Abstract
The field of high-assurance cryptography is quickly maturing, yet a unified foundational framework for end-to-end formal verification of efficient cryptographic implementations is still missing. To address this gap, we use the Coq proof assistant to formally connect three existing tools: (1) the Hacspec emergent cryptographic specification language; (2) the Jasmin language for efficient, high-assurance cryptographic implementations; and (3) the SSProve foundational verification framework for modular cryptographic proofs. We first connect Hacspec with SSProve by devising a new translation from Hacspec specifications to imperative SSProve code. We validate this translation by considering a second, more standard translation from Hacspec to purely functional Coq code and generate a proof of the equivalence between the code produced by the two translations. We further define a translation from Jasmin to SSProve, which allows us to formally reason in SSProve specifications to imperative SSProve code. We validate this translation by considering a second, more standard translation from Hacspec to purely functional Coq code and generate a proof of the equivalence between the code produced by the two translations. We further define a translation from Jasmin to SSProve, which allows us to formally reason in SSProve specifications to imperative SSProve code. Finally, we demonstrate the usefulness of our approach by giving a foundational end-to-end Coq proof of an efficient AES implementation. For this case study, we start from an existing Jasmin implementation of AES that makes use of hardware acceleration and prove that it conforms to a specification of the AES standard written in Hacspec. We use SSProve to formalize the security of the encryption scheme based on the Jasmin implementation of AES.

Keywords: high-assurance cryptography, formal verification, computer-aided cryptography, AES, Coq

1 Introduction
Research on high-assurance cryptography recently led to significant practical success, with formally verified cryptographic code making its way into mainstream libraries and software products [7, 14, 16, 19, 21, 34, 37, 41, 42]. Since in this area missing any bugs can have a serious security impact, some additionally try to reduce the trusted computing base of their verification tools for cryptographic code and construct foundational proofs [5, 14, 21, 25, 29, 32]. Such foundational proofs rely on strong logical foundations—usually by working in a proof assistant like Coq or Isabelle/HOL—and only on standard, clearly stated assumptions. Yet despite good progress in this direction, a couple of important gaps remain for foundational end-to-end cryptographic verification.

First, there is a specification gap. Currently, cryptographic primitives and protocols are specified only using informal pseudo-code in the standards (e.g., in IETF RFCs). The Hacspec language [15, 31] aims to improve this, by making the code of these cryptographic specifications executable, which allows them to also serve as reference implementations that can be used as oracles for testing more efficient implementations. Hacspec is a simple subset of the Rust programming language, which aims to be understandable for both ordinary developers and cryptographers. Hacspec can be translated to the typed, purely functional language of proof assistants such as Coq, EasyCrypt, or F*, which allows sharing cryptographic specifications across these proof assistants.

Second, there is an implementation gap. Implementing cryptography in C has pitfalls: (1) unverified C compilers cannot be trusted to be always correct and secure [39], and (2) the CompCert verified C compiler does not perform aggressive optimizations and generates code with efficiency comparable only to GCC at optimization level 1 [2, 28]. Moreover, even

*Equal Contribution.
aggressively optimized C programs are sometimes not fast
even if these programs do not make use of special instructions

providing hardware acceleration for cryptographic primitives (e.g., Intel AES-NI [23]). So cryptographic primitives
are often implemented directly in assembly, at the cost of
loss of abstraction, clarity, and convenience. The Jasmin lan-
guage [4] was proposed as a solution to this problem. It is a
language for implementing cryptographic primitives com-
bining structured control flow with assembly instructions,
which allows one to produce efficient code for x86 and ARM.
Moreover, the Jasmin compiler comes with Coq proofs that
it preserves the semantics of the source code [4, 5] and that
it does not introduce timing side-channel attacks [6].

In the fundamental 'Last Mile' paper [5], Jasmin programs
are given semantics in Coq and compiled with a compiler
verified in Coq, but reasoning about the security and cor-
rectness of Jasmin programs is done only after an unverified
translation to EasyCrypt. In this paper, we close this gap by
providing a verified translation from Jasmin to SSProve. Staying
in Coq not only allows us to reduce the trusted computing
base, but it also facilitates reusing existing mathematical Coq
libraries [3, 30] to verify Jasmin implementations.

