyManage) with two interactive sub-protocols.

- **Management.** (key', π') ⨿ Manage(ct, P); A trustee TS executes this protocol, producing a key called key' and a piece of evidence π if e ⊲ P.
- **Key generation.** key ← KeyGen(key'); A decryptor D derives its decryption key from key'.

In the scenario above, D must obtain the key from TS before executing decryption, preventing the issue of evidence withholding. However, this brings a new problem: TS may behave maliciously. Therefore, we propose two definitions for accountable decryption, considering a trusted TS and an untrusted TS.

A trusted TS must fulfill a new requirement: TS should provide authentic keys and evidence. Formally, we define this requirement by evd-key-soundness game. In this game, we consider a game in which an adversary plays the role of TS and is allowed to interact with other honest roles. The adversary wins if it generates illegal evidence that cannot represent its decryption behavior (π* ≢ ε*) or generates an illegal key that cannot decrypt the ciphertext.

### Definition 11 (Evd-key-soundness). Suppose \( G_{A}^{\text{sound}}(\lambda) = \Pr[G_{A}^{\text{sound}}(\lambda)] \), where \( G_{A}^{\text{sound}}(\lambda) \) is defined as follows:

\[
G_{A}^{\text{sound}}(\lambda)
\]

\[
\begin{align*}
\text{params} & \leftarrow \text{Setup}(1^\lambda) \\
(ct, P) & \leftarrow \text{Enc}(\text{aux}, m) \\
(m, \pi) & \leftarrow A^{\text{Dec}(key, ct)} \\
\text{tag} & \leftarrow \text{CheckViolation}(\pi, ct, P) \\
\text{return} & (\pi = \text{Punish}(\text{tag}, (ct, P)) \land (\pi \not\equiv \epsilon))
\end{align*}
\]

A protocol satisfies evd-key-soundness, if for all PPT adversaries \( A \), there exists a negligible function \( \text{negl}(\lambda) \) satisfying \( \text{adv}_{A}^{\text{sound}}(\lambda) < \text{negl}(\lambda) \).
Definition 12 (Practical Accountable Decryption with trusted Trustee, PAD-TTS). A system achieves PAD-TTS if it satisfies non-repudiation, non-frameability and evd-key-soundness.

We now consider the worst-case scenario where TS is not fully trusted. (1) if TS is compromised, it attempts to decrypt the ciphertext using D’s partial key, key*; (2) TS, when compromised, also tries to evade detection of its compromised status. To capture them, we define two additional properties: compromise-security, which says that even if TS is compromised, the compromised TS cannot learn the plaintext based on D’s partial key key*; compromise-awareness, which say that it has a certain probability of detecting and learning the TS status of being compromised.

In the compromise-security game, we consider a game in which an adversary takes on the role of TS and is allowed to interact with other honest roles. The adversary wins if it can learn D’s plaintext based on the user’s partial key.

Definition 13 (Compromise-security). Define adv\textsuperscript{csec}_A(\lambda) = \Pr[G_{csec}^A(\lambda)], where G_{csec}^A(\lambda) is defined as follows:

\[
\begin{align*}
g_{csec}^A(\lambda) & \leftarrow \text{Setup}(1^\lambda) \\
(ct, P) & \leftarrow \text{Enc}(aux, m) \\
(key^*, \pi^*) & \leftarrow A^\text{Manage}(ct, P) \\
key & \leftarrow A^\text{keyGen}(key^*) \\
\text{return } m & = A^\text{Dec}(key, ct)
\end{align*}
\]

A protocol satisfies compromise-security, if for all PPT adversaries A, there exists a negligible function negl(\lambda) satisfying adv\textsuperscript{csec}_A(\lambda) < \text{negl}(\lambda).

We further introduce an additional detection protocol to capture compromise-awareness, namely, true/false \leftarrow Trace(key, D); The algorithm outputs false only when the provided key key* is the same as the decryption key D. false \leftarrow Trace(key, D) means that the misbehavior \tilde{c} is not captured. We then consider a game in which an adversary takes on the role of TS and is allowed to interact with other honest roles. The adversary wins if it generates a \pi which cannot reflect \tilde{c}, namely \pi \not\equiv \tilde{c}, and such misbehavior cannot be detected.

Definition 14 (Compromise-awareness). Supposing adv\textsuperscript{aware}_A(\lambda) = \Pr[G_{aware}^A(\lambda)], where G_{aware}^A(\lambda) is defined as follows:

\[
\begin{align*}
g_{aware}^A(\lambda) & \leftarrow \text{Setup}(1^\lambda) \\
(ct, P) & \leftarrow \text{Enc}(aux, m) \\
(key^*, \pi^*) & \leftarrow A^\text{Manage}(ct, P) \\
\text{return } (\pi^* \not\equiv \tilde{c}) & \text{ and } (false = \text{Trace}(key, D))
\end{align*}
\]

A protocol satisfies compromise-awareness, if for all PPT adversaries A, there exists a negligible function negl(\lambda) satisfying adv\textsuperscript{aware}_A(\lambda) < \text{negl}(\lambda).

Definition 15 (Practical Accountable Decryption with untrusted Trustee, PAD-uTS). A system achieves PAD-uTS if it satisfies compromise-security and compromise-awareness.

5 A Secure Construction

Philosophy of our design. The main idea behind our construction is to establish a dependable party TS using TEEs [13][14][15]. Traditional methods of ensuring accountability in decryption rely heavily on a judge to verify the legality of each decryption. However, even if the judge is assumed to be fully honest, obtaining evidence is challenging if a decryptor refuses to comply with the protocol or provides falsified information. To address this issue, we introduce a new role called trustee operating within TEEs. It receives decryption requests from decryptors and ensures the visibility of these requests to the judge. By integrating TEEs, our construction improves the reliability of trustees, implementing tamper-evident measures during key distribution to enhance key security and traceability in the distribution process. We have observed that TEEs are susceptible to numerous attacks such as [16][17][18]. Achieving a completely secure TEE remains a challenge. In response, we propose a design that enables the detection of compromised trustees.