Contributions. We formally connect three existing tools,
Hacspec, Jasmin, and SSProve, into a unified foundational
Coq framework for the end-to-end verification of high-speed
cryptography (Figure 1). This includes the following novel
contributions:

- We provide a translation validation infrastructure,
which automatically produces Coq proofs of program
equivalence between the results of this imperative
translation and those of a more standard functional
translation. We do this by performing a compositional
symbolic evaluation, relating imperative code to its
mathematical model.
- We connect the Jasmin language and verified compiler
to SSProve, by providing a translation of Jasmin source
code to SSProve. We overcome the challenge created
by the fact that SSProve only supports global state
while Jasmin programs can use local state.
- We give a mechanized proof in Coq that this transla-
tion from Jasmin to SSProve preserves Jasmin’s oper-
ational semantics.
- We demonstrate the usefulness of our approach on a case study by producing a foundational end-to-end
Coq proof of an efficient AES implementation. We start from an existing Jasmin implementation of AES
using the Intel AES-NI instructions for hardware ac-
celeration [23] and prove (in ~2500 lines of Coq code)
that it conforms to a Hacspec specification of the AES
standard [20]. Finally, we instantiate a PRF-based sym-
metric encryption scheme with the implementation
of AES, and use SSProve to prove IND-CPA security
of this scheme under the (standard) assumption that
AES is a pseudo-random function (PRF).

Outline. We start by giving an overview of our method-
ology and illustrating it on a very simple one-time pad ex-
ample (Section 2). We then discuss necessary background
(Section 3), before diving in the two formal connections we
establish: the one between Hacspec and SSProve (Section 4),
the other between Jasmin and SSProve (Section 5). We finally present the AES case study (Section 6), before discussing related (Section 7) and future work (Section 8).

2 Foundational End-to-End Verification, from Specification to Efficient Implementation

In this section, we first give an overview of our methodology following Figure 1 and then demonstrate its workings on the very simple example of a one-time pad. At a high level, we provide a foundational framework for proving the equivalence between a specification in Hacspec and an efficient, low-level implementation in Jasmin, by translating both to imperative SSProve programs. Once translated, we relate the programs and prove properties about them in Coq using SSProve’s probabilistic relational Hoare logic.

2.1 Workflow

The workflow is illustrated in Figure 1. Starting from an informal description, such as an official standard (e.g., published by NIST or IETF) for a cryptographic primitive or protocol, one uses a subset of Rust with a simple, well-defined semantics to develop a Hacspec specification.1 We then automatically translate this specification in two ways:

- once to the purely functional language of Coq; this translation produces a functional specification; and
- once to the imperative language of SSProve; this translation produces an SSProve specification.

The functional translation [35] targets Coq’s mathematical language, and is similar to the usual functional semantics of Hacspec in F* and EasyCrypt. The imperative translation serves as a stepping stone towards a Jasmin implementation, which is inherently imperative.

We then perform translation validation [33] to automatically construct an equivalence proof in Coq, which formally shows that the functional and imperative Hacspec translations produce equivalent SSProve code from a given Hacspec program. More specifically, we prove that in a clean state, the program produced by the imperative translation will return the same value as the one produced by the functional translation. The proof is conducted in SSProve’s relational Hoare logic (see Section 3.3.4).

The second part of our framework concerns efficient cryptographic implementations written in Jasmin. We implemented a translation from Jasmin to the imperative language of SSProve and proved that it preserves semantics. This proof is entirely mechanized in Coq, which is possible because both SSProve and Jasmin already have formal semantics in Coq [4–6, 25]. So from the same Jasmin implementation (1) we can produce an assembly implementation using the existing Jasmin compiler, which was proved in Coq to preserve the source language semantics [4, 25]; and (2) we can obtain the Jasmin Coq AST of the Jasmin implementation, which we then translate to an SSProve implementation in a way that we proved to preserve semantics.

We are now in a position to reason about the SSProve implementation using the relational probabilistic Hoare logic of SSProve. On the one hand, we can conduct an equivalence proof between the SSProve implementation obtained from Jasmin and the SSProve specification obtained from Hacspec. On the other hand, we can connect the translated Hacspec specification with security proofs done in the SSProve framework. These proofs use the standard security games from the cryptographic literature [13, 24, 36, 38].

Formal Guarantees. By combining the correctness theorems of the Jasmin compiler and our translation to SSProve, we get the following corollary: for any function in a Jasmin program with well-defined semantics, there exists a corresponding compiled assembly function and translated SSProve function with the same semantics, i.e., which maps equal arguments to equal results and which modifies memory in an equivalent manner. In particular, the semantics of the SSProve and assembly functions agree and we can prove the properties of the assembly program by analyzing the corresponding SSProve program; probabilistic properties cannot however be carried to the assembly level, since the semantics there are deterministic. Note that we inherit some assumptions from the compiler proof (e.g., assuming sufficient stack-space) and introduce some in the translation proof (e.g., functions cannot use while-loops), see also Section 5.