Strawman protocol. Our naive solution involves four steps. ① E, defines the decryption policy, encrypts a message, and sends the ciphertext to D. ② To decrypt the ciphertext, D submits a decryption request to TEE-based TS with a signature to prove the identity. ③ TEE retrieves the decryption key, generates a piece of evidence about the key request, stores it in a log, and then sends the decryption key to D. Then, D decrypts the ciphertext. ④ J checks the evidence and imposes penalties against malicious decryption. The above approach immediately achieves Definition [11] when we assume that TEE is fully trusted. Under this assumption, the codes are executed as loaded, ensuring the integrity of the execution; when a key request is made by the decryptor, both the evidence and the key are produced accurately.

Technical challenges. Definition [15] further assumes that the trustee can be compromised. Indeed, this is aligned with the fact that TEE products suffer from architectural vulnerabilities [30], side-channel attacks [31], and fault attacks [16]. Therefore, we need to provide a solution that satisfies Definition [15]. However, a few technical challenges still exist in building a fully-fledged solution.

Challenge-1: How to protect decryption keys under compromised TEEs. In the above approach, if a TEE is compromised, the adversary can access private keys. This not only renders the accountable mechanism ineffective but also jeopardizes the confidentiality of ciphertexts. In fact, this issue is a major drawback of existing TEE-based accountability systems, such as those presented in [32][34].

Inspired by the key management solutions used in [21], [22], we introduce a key-splitting mechanism wherein TEE only stores a partial key while the user holds another partial one. Even if an attacker accesses the key inside TEEs, it cannot obtain a full decryption key.

Challenge-2: How to detect the compromised TEE. Within the present design paradigms, TEE functions as an encapsulated entity (black box), precluding any interrogation of...
its internal states by unauthorized peripheral components. However, this attribute also engenders a notable challenge: the dearth of visibility for overseers seeking potential compromise or deviations from established protocols.

We develop a detection algorithm to find potential compromises by inspecting TEE’s outputs. Our algorithm is based on the concept of deception technology [34]: using tactics to deceive malicious TEE into attacking the wrong targets and thus producing potentially useful information. To create wrong targets, we introduce two new roles: encryption inspector $P_e$ and encryption inspector $P_d$. They emulate conventional encryptors and decryptors, respectively. If TS outputs inconsistent results, $P_e$ and $P_d$ will learn potential compromise of TEE. Beyond that, by leveraging the commitment scheme, our newly proposed key generation algorithm guarantees that TS cannot generate a decryption key identical to the key requested by users. Thus, a pair of private keys, which are honestly generated under D’s request and maliciously generated by TS, can serve as evidence of a fraudulent TS.

Overview of our construction. In our design, TS comprises two essential elements: private key generator (PKG) and log manager (LM). These elements can operate on the same server but within distinct domains for specific functionalities. PKG is executed within TEEs and handles the generation of decryption keys. LM operates in untrusted environments and is responsible for maintaining and updating the evidence $\pi$ related to the key extraction process.

Threat model. We assume that the decryptor’s public key can be linked to a unique identifier. This assumption is common in the literature and reasonable in practice. Instead of fully trusting the TEE like previous TEE-based solutions [3][4][5][8], we make TEE work in the “trust, but verify” model where a compromised state is detectable. Also, we require cryptographic primitives that we rely upon to be provably secure.

At a high level, our system studies as follows. Initially, $E$ defines the condition (i.e., $P$) of key extraction; TS runs PKG in TEE while providing public interfaces. Then, $E$ encrypts a message and sends the corresponding ciphertext $c_t$ and $P$ to D. $D$ for decrypting $c_t$, D sends a key request message with a commitment for his random number to TS. TS generates decryption keys and updates the evidence $\pi$ of key extraction. Specifically, LM first stores D’s key request in a log and transforms it as evidence $\pi$, while PKG generates the partial decryption key based on the received commitment. Then D’s key request in a log and transforms it as evidence $\pi$, while PKG generates the partial decryption key based on the received commitment. TS generates partial decryption keys. $J$ traces log to find the misbehavior of decryption and imposes penalties against the decryptor. $E$, the inspectors (i.e., $E$, $D$, $J$) identify and prove the guilty of dishonest/compromised TEE who suppressed the evidence/key and provided the forged evidence/key.

Final design. Our solution generally follows the strawman approach mentioned in Section 5. The concrete decryption scheme follows the design of identity-based encryption (IBE) [35][36]. We run PKG inside TEE, and thus, the master private key of IBE is securely protected. Every ciphertext is encrypted using the decryptor’s identity and a serial number. To perform decryptions, a decryptor D has to request the key from PKG. An essential aspect of this procedure is that the request is forced to be stored in a log, and PKG issues a decryption key only if the request is proven to be securely stored. The log is structured as an append-only Merkle tree, as used, for example, in certificate transparency [37] to improve security and efficiency. Below, we describe the technical details.

1) Key management. $E$ encrypts a message using the receiver’s identity (e.g., email addresses) and E-generated serial number. This brings two benefits. First, it eliminates the need for $E$ to request a new key for every encryption operation and thus improves practicality. Second, due to the nature of IBE scheme, the dynamic serial number makes a fresh key. $D$ never knows the serial number until he obtains the ciphertext, which forces him to request a new key each time for decryption and then leaves a piece of unique evidence. Meanwhile, we require TS to only maintain a partial private key. Through a local calculation process, $D$ combines his partial key with that of TS to obtain the final private key. This design ensures that, even if an attacker fully gains access to the TEE-based PKG, it cannot deduce the complete decryption key (adhering to Definition [15][21]).

2) Evidence management. We use an append-only Merkle tree based log $LOG$ to store the decryption evidence $\pi$. Whenever a decryption occurs, trusted hardware updates the Merkle tree by extending the leaf from the rightmost branch. This unique structure enables the generation of two distinct types of proofs to ensure the integrity of the evidence: proof of presence $\rho$ guarantees that the specific evidence is stored within a tree; the proof of extension $\varepsilon$ proves that such a tree is an append-only extension of $LOG$. We give an example to explain how to verify the $\rho$ and $\varepsilon$. As shown in Figure 2, it depicts the Merkle tree before and after the insertion of node $N_7$. The $\varepsilon$ is valid only if the root hash $H$ is the hash of $\{H(6, 6), H(4, 5), H(0, 3)\}$, and the $\rho$ is valid only if the current root hash $H'$ is the hash of $\{H(7, 7), H(6, 6), H(4, 5), H(0, 3)\}$.

3) Decryption checking. Based on the decryption activities, a judge $J$ conducts log queries, thereby acquiring supplementary details pertinent to the decryption event. Subsequently, $J$ compares these supplementary details with predefined decryption policies to validate the legitimacy of the decryption process.

![Figure 2: Merkle tree update](image-url)
Central to this algorithm lies the deployment of inspectors. In a bid to mimic a conventional encryptor and decryptor, $P_d$ and $P_s$ dynamically engage in standard interactions with TS (behaving like a challenger). Based on the observations meticulously gathered by $P_e$ and $P_d$ throughout these interactions, our algorithm possesses the capability to effectively discern whether TS has been compromised.

(1) TS provides forged evidence or forged key. When $P_d$ requests a private key, it is required to submit a signature on the identity and timestamp. Then, signatures are organized into a secure Merkle tree structure by extending the tree to the right, following an append-only policy. This empowers $P_d$ to detect any forged evidence originating from TS. Meanwhile, if the issued partial key lacks the capability to yield a complete key, then $P_d$ knows TS has been compromised, e.g., TS provides an invalid partial key.

(2) TS suppresses the evidence or key. An inspector $P_d$ pretends to be a regular D and asks for a private key from TS. If the request is granted, but TS fails to show the necessary evidence or the decryption key, $P_d$ knows that TS has hidden them.

We now delve into the most tricky scenario: TS effectively conceals both the key and evidence. If TS refrains from any communication with $P_d$, its malicious actions may remain undetected. In our solution, the private key is generated based on $P_d$’s commitment to an undisclosed random number, unbeknownst to TS. In the event that a decryptor, $P_d$, subsequently uncovers a new key not linked to the commitment, and no traces are left behind, it becomes evident that this key must have been clandestinely generated by TS. Therefore, for a given identity, the existence of a pair of private keys stemming from different sources acts as evidence against a deceitful TS. Admittedly, this relies on probabilistic grounds since $P_d$ cannot guarantee a 100% probability of finding a malicious key. Nevertheless, it at least exposes $P_d$ to the risk of being detected.

(3) TS, privately generates key without leaving any evidence. When $P_d$ requests a private key, it is required to use a commitment to conceal a random number. Under normal circumstances, the private key should be tailored to this specific commitment. If a new key that is not associated with the commitment is later discovered, $P_d$ will learn TS must have conducted an invalid decryption.

Notably, existing TEE-based studies assume that the hardware is fully trusted. However, in practice, real-world scenarios diverge from this ideal, as even reliable hardware like TEEs exhibit vulnerabilities, as evidenced by studies such as [30, 31]. Our work takes a step forward and considers accountable decryption under the bad cases of trusted hardware being compromised. Our construction is critical for building practical decryption with accountability.

6 Detailed Protocol

In this section, we present our detailed protocol (see Figure 3). We instantiate TEE using Intel SGX [13].

Setup the system. $\text{Portex.Setup}(\lambda)$: This is a preparation phase aiming to set up the system. The algorithm takes as input a security parameter $\lambda$, and outputs public parameters $pms$. In particular, it first calls HW.Setup to initiate the HW and generates $pms_{hw}(L)$. Then, it runs HW.Load to load PKG code (e.g., Portex.EvidenceKeyManage as defined in Figure 3) into a generation enclave GE ($L$). Next, it runs ($^\text{"init"}$, $\lambda$) to set up the enclave and then publish the public keys $(mpk, vk_{GE}) (L)$. Meanwhile, the log manager LM calls MT.Init($\lambda$) to initialize the log and runs S.Gen($\lambda$) to generate a signature key pair $(vk_{LM}, sk_{LM}) (L)$. For D, it generate a key pair $(pk_{cl_i}^\text{enc}, sk_{cl_i}^\text{enc})$ and signing key pair $(vk_{cl_i}^\text{sig}, sk_{cl_i}^\text{sig})$ for secure data transfer ($L$). Here, parameters $(pms_{hw}, mpk, vk_{LM/GE}, pk_{cl_i}^\text{enc}, vk_{cl_i}^\text{sig})$ are publicly accessible, and default inputs of the rest of algorithms.

1. The encryption phase. $\text{Portex.Enc}(ID, m)$: In this phase, $E$ encrypts a secret/message $m$ and generates a ciphertext $ct$ and corresponding policy $P$. In particular, it first generates a random serial number $SN$. Then, it runs $\text{IBE.Enc}(mpk, ID|SN, m)$ to encrypt a message $m$ using $mpk$ and a combination of user identity $ID$ and $SN (L)$.