2.2 One-time Pad Example

We now illustrate this methodology using a very simple example: We construct a one-time pad (OTP) from exclusive or (XOR). This toy example should convey intuition on the methodology. A more interesting case study for the AES encryption scheme is presented in Section 6. This section is to get an idea of the workflow and the ideas, however, we will introduce the background theory in more detail in Section 3.

2.2.1 Specification. The Hacspec specification for xor takes two 64-bit words as input, puts them into mutable variables, and computes their XOR (∘ in Hacspec). The result is stored in a mutable variable2, which is then returned.

```r
fn xor(w1 : u64, w2 : u64) -> u64 {
  let mut x : u64 = w1;
  let mut y : u64 = w2;
  let mut r : u64 = x ∘ y;
  r
}
```

1In fact, Hacspec is directly used in the upcoming hash-to-curve IETF standard [22] for writing a reference implementation.

2This use of mutability is for illustrative purposes only.
Our framework produces an automatic translation of this code to the following Coq function of type both.

\[
\text{Definition hacspec_xor} \ (w1 : \text{int64}) \ (w2 : \text{int64}) \ := \\
\quad \text{letbm } x_0 \ := \text{int64 loc} (x_0 \text{ loc}) \ := \ w1 \text{ in} \\
\quad \text{letbm } y_1 \ := \text{int64 loc} (y_1 \text{ loc}) \ := \ w2 \text{ in} \\
\quad \text{letbm } r_2 \ := \text{int64 loc} (r_2 \text{ loc}) \ := \ x_0 \oplus y_1 \text{ in} \\
\quad r_2.
\]

Here letbm stands for "let bind mutable". The type both can be projected both to pure Coq and to SSProve code (see Section 4.3), resulting in the following two functions:

\[
\text{Definition hacspec_xor_state} \ x \ y \ := \ x \oplus y.
\]

\[
\text{Definition hacspec_xor_pure} \ x \ y \ := \ x \land y.
\]

\[
\forall x \ y, \{ \lambda (h_0, h_1), \top \} \\
\quad \text{hacspec_xor_state} x y \approx \\
\quad \text{ret} \ (\text{hacspec_xor_pure} x y) \\
\quad \{ \lambda ((v_0, h_0) \ (v_1, h_1)), v_0 = v_1 \}.
\]

2.2.2 Jasmin Implementation. A Jasmin implementation of xor could look as follows.

\[
\text{export fn xor} \ (\text{reg u64} x, \text{reg u64} y) \rightarrow \text{reg u64} \{ \\
\quad \text{reg u64} r; \\
\quad r = x; \\
\quad r ^= y; \\
\quad \text{return } r; \\
\}
\]

It takes two register-allocated arguments x and y (as indicated by the reg keyword) and writes the XOR of x and y into the return register r.

2.2.3 SSProve Implementation. The next step is to translate the Jasmin code to the following SSProve function.

\[
\text{Definition JXOR id0 w1 w2} := \\
\quad \text{put } x := w1 \text{ in} \\
\quad \text{put } y := w2 \text{ in} \\
\quad \text{put } r := w1 \oplus w2 \text{ in} \\
\quad r1 \leftarrow \text{get } r \text{ in} \\
\quad \text{return } r1.
\]

While this readable code is not the literal output of the translation, it is the result of some careful (but semi-automated and verified) unfolding and simplification. The produced code also takes an "identifier", id0, as input: this determines which locations on the heap it will use for its local memory.

This technical detail will be explained in Section 5 and can safely be ignored for now.

2.2.4 Equivalence of Implementation and Specification. Now that we have both translations to SSProve, we can prove that they are equivalent in our program logic.

\[
\text{Theorem xor_equiv} : \forall \text{id0 w1 w2,} \\
\quad \{ \lambda \ (h_0, h_1), \top \} \\
\quad \text{JXOR id0 w1 w2} \approx \text{hacspec_xor_state} w1 w2 \\
\quad \{ \lambda \ ((v_0, h_0) \ (v_1, h_1)), v_0 = v_1 \}.
\]

The precondition is a predicate over the two initial heap states and the postcondition is a predicate over the two final heaps and values. The notion of equivalence we use here to relate the two functions only requires the return values v0, v1 of the two programs to be equal, provided we run them both on the same inputs. In particular, we do not make assumptions or restrict how the two programs use the heaps h0, h1. The programs are thus allowed to use different locations to store their intermediate values. This theorem is proved using the rules of the relational program logic of SSProve [1].