2. The decryption phase. A decryptor $D$ recovers the plaintext, before which he needs to request the corresponding private key. This is an interactive protocol between TS (including KM, LM), and D with two algorithms as follows. $\text{Portex.EvidenceKeyManage}(ID, SN, \sigma_{cl_i})$: The algorithm takes as input $ID$, $SN$, and D’s signature $\sigma_{cl_i}$, and outputs a decryption key $pkey_i$ and the evidence $\pi$ of key extraction. Inspired by [32], we separate the key generation into three sub-algorithms (IBE.KGen_{D1}, IBE.KGen_{PKG}, IBE.KGen_{D2}). The detailed algorithms are as follows.

- $(L \overrightarrow{L} L \overrightarrow{L})$: D first locally runs IBE.KGen_{D1} to select $(t_0, \theta)$ and to generate a commitment $C$. Then, it generates a signature $\sigma_{cl_i}$ on $ID$ and $SN$. After that, it sends $(ID, SN, C)$, and $\sigma_{cl_i}$ to LM.

- $(L \overrightarrow{L} L \overrightarrow{L})$: LM runs MT.Insert. If the verification of $\sigma_{cl_i}$ fails, the algorithm aborts. Otherwise, it runs MT.Insert adds a tuple $(ID, SN, C, \sigma_{cl_i})$ to an append-only log $LOG$. To be specific, LM first records the timestamp $T$ of the D’s request. Then, it calls MT.Insert and outputs evidence $\pi$, which contains the newly inserted tuple $N$, current tree root hash $H_{tree}$, old tree root hash $H_{old}$, proof of presence $\rho$, proof of extension $\varepsilon$. Next, LM signs a tuple $(ir(\pi, C))$ by calling $S.$ Sign$(sk_{LM}, ir)$ and obtains a signature $\sigma_{ir}$. Finally, LM sends $(ir, \sigma_{ir})$ to PKG.

- $(L \overrightarrow{L} L \overrightarrow{L})$: Once PKG receives $(ir, \sigma_{ir})$, it calls the Portex.EvidenceKeyManage inside GE. Specifically, it first verifies $\sigma_{ir}$ using $vk_{LM}$. If the above steps fail, the algorithm aborts. Next, GE runs MT.Verify to check the validity of the proof of presence $\rho$ and the proof of extension $\varepsilon$. $(L \overrightarrow{L} L \overrightarrow{L} L \overrightarrow{L})$: If the evidence $\pi$ is valid, GE selects $(r^i, t^i)$ from $Z_p^*$ and starts to calculate a partial decryption key $pkey$ by calling IBE.KGen_{PKG}, where $pkey$ consists of $(d_{cl_i}^e, d_{cl_i}^d, c)$, and C is used to calculate $d_{cl_i}^d$. Then, GE encrypts $pkey$ to $ct_{pkey}$ with D’s public key $pkey_{cl_i}^\text{enc}$. PKG sends quote of $ct_{pkey}$ to D.

- $(L \overrightarrow{L} L \overrightarrow{L})$: D finally runs HW.VerifyQuote to verify quote. If the verification fails, the algorithm aborts. Otherwise, it calculates the final decryption key by calling IBE.KGen_{D2}. The final decryption key is calculated from $pkey$, and consists of $(d_1, d_2, d_3)$. 

8
The checking phase. Portex.CheckViolation(π, ct, P): In this phase, J examines the actions of the decryptor based on the evidence π stored in LOG. Precisely, it finds π in LOG, and then checks whether π satisfies P (L ⊆ L). If misbehavior is found, the protocol outputs true. Otherwise, it outputs false.

The punishment phase. Punish(tag, P): The judge J imposes penalties against D who has conducted malicious decryption. These penalties include measures such as deposit forfeiture and credit downgrade, which are not detailed here for brevity.

The detection for the compromised trustee. For identifying potential compromises of TS, we introduce two sub-algorithms: deterministic detection algorithm and probabilistic detection algorithm. The deterministic detection algorithm infers a compromised state through a challenge-response mechanism, while the probabilistic detection algorithm identifies potential compromises by comparing the final keys issued by D with those issued by TS.

Deterministic detection algorithm. We make the inspector P pretend to be a regular decryptor D (as a challenger) and ask for the private key and evidence from the trustee TS. If any inconsistency is detected, it suggests that TS has been compromised. In particular, if P generates a partial key without evidence in LOG, TS must have forged the evidence (L ⊆ L in Algorithm 1); if P’s evidence is aligned with LOG, but the partial key lacks the capability to yield P’s complete key, TS has attempted to manipulate P’s key (L ⊆ L in Algorithm 1); if P’s partial key arises but no evidence is shown, decryption evidence suppression has happened (L ⊆ L in Algorithm 1); if evidence appears without P’s partial key issuance, it implies decryption key concealment by TS (L ⊆ L in Algorithm 1).

Probabilistic detection algorithm. We now consider the trickiest
To win the game, two scenarios where TEE is secure or compromised.

In the decryption phase, as evidence. We argue if $\text{TS}$ hides the newly generated key as well as evidence. We argue if $\text{TS}$ leaks any information on its misbehavior, it runs the risk of being caught and prosecuted. In the decryption phase, as $(t_0, \theta)$ are chosen randomly by $P$ that are unknown to PKG, PKG cannot generate a decryption key that is same as $\text{key}$. This laid the foundation for detecting the PKG’s misbehaviors. For a valid decryption key, $d_3$ contains the parameter $t_0$ that only knows to $P$. If any $P$ finds another valid key but does not equal $\text{key}$, then it demonstrates that $D$ is maliciously generated by $\text{TS}$, and thus shows $\text{TS}$’s misbehavior.

### 7 Security Analysis

This section provides a security analysis, considering two scenarios where TEE is secure or compromised.

**Security analyses under secure TEEs.** Assuming that TEE and the used cryptographic primitives are secure, our construction achieves PAD-$t\text{TS}$ defined in Definition 12. We prove the theorem by contradiction. If an adversary $A$ made our construction fail to achieve properties in PAD-$t\text{TS}$, we could use such abilities to break our assumptions.