2.2.5 Security Proof for the OTP Implementation. We now prove perfect cryptographic security of the Jasmin implementation of OTP using XOR. To this end, we first need to define some terminology. In SSProve a package is a finite set of procedures that might contain calls to external procedures. The set it implements is called its export interface and the set on which it depends its import interface. A game is a package with no imports and a game pair is a pair of games that export the same procedures. These can be used to model cryptographic games, e.g., a game pair might consist of a real encryption scheme and an oracle: these have the same interfaces but different implementations.

For OTP we define the game pair consisting of an implementation of OTP using the Jasmin code and an implementation which is obviously secure. The Jasmin game is the package JOTP_real exporting the single procedure:

\[
\text{Definition JOTP id0 m} := \\
\quad \text{k_val} \leftarrow \text{sample uniform} \ (\text{word} \ n); \\
\quad \text{JXOR id0 m k_val}.
\]

We already have a security proof for the package OTP_real exporting the single procedure:

\[
\text{Definition OTP m} := \\
\quad \text{k_val} \leftarrow \text{sample uniform} \ (\text{word} \ n); \\
\quad \text{return m} @ \text{k_val}.
\]

This game is already proven to be indistinguishable under chosen plaintext attack from an implementation where the message is chosen at random. The statement and proof are in the SSProve library. This is done by proving that, when the input is disregarded and a random message is encrypted, the advantage of an attacker in distinguishing between OTP_real and a game OTP_ideal is zero.
If we can prove that JOTP_real is perfectly indistinguishable from OTP_real, then we can combine the two results using the triangle inequality for advantages of games (Lemma 1 in the SSProve paper [1]) and prove that an adversary also cannot distinguish between JOTP_real and OTP_ideal, i.e., the Jasmin implementation is IND-CPA. That is, we only need to prove the following theorem.

**Lemma** JOTP_OTP_perf_ind id : JOTP_real id ≈ OTP_real.

Here ≈ means that the advantage of an adversary trying to distinguish between the two games is zero. To prove this lemma we use Theorem 1 from the SSProve paper [1], which allows us to conclude if we can prove the following code equivalence for all m and some stable invariant \(\text{inv} \):

\[
\begin{align*}
\lambda \ (s_0, s_1) \ & \ \text{inv} (s_0, s_1) \\
\text{JOTP id0} \ m & \approx \ \text{OTP m} \\
\lambda \ (b_0, s_0) & \ (b_1, s_1), \ b_0 = b_1 \land \text{inv} (s_0, s_1).
\end{align*}
\]

For the precise definition of stable invariant see Section 4.2 of the SSProve paper [1]. In our case, we can use the invariant heap_ignore, which asserts that both heaps are preserved during execution if the locations used by JXOR are ignored.

Combining this result with the already established security of OTP_real we get security of JOTP_real.

**Theorem** unconditional_secrecy_jas : \(\forall \ A, \ 
\text{fdisjoint LA xor_locs} \rightarrow \text{ValidPackage LA} \\
\text{interface #val #[i1] : \ 'word \ \rightarrow \ 'word} \\
A\_export A \rightarrow \\
\text{Advantage IND_CPA_jasmin A} = 0.
\]

That is, for all valid adversaries \(A\) with a matching interface, and all regions of adversarial memory LA, if the adversary cannot use the same locations as JOTP real then their advantage in distinguishing between JOTP_real and OTP_ideal is zero.

## 3 Background & Technical Preliminaries

### 3.1 Hacspec

Hacspec is a High Assurance Cryptography SPECification language [15, 27, 31] aiming to provide a common language to programmers, cryptographers and proof engineers. It proposes to make future internet standards, such as those published by IETF and NIST, machine-readable. Hacspec is a subset of Rust which makes it executable and accessible to cryptographic engineers.

The Hacspec language was carefully crafted to have a functional semantics, in which assignments are translated to let-expressions. The Hacspec tool comes with functional translations to the purely functional languages of several proof assistants, currently F*, Coq, and EasyCrypt. As such it is a convenient tool to share specifications across proof assistants.\(^3\) Hacspec also comes with an operational semantics [31], but since the semantics is not formalized in the backends, the functional translation cannot be verified against it. Instead, this translation constitutes the authoritative semantics. This motivates our choice to relate our imperative translation via translation-validation\(^4\).

Currently, all Hacspec backends use a functional semantics. However, both in EasyCrypt and in Coq/SSProve, one could also choose to use a translation to an embedded imperative language. This can be seen as one of the benefits of Hacspec, as anyone familiar with either functional or imperative coding paradigms will understand the Hacspec specification. We will explain how to do so in Section 4.

### 3.2 Jasmin

Jasmin [4] is a low-level language designed for implementing high-speed cryptography, with a verified compiler backend supporting the x86 and ARM architectures. The language has a formal big-step operational semantics in Coq. The Jasmin compiler is also implemented and verified in Coq, in the sense that it preserves the semantics of the Jasmin source [4, 5] and also that it does not introduce timing side-channel attacks [6]. We give a condensed overview of Jasmin, focusing on the aspects that are interesting for the sake of our discussion, and limiting the explanation to a few representative examples. For more details please see the Jasmin paper [4].

#### 3.2.1 The Language.

Jasmin is an imperative language with structured control flow in the form of loops, conditionals, and procedure calls. Jasmin has types for booleans, integers, bit-words of various sizes, and arrays. Despite these high-level features, the Jasmin compiler produces predictable assembly code, which enables efficient and secure cryptographic implementations. For instance, the programmer can use architecture-specific assembly instructions and can specify whether procedure-local variables should be stored in registers (using the reg keyword) or on the stack (using the stack keyword). Jasmin’s operational semantics was carefully crafted to hide low-level details such as the distinction between the storage types reg and stack. Our correctness theorem for the translation from Jasmin to SSProve, like Jasmin’s compiler correctness theorem, is proven with respect to this operational semantics, and we can thus safely ignore such distinctions.

A Jasmin program \(P\) consists of a list of non-recursive function definitions, associating to each function name \(f\) a list of variables used for arguments \(P(f)\_\text{params} \), variables used

\(^{\text{3}}\) This also allows one to combine code generated from different proof assistants. For example, one could combine a hash function from F* and an elliptic curve implementation from Coq, both of which would be specified in Hacspec, verified, and then extracted to C (or Rust, or ASM). This is the methodology proposed in the libcrux library [27].

\(^{\text{4}}\) The operational semantics of Hacspec would be a good target for future formalization.
for returning results \( P(f)_{\text{res}} \), and a command, i.e., a sequence of instructions \( P(f)_{\text{body}} \) for the body of the function.

Instructions include assignments, operators, conditionals, for and while loops, and function calls. Expressions occurring in instructions include variable and array access, arithmetic and logical operators, as well as assembly operations such as shifts, increments, etc.

3.2.2 Jasmin State. Jasmin features both global and local state, denoted by a pair \((m, \rho)\) of a global memory \(m\) and local variable memory \(\rho\). A variable is local when it is declared within a function, and global when declared at the top level. We will write \(\rho[]\) and \(\rho[\cdot \leftarrow \cdot]\) respectively for local variable memory lookup and update. For global state, we will write \(m[\cdot]\) and \(m[\cdot \leftarrow \cdot]\) for lookup and storage of size \(i\), given in bits (possible values are 8, 16, 32, 64, 128, 256). Global state is indexed by integers (pointers) and local state by variables (strings). Note that looking up memory in Jasmin can fail, so we will abuse notation by denoting by \(m[p_i] = v\) that \(v\) is stored at \(p\) in \(m\) and that it is valid to make a read of size \(i\) at \(p\) in \(m\). We will do the same for writes.

3.2.3 Jasmin Operational Semantics. The operational semantics of Jasmin is mostly standard. A judgment of the form \(\langle e | (m, \rho) \rangle \Downarrow (m', \rho')\) means that for an initial state \((m, \rho)\), execution of the command \(e\) terminates in the final state \((m', \rho')\), and \(\langle e | (m, \rho) \rangle \Downarrow \exp v\) means that the expression \(e\) evaluates to the value \(v\) under state \((m, \rho)\) (expressions can only read, not modify the state). All judgments are implicitly parametrized by an ambient program (i.e., list of function definitions), which will not be mentioned explicitly unless required. For instance, in the rule for assigning a local variable in Figure 2 we start by evaluating the expression \(e\) to \(v\). We then look up the type \(\alpha\) of the variable \(x\), and perform a truncation\(^5\) of \(v\) at type \(\alpha\), yielding \(v'\) compatible with the type of \(x\). Finally, we update the local state to \(\rho[x \leftarrow v']\), while the global state remains unchanged.