**Theorem 1.** If $\text{HW}$ is Exelnty secure and $S$ is Existential Unforgeability under Chosen Message Attack (EUF-CMA) secure, our construction achieves PAD-$t\text{TS}$ as defined in Definition 12.

**Proof.** We prove this theorem by demonstrating that the probabilities of the adversary winning the non-repudiation game, non-frameability game, and evd-key-soundness game are negligible. We discuss each of these in turn.

**Non-repudiation:** To win the game $G_{A}^{\text{NP}}(\lambda)$, an ad-

---

**Figure 4:** IBE algorithm and evidence management algorithm
versary \( A \) must let Punish\((\text{tag}, \mathcal{P})\) return false, after it legally decrypts a ciphertext, i.e., \( (m, \pi) \leftarrow \text{Dec}(\text{key}, ct) \) and \((\varepsilon \neq \mathcal{P})\). Punish\((\text{tag}, \mathcal{P})\) returning false implies that CheckViolation\((\pi, ct, \mathcal{P})\) also returns false. In context, CheckViolation returns false indicates that \( \pi \) does not exist in \( \mathcal{LOG} \) or \( A \) has produced new illegal evidence \( \pi' \).

We define the first event, where \( \pi \) does not exist in \( \mathcal{LOG} \) as event \( E_1 \), with its corresponding probability denoted as \( \Pr[E_1] \). Similarly, we define the second event, where \( A \) has produced new illegal evidence \( \pi' \), as event \( E_2 \), with its probability denoted as \( \Pr[E_2] \). We will now prove that the probabilities of \( E_1 \) and \( E_2 \) occurring are negligible, i.e., \( \Pr[E_1] \) and \( \Pr[E_2] \) are negligible.

\( E_1 \) indicates that \( A \) has successfully obtained decryption key while \( \text{LM} \) cannot provide valid decryption evidence. As shown in Figure 3 when \( \text{LM} \) cannot provide valid decryption evidence in the form of \( (ir, \sigma_{ir}) \), the algorithms \( L[1] \) and \( L[2] \) are programmed to abort. This further leads to the failure of algorithm \( L[3] \). Suppose \( A \) has successfully conducted a decryption. This means that \( A \) has either manipulated the TEE code (e.g., Portex.EvidenceKeyManage as defined in Figure 3) or provided a forged signature of log manager, i.e \( \sigma_{ir} \). However, the manipulation of the TEE code contradicts our assumption regarding the execution integrity of the TEE (Exelenty secure), while the forged signature breaks the security of EULIF-CMA of \( S \). Thus, we have \( \Pr[E_1] \leq \text{Adv}_{A,HW}^\text{sound}(\lambda) + \Pr[\text{Sig-forg}_{A,S}^\text{CMA}(\lambda) = 1] \).

\( E_2 \) indicates that \( A \) has successfully obtained decryption key while \( A \) has produced new illegal evidence \( \pi' \). As shown in Figure 3 when a decryptor \( D \) cannot provide a valid signature in the form of \( \sigma_{ir} \), the algorithm \( L[1] \) is programmed to abort. Suppose \( A \) has successfully produced a new signature \( \pi' \) that can be accepted by \( \text{LM} \), we can use this ability to break the security of EULIF-CMA of \( S \). Thus, we have \( \Pr[E_2] \leq \Pr[\text{Sig-forg}_{A,S}^\text{CMA}(\lambda) = 1] \). Thus, we have \( \text{adv}_{A}^\text{sound}(\lambda) \leq \text{Adv}_{A,HW}^\text{sound}(\lambda) + 2\Pr[\text{Sig-forg}_{A,S}^\text{CMA}(\lambda) = 1] \leq \text{negl}(\lambda) \).

Non-frameability: To win \( \text{G}_{\text{frame}}^\text{A}(\lambda) \) game, an adversary must produce illegal evidence for an honest decryptor’s “misbehavior” to ensure its punishment. According to the algorithm \( L[1] \) we have known that Portex.CheckViolation returns true only when all three conditions defined in \( L[1] \) returns true. We define three events for these conditions. In particular, we define the first event, where \((ID, SN, \tau) = (ID^*, SN^*, \tau^*)\) as event \( E_3 \), with its corresponding probability denoted as \( \Pr[E_3] \); the second event, where \((true = \text{MT.Verify}(\sigma)) \) as event \( E_4 \), with its corresponding probability denoted as \( \Pr[E_4] \); the second event, where \((true = \text{S.Verify}(\nu^{\Delta \Pi}_{\text{S}, \text{L}}), \sigma_{\text{S, L}})) \) as event \( E_5 \), with its corresponding probability denoted as \( \Pr[E_5] \). The first and third events happen only \( A \) generates a valid signature \( \sigma_{\text{S, L}}^{\Delta \Pi} \) without knowing \( sk^{\Delta \Pi}_{\text{S, L}}, \) which can be used to break the security of ELIF-CMA of \( S \). The second event occurs only if the TEE codes are manipulated, which contradicts our assumption regarding the execution integrity of the TEE (Exelenty secure); Thus, we have \( \text{adv}_{A}^\text{sound}(\lambda) \leq \text{Adv}_{A,HW}^\text{sound}(\lambda) + \Pr[\text{Sig-forg}_{A,S}^\text{CMA}(\lambda) = 1] \leq \text{negl}(\lambda) \).

Analysis under compromised TEE. We now consider cases of \( TS \) being compromised. We prove that even in this extreme case, our construction is still secure, and users can be aware of such compromises.

Theorem 2. If discrete logarithm problem (DLP) assumption holds, \( HW \) is Exelenty secure and \( S \) is ELIF-CMA secure, our construction achieves PAD-uTS defined in Definition [15].