The main subtlety for translating Jasmin to SSProve arises from function calls and their treatment of local state. The execution of function calls in Jasmin is split into two rules. The perspective of the caller is captured by \textsc{funcall}: We evaluate the arguments \(e_i\) and perform the call to the function \(f\) according to the callee’s perspective. We obtain a new global state \(m'\) and store the resulting values \(w_j\) in the caller-local variables \(x_j\). Jasmin’s type checker guarantees that the number of returned values equals the number of the \(e_i\). Crucially, when switching from caller to callee, we retain the local state \(\rho_0\) and pass only the global state \(m\) to \textsc{callrun} as witnessed by the use of \(\downarrow_{\text{call}}\) relating pairs of instructions and global memories and values and global memories.

\[\text{ASSGN}\]
\[
\frac{e \mid (m, \rho) \Downarrow \exp v \quad \alpha = ty(x) \quad v' = ||v||^\alpha}{(x = e | (m, \rho)) \Downarrow (m, \rho[x \leftarrow v'])}
\]

\[\text{FUNCALL}\]
\[
\frac{\langle e_i | (m, \rho_0) \rangle \Downarrow \exp v_i \quad i = 1, \ldots, k}{(f(v_1, \ldots, v_k) | m) \Downarrow_{\text{call}} ((w_1, \ldots, w_n) | m'')}
\]

\[\text{CALLRUN}\]
\[
\frac{\langle x_j = w_j | (m', \rho_{j-1}) \rangle \Downarrow (m', \rho')}{(f(v_1, \ldots, v_k) | m) \Downarrow_{\text{call}} ((w_1, \ldots, w_n) | m'')}
\]

Figure 2. Excerpt of Jasmin operational semantics

To describe the callee perspective, we write \(\rho_0\) for the empty local state, and \(c, y_i, x_j\) for the body, parameter-, and result-variables of \(f\) respectively. Each argument \(v_i\) is stored in the local variable \(y_i\) according to the definition of parameters of \(P(f)_{\text{param}}\). We then execute \(c\) from state \((m, \rho_k)\), yielding \((m', \rho')\). We obtain the values \(w_1, \ldots, w_n\) by reading the result variables \(x_j\) from the local state \(\rho'\) and truncating as necessary. Finally, the local state \(\rho'\) is discarded, and the result values and updated global state \(m''\) are returned.

3.3 SSProve

SSProve is a Coq library for modular cryptographic proofs introduced by Abate et al. [1]. We only review the concepts needed to understand the current paper. More details can be found in the extended version of the SSProve paper [25].

3.3.1 Code. In this paper, we de-emphasize the probabilistic capabilities of SSProve, as they are not currently reflected in Jasmin. Thus, for our purposes, SSProve essentially embeds a stateful language inside Coq using a monad called \texttt{raw_code}. In \texttt{raw_code} \texttt{A} one can (1) embed any pure value \(x\) of type \(A\) using \texttt{ret} \(x\), (2) read from a memory location \(\ell\) to a variable \(x\), and use \(x\) in a continuation \(k\), written \(x \leftarrow \texttt{get} \ell \;;\; k\), (3) write a value \(v\) to a memory location \(\ell\) and then continue with \(k\), written \(\texttt{put} \ell \;;\; k\), (4) sequentially combine \(u:\texttt{raw_code} X \land k: X \rightarrow \texttt{raw_code} A\) using the bind operator that we write \(x \leftarrow u \;;\; k\ x\). It is also possible to sample from a distribution \(D\) in this monad using \(x \leftarrow \texttt{sample} D \;;\; k\ x\) as shown in Section 2.

3.3.2 Memory Model. Memory locations consist of a natural number and a type that together serve as an index in

\(^5\)This truncation only exists at the high level to mimic the implicit truncations happening at the assembly level. In practice, the types of \(v\) and \(x\) mostly agree and the truncation can be simplified away.
a global shared memory. This global state is represented as a map from locations to values. We say that a state is valid for a set of (typed) locations when all locations point to values of the matching type. Note that to be able to use the type in the key of the memory, we must in fact use codes of types; since SSProve is built for probabilistic programs, these codes represent types on which one may build (discrete) distributions. In type-theoretic terms, they encode a universe of datatypes choice_type which represents a subset of mathcomp’s choiceType [30, §8.3]. For the purposes of our translation, we use a modified version of SSProve where choice_type is extended to include sums, words and lists. This allows us to encode all the types needed to represent Hacspec and Jasmin programs. Memory is simulated using a structure we call heap, essentially a map from locations to values. We would like to stress the fact that in SSProve the memory is global, in contrast to Jasmin’s function local state. Thus, one must take care to generate code without overlapping locations. We address this in Section 5.