Proof. We prove this theorem by demonstrating that the probabilities of the adversary winning the compromise-security and compromise-awareness game are negligible. We discuss each of these in turn.

Compromise-security: We prove this property by demonstrating that the probability of the adversary winning the compromise-security game is negligible. From the algorithm \( L[2] \), we have known that \( m^* = C_4 \cdot \left( e(C_1, d_1) \right)^{1/(e(C_2, d_2) \cdot C_3^3)} \) where the provided key \( \text{key} = (d_1 = (Y \cdot h^{t+1})^{1/x} \cdot H_2(\text{ID})^r, d_2 = X^r, d_3 = t+1, msk = x) \). Here the provided key \( \text{key} \) is derived from decryptor’s partial key \( \text{key}^* \). Let the plaintext decrypted from ciphertext \( C \) as \( m^* \), the original message as \( m \), and decrypt \( C \) with the provided key \( \text{key} \), then we have the following equation:

\[
m^* = C_4 \cdot \left( e(C_1, d_1) \right)^{1/(e(C_2, d_2) \cdot C_3^3)} = C_4 \cdot e(C_2, X^r) \cdot C_3^3 \cdot \left( e(C_1, d_1) \right)^{1/(e(C_2, d_2) \cdot C_3^3)} = e(C_1, d_1) \cdot H_2(\text{ID})^r
\]

\[
= m \cdot e(g, Y^r) \cdot e(H_2(\text{ID})^r, X^r) \cdot e(g, h)^{s(t+1)}
\]

\[
= e(X^r, (Y H_2(\text{ID})^r)^r) \cdot e(H_2(\text{ID})^r)
\]

\[
= e(g, s(t+1)) \cdot e(H_2(\text{ID})^r)
\]

\[
= e(g, s(t+1)) \cdot e(H_2(\text{ID})^r)
\]

The output value satisfies \( m^* = m \) only if \( t' = t_0 \) and \( \theta' = \theta \). As \( r, t_0 \) is randomly selected from \( Z_p^* \). Even if \( A \) fully controls
We prove this property by demonstrating that the probability of the adversary winning the compromise-aware game is negligible. We consider two cases: (Case-1) TS does not provide any result at all, i.e., TS simultaneously suppresses the evidence and associated keys, and (Case-2) TS provides inconsistent or forged results. Case-1: The proof is straightforward. If TS fails to provide the private key or the corresponding evidence, or TS provides the original evidence π\*, then the value of (π\* \(\neq\) \(\tilde{e}\)) is false, an inspector P immediately learns that TS is compromised. Case-2: We prove this case by demonstrating that the probability of false = Trace(\(\tilde{e}\), D) is negligible.

Given a decryption key D = (D_1, D_2, D_3) generated by Portex.EvidenceKeyManage, where D_1 = (Y \cdot h^{t_0 + t_1})^{1/z} \cdot H_2(\(D\))\^', D_2 = X', and D_3 = t_0 + t_1 for distinct t_0, t_1 \(\in\) \(\mathbb{Z}_p\). As we discussed in compromise-awareness, the TS lacks information about t_0, which implies that the probability of the provided key satisfies false = Trace(\(\tilde{e}\), D) is \(\frac{1}{\tilde{p}}\), where \(\tilde{p} > 2^k\) (as defined in IBE.Setup). Consequently, the probability Pr\(\tilde{e}\) = \(Pr[\text{false} = \text{Trace}(\tilde{e}, D)] \leq \frac{1}{\tilde{p}} \leq \frac{1}{2^k}\) □

8 Implementation and Evaluation

We implement Portex in C++ and use Intel SGX SDK [24] as the TEE. The implementations of IBE algorithms, including key generation, encryption, decryption, and trace, are based on the Pairing-Based Cryptography (PBC) library [38]. Our Merkle Tree implementation is based on the merklecpp library [39]. The public key encryption and signature algorithms are based on the OpenSSL library [40]. The SGX Enclave does not support the original OpenSSL. Therefore, in the PKG program, we utilize SGXSSL as an alternative [41].

Performance&scalability. It involves two aspects: (a) evaluating decryption performance, misbehavior-checking performance, and detection performance for finding the compromised TEE; (b) examining how scalability is affected when the number of decryptors increases. We evaluate the performance of Portex on a machine with 3.5GHz Intel Xeon CPU (Ice Lake). The symmetric bilinear pairing \(e : \mathbb{G} \times \mathbb{G} \rightarrow \mathbb{G}_\tau\) is constructed on the curve \(y^2 = x^3 + x\), and the security parameter \(\lambda\) is selected as 512. We report the average time of each algorithm by repeating the experiments 1,000 times.

Performance evaluation with static parameters. We first evaluate performance with static parameters. As an example, we consider the following scenario. We assume that there are 1000 decryptors, and each decryptor can launch one decryption. Our evaluation shows that the full decryption process, including two sub-algorithms: evidence-key management and decryption, concludes within 10ms. In particular, evidence-key management takes approximately 1.31ms, 3.15ms, 2.56ms to finish IBE.KGen_{D_1}, IBE.KGen_{D_2}, and IBE.KGen_{PKG}, respectively; It takes about 1.69ms and 6.05ms to generate and verify the decryption evidence. Simultaneously, the decryption of the ciphertext exhibits remarkable efficiency, demanding less than 1ms: the Dec.Setup operation concludes within an incredibly short span of 0.1ms, while IBE.Dec finalizes in a mere 0.6ms.

Meanwhile, tracing malicious decryption is significantly efficient, as it only takes at most 0.002ms to trace the evidence of malicious decryption. The process of identifying potential forgeries within the TEE unfolds in two stages. Specifically, detecting forged evidence and forged keys takes approximately 0.02 milliseconds and 0.01 milliseconds, respectively. Should the evidence or the key be suppressed, their compromise is swiftly ascertained. The probabilistic detection hinges on the methodology employed to distinguish these two elements. Remarkably, the comparison itself concludes in a mere 0.001 milliseconds upon the discovery by the decryptor D.