For a heap $h$, location $\ell$ and value $v$, we will write $h[\ell] = v$ for heap lookup and storage (as for Jasmin state).

### Packages

Another defining feature of SSProve is that of packages. Packages are used extensively to compose modular security games in the style of state-separating proofs [17]. Since our methodology allows us to reuse existing security proofs [25], we will not get into the details of security proofs, so we only introduce packages briefly. Packages are collections of procedures that can all refer to the same set of locations and invoke certain procedures that are part of an import interface. The signature of this collection defines the export interface of the package. Packages can thus be combined modularly to create bigger packages. For instance, a package can be linked to another that implements its import interface or they can be composed in parallel to export the union of their respective export interfaces.

### Relational Hoare Logic

Finally, SSProve features a (probabilistic) relational Hoare logic that allows us to prove the relational properties of programs. Once again, we will focus on the stateful but deterministic fragment. In this program logic, we prove judgments of the form

$$\vdash \{ \phi \} \quad c_0 \sim c_1 \quad \{ \psi \}$$

where $c_0$ and $c_1$ are two code pieces we compare and $\phi$ and $\psi$ are respectively a pre- and a postcondition relating (1) the initial heaps (for $\phi$); (2) the final heaps and final return values of both code pieces (for $\psi$). For deterministic code, this is equivalent to: for all initial memory states $m_0$ and $m_1$ such that $\phi(m_0, m_1)$ holds, running $c_1$ in state $m_1$ will yield final state $m'_1$ and final value $v_1$ such that $\psi(v_0, m'_0)(v_1, m'_1)$ holds.

SSProve comes with a number of rules for this logic and provides tactics to facilitate writing proofs. Moreover, one can fall back on the semantics above to prove judgments [25].

### Interoperability

For the sake of getting Hacspec, Jasmin, and SSProve to interact smoothly, we had to extend each of them in a minor way. We did not, however, make any modifications to the core projects that would change the interpretation of any of the statements that can be found in the published literature.

Specifically, besides the translations which constitute the core contributions of this work, we made the following additions. For SSProve, we added sum types to represent the result types of Hacspec. We also added bitwidth-indexed machine words as well as lists. For Jasmin, we added the ability to pretty-print the Coq abstract syntax tree of a parsed Jasmin program, and we added the definition of the Intel AES-NI instructions [23] to Jasmin’s x86 semantics, since the AES-NI instructions are used in the AES case study. Hacspec remained unchanged.

### Hacspec & SSProve

Hacspec facilitates proving the correctness of efficient implementations with respect to a specification by translating it to multiple proof assistants. We further this goal by adding a translation from any valid Hacspec specification to SSProve. This imperative translation is accompanied by a pure translation, which adds a wrapper around the existing Coq translation to embed it into SSProve. We can thus compare the imperative and pure translations using SSProve’s relational logic and automatically generate a proof stating that they return the same values.

### The Functional Translation

The pure translation constitutes a minor modification of Hacspec’s existing Coq backend [35] that we undertook to facilitate the connection to Jasmin. Coq does not provide a standard library for machine integers, so the existing backend chose the CompCert library to model machine integers [28]. Jasmin uses its own word library. In the long run, we would hope for a unified word library in the Coq ecosystem. Meanwhile, we changed the backend to use Jasmin words.

We translate for-loops as a fixed point with an accumulator of all the mutable variables changed inside the loop. Hacspec has support for early return of option or result types. We model these early returns using the option and error monad. We thus need a fold operation that respects the monadic operations to allow early returns in for-loops.

### The Imperative Translation

Since we provide the first translation from Hacspec to an imperative programming language, we need to extend the information gathered in the translation from Hacspec to the various backends. SSProve needs information about what memory locations and functions are used in a given scope. To compute this, we add static dependency analysis to the Hacspec pipeline. This is done by walking the AST for every
We leverage this information to select between this custom which are then passed to the function. This makes it easier to prove equality to another SSProve implementation, as we can first prove that all the arguments are equal, and then show that the functions agree on equal input.