We then assess the execution time of each basic cryptographic primitive used in IBE, and report them in Table 1. Right. In this table, we use the following symbols to represent the running time of each function. \(T_{\text{bp}}\): The execution time of one bilinear pairing operation \(e(P, Q)\), where \(\{P, Q\} \in \mathbb{G}; T_{\text{ep.g1}}\): The execution time of one exponentiation operation \(P^p\), where \(P \in \mathbb{G}, x \in \mathbb{Z}_p\); \(T_{\text{tp.g1}}\): Except for \(P \in \mathbb{G}_\tau\), similar to \(T_{\text{tp.g1}}\); \(T_{\text{hu}}\): The execution time of one scale multiplication operation \(P \cdot Q\), where \(\{P, Q\} \in \mathbb{G}; T_{\text{hu}}\): The time of context switch to TEEs. These results closely align with our estimated times for each primitive, which offers robust evidence supporting the accuracy of our experimental findings.

Evaluation with dynamic parameters. To determine if deployment might be feasible in practice, we further evaluate how scalability is affected by dynamic parameters. We consider two scenarios: the performance overhead of decryption, evidence tracing, and compromise detection under (a) escalating sizes of security parameters and (b) an increasing number of decryption instances.

Intuitively, a larger security parameter enhances resilience against attacks. This enhancement comes at the cost of increased execution time for cryptographic operations.

Empirical findings align with our expectations: The time costs of encryption, evidence-key management, and decryption consistently increase with higher security parameter settings. This phenomenon stems primarily from the augmented computational load of the underlying sub-algorithms. For example, the execution time of IBE.KGen_{D_2} within the key-request algorithm expands from 4.2ms at a security parameter of 512 to 11.2ms at a heightened security parameter of 1024 (cf. Figure 5(c)). Nonetheless, the evidence tracing and compromise detection exhibit relatively steady performance, as they involve fewer time-intensive primitives.

We now consider the performance overhead arising from an escalating number of decryption operations (cf. Figure 5(a), 5(e) and 5(f)). To illustrate, we consider a specific scenario where the number of decryption operations grows from an initial 1,000 to a substantial 300,000. Our evaluation reveals that encryption time remains invariant with increased decryption operations as it is independent with TS, relying solely on the decryptor’s ID and the encryptor’s sequence number provided. In contrast, the time required for decryption directly correlates with the historical count.
Table 1: Theoretical complexity (L) and experimental time on IBE (R): (a) Line 2 of Portex.EvidenceKeyManage in Figure 3; (b) Line 9-14; (c) Line 4-7; (d) Line 1-8 of GE on input Manage; (e) It costs 3.0121 ms for running KGenPKG in CPU.

Figure 5: Experimental performance results of decryption operations. In particular, the execution time of operations such as evidence generation and evidence verification (L, M, I in Figure 3), both integral to TS, experiences an increment. Consequently, this rise in process-
ing time within TS contributes to an overall elongation of the decryption process. Meanwhile, the execution time of the trace algorithm is directly correlated with the size of the log. As the log size increases, the time required to query a malicious decryption operation from the log also increases. Upon augmenting the log size of 300,000 entries, the execution time of the trace algorithm increases to 69.2ms. Notably, the time cost of compromise detection is stable. Also, to maintain the integrity of evidence during decryption, it is required to choose a new sequence number for each encryption. As depicted in Figure 6, when the sequence number length is increased, the running time for evidence-key management displays a clear increasing trend. Fortunately, the impact on the running time for encryption and decryption is relatively minimal.

Performance comparison with other solutions. Table 2 compares the performance of our proposed solution with that of existing works. As different works use different decryption algorithms, conducting a direct comparison based on actual runtime performance is unfair. Therefore, we examine the workflows of these protocols and quantify the frequency of critical operations within each protocol to analyze their computational costs. These critical operations contain inter-party interactions $T_{inter}$, encryption $T_{enc}$, decryption $T_{dec}$, signing $T_{sign}$, and signature verification $T_{verify}$. The inter-party interaction $T_{inter}$ refers to the communication or exchange of information between different parties involved in a protocol, such as between the encryptor and potentially a third-party entity like a storage center or log manager.

Our solution has less interaction complexity compared to prior related works. For example, Severinsen’s protocol ($\mathbb{P}_{sever}$), Luo’s protocol ($\mathbb{P}_{luo}$), and Fialka ($\mathbb{P}_{fialka}$) mandate that the encryptor sends a copy of the ciphertext or auxiliary information to a storage center (termed as the Application Provider in $\mathbb{P}_{sever}$ and $\mathbb{P}_{luo}$, and Privacy-Preserving Smart Contracts (PPSC) in $\mathbb{P}_{fialka}$, cf. Figure 5) in addition to the intended recipient. In contrast, our protocol ($\mathbb{P}_o$) eliminates the need for encryptors to send an additional ciphertext backup, thereby obviating the requirement for a storage center and reducing interaction complexity. In $\mathbb{P}_o$, the encryption, decryption, and tracing operations require $T_{inter}$, $4T_{inter}$, and $2T_{inter}$, respectively.

Furthermore, we present the computational complexities associated with encryption and decryption in different protocols (see Table 2). The protocol $\mathbb{P}_{sever}$ requires one encryption and one decryption ($T_{enc} + T_{dec}$), while the protocols $\mathbb{P}_{luo}$, $\mathbb{P}_{fialka}$, and $\mathbb{P}_o$ each necessitate an additional encryption and decryption ($2T_{enc} + 2T_{dec}$). Although $\mathbb{P}_{sever}$ involves fewer encryption and decryption operations, it does not consider the message transmission after encryption, rendering the protocol incomplete.

Space evaluation. We also consider the feasibility of storage requirements. First, we evaluated the storage usage across four types of data (namely, key, ct, nsgt, and mpk). Our evaluations were conducted using SHA256 hashing, which generates a 32-byte length digest. Results indicate that the storage load for mpk with 1,000 entries requires approximately 780 bytes of storage, which is the most significant usage we observed. Secondly, we evaluated the trend of evidence size as the number of log entries increased. We found that the trend remains relatively stable, indicating the evidence size will occupy a constant amount of storage.

9 Discussion

We clarify the difference between the concepts of access control, traceability, and accountability, and provide potential applications to emphasize the necessity of our scheme.

9.1 Access Control, Traceability, and Accountability

The access control describes who and when can access data and resources. It prevents unauthorized access before
it occurs. Traceability records the activities of how the data has been created, modified, accessed, or transferred. It starts to work after accessing the resources. Accountability holds individuals responsible for their actions (based on traceability), emphasizing the punishment of inappropriate access (see Table 3).

Table 3: Description and example

<table>
<thead>
<tr>
<th>Concept</th>
<th>Description</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>Access control</td>
<td>Governing who can access specific resources, defining user permissions, privileges, and restrictions.</td>
<td>A nurse may access patient records in his/her department but not in other departments.</td>
</tr>
<tr>
<td>Traceability</td>
<td>Providing a documented trail of how the data has been created, modified, accessed, or transferred.</td>
<td>A nurse accesses a patient’s record in his/her department. The system records the nurse’s name, time of access, and the reason for access (e.g., treatment, diagnosis).</td>
</tr>
<tr>
<td>Accountability</td>
<td>Checking the documented trail to make users accountable for any misuse.</td>
<td>A nurse has improperly accessed a patient’s records, he/she is not allowed to access. The improper access to the data cannot be denied.</td>
</tr>
</tbody>
</table>

In the context of accountable decryption, the access control can be more fine-grained, e.g., one can even specify the legitimate decryption timeframe. For example, one can ask the decryptor to decrypt only between 3:00 PM and 5:00 PM on some day. Traceability underscores the recording of the specific decryption time to ensure a traceable trail. Meanwhile, accountability focuses on verifying whether decryption occurred within the specified time frame. If decryption takes place outside the permitted timeframe, the decryptor is accountable for its behavior and the owner of the data is aware of such behavior.

9.2 Potential Applications

Accountable ePHI. Electronic protected health information (ePHI) [43] refers to any health information that can identify a patient. Balancing ePHI privacy and accessibility is challenging. Sharing ePHI with all doctors increases the potential risk of information leakage. Conversely, sharing needed health information with only authorized doctors and meanwhile making any improper access undeniable is crucial. While one can use conventional access control mechanisms to achieve the same goal, this can slow down treatment as additional access control procedures are required, which is not desirable during emergencies. Our system provides a solution to address the challenges. It allows for information sharing while auditing unauthorized access and potential breaches. We consider patients as encryptors (i.e., E) who possess sensitive data, such as congenital genetic disorders. E encrypts their data and stores it in the hospital’s cloud server, making it inaccessible to general practitioners (e.g., dental consultants). For instance, when a patient requires emergency treatment, dentists (i.e., D) can bypass rules and access ePHI. After that, a designated auditor J (e.g., regulatory authorities) accesses the audit trail to monitor whether patient data is being accessed for the right purpose.

Accountable warrant. In an ideal scenario, law enforcement agencies could access citizens’ data stored in the cloud center based on electronic warrants [43]. However, in practice, warrants are processed confidentially to maintain the integrity of investigations and abuse by malicious law enforcement agencies are not always risk. Our solution addresses these concerns by requiring the law enforcement (D) to maintain a documented trail when accessing an individual (E)’s encrypted data. This trail enables public verification of law agencies’ decryption activities and ensures the safe and legal use of warrants, thereby mitigating the risks of abuse.

10 Related Work

Trusted hardware has been proposed as an effective tool for achieving accountability protocols. Pasture et al. [47] devised a secure messaging and logging library incorporating offline data access safeguarded by trusted hardware. Their approach ensures that access actions are irrefutable and revocations are verifiable. Ryan [3] proposed an accountable decryption protocol assisted by trusted hardware. Under the security of trusted hardware devices, the private key is stored inside TEs, and the information of each decryption will be recorded in a transparent log. Severinsen [32] implemented Ryan’s protocol using Intel SGX [13], guaranteeing that encryptors can detect every decryption. In this scheme, decryptors can only decrypt the ciphertext after updating the Merkle tree in logs. Liang et al. [48] proposed a decentralized accountable system for healthcare data using Intel SGX and blockchain. Luo et al. [42] applied the blockchain and SGX to an accountable decryption scheme. The decryptor is assisted by SGX, similar to Severinsen’s solution, but the log information is recorded on the blockchain. Fialka [4] employed a TEE-based confidential smart contract to make decryption accountable, where the transaction is used as evidence to trace a user’s decryption.

Different from prior studies that merely provide prototypes, our work formally defines the security properties of accountable decryption and proves the correctness of our concrete construction. Besides, this line of work often assumes that TEs are fully trusted. If the hardware is compromised, it is not hard to see that the solutions no longer work. Worse still, Overseers cannot learn whether the hardware has been compromised. To our knowledge, our scheme is the first work that considers compromised TEs. This is achieved by introducing a detection algorithm as part of our solution.

11 Conclusion

In this paper, we focus on achieving the practical accountability of decryption operations. We introduce a novel set of definitions tailored for accountable decryption. Our
definition aims to capture all possibilities and impossibilities in the formulation. We further construct a scheme aligning with the definitions by using trusted hardware. Our prototype and evaluations prove the practicability and efficiency.