A subtlety arises from the fact that Hacspec supports early return statements: \( x = e? \) is operationally equivalent to

\[
x = \text{match } e \{ \text{Some}(v) \Rightarrow v, \text{None} \Rightarrow \text{return None} \}
\]

In particular, if \( e \) evaluates to \text{None}, the ambient function in which the statement \( x = e? \) occurs returns early with the result \text{None}. Since SSProve’s \text{raw_code} does not support control effects, we cannot directly represent this \text{return}. We instead embed Rust code with early returns into the option monad. To ensure that this encoding interacts well with the effectful operations of SSProve which manipulate state, we define a special bind operation, combining the two monads.

\[
\text{Definition obind } (x : \text{raw_code}(\text{option} A)) (f : \lambda x \rightarrow \text{raw_code}(\text{option} B)) : \text{raw_code}(\text{option} B) := t_x \leftarrow x ;;
\]

\[
\text{match } t_x \text{ with } \text{Some } s \Rightarrow f s | \text{None} \Rightarrow \text{return None} \text{ end.}
\]

The Hacspec code we translate carries sufficient typing information to determine whether a function may return early. We leverage this information to select between this custom bind operator and SSProve’s standard bind. For example:

\[
x = f(v)? ; y = g(x) ; y + 2
\]

is translated to the following SSProve code:

\[
\text{temp}_x \leftarrow f(v) ;;
\]

\[
\text{obind temp}_x (\lambda x. \text{temp}_y \leftarrow g(x) ;; \text{temp}_y + 2)
\]

### 4.3 Equivalence Between the Hacspec Translations

On the one hand, it is often easier to define and prove properties for a functional specification. On the other hand, it is easier to show an efficient imperative implementation equivalent to an imperative specification. So, it is desirable to derive an equality between the imperative and functional translations. We automatically generate such a proof, as part of the translation from the Hacspec specification. To achieve this we first define a record both, which has projections to a piece of code for the functional translation and for the imperative translation. It also contains the proof of equivalence for the two pieces of code. We traverse the AST building the functional translation, the imperative translation and their equivalence at the same time. This is achieved by using compositional blocks for the control structures of Hacspec.

An example of such block is the one used for \text{let} expression in Hacspec, where the functional translation is a functional let binding in Coq, while the imperative translation uses bind in SSProve. The equivalence can be proven using the bind rule in SSProve, since we have a proof of equality of the arguments and a proof of equality of the rest of the code bodies. Other blocks are loops, mutable state (where a location is used, as shown in Section 2.2.1), early returns, operator calls, lifting pure values, etc. We can therefore get the full translation to the imperative and functional code, together with the equality between them, by chaining these compositional blocks. This also requires us to define all the library functions in Hacspec in the \text{both} type. Using this combined type, we can write elements in a style where the translation looks close to the original specification and can be made more readable by the notation engine of Coq.

### 5 Jasmin & SSProve

#### 5.1 Memory

A major difference between the Jasmin and SSProve semantics is how memory is handled: SSProve only has a global notion of memory and Jasmin supports both global and local variables. To model local variables in SSProve, we parameterize all translated code over a “base stack frame ID” which reserves an (a priori unbounded) region of SSProve’s global memory for local variables. Then instantiating translated code with a concrete base stack frame ID correctly assigns new stack frame IDs to all its called functions. In particular, we prove that variables translated with different stack frame IDs never overlap, i.e., translation of variables is injective w.r.t. IDs. We store the Jasmin global memory in a map (from integers to bytes) at a static location called \text{MEM}.

#### 5.2 Program Translations

We now describe our translation from Jasmin to SSProve, meaning the translation of programs, but also of types, values, expressions and commands. As a first step, we use the Jasmin compiler to pretty-print the internal AST corresponding to a Jasmin source program to Coq syntax. Since this AST datatype was extracted from Coq in the first place, it amounts to ’de-extracting’ it back to Coq. Our translation thus translates Coq’s datatype of Jasmin programs to SSProve programs (i.e., the \text{raw_code} monad).

##### 5.2.1 Types and Values

The only base types missing from SSProve’s \text{choice_type} (the restricted set of types which \text{raw_code} can return; see Section 3.3.2) were words and arrays. Following Jasmin, we use the coqword library’s type of words, which is based on the mathcomp library [30]. We represent arrays as maps from integers to bytes. The only minor difference is our implementation of maps differs from Jasmin. Using similar types makes it easy to embed Jasmin values into SSProve values (via the identity) for all except...
array values. We denote the function taking Jasmin values to SSS-Prove values by translate_value.

5.2.2 Expressions. For the translation of expressions (denoted translate_pexpr) we have to be careful and do the right casts and truncations, as dictated by the semantics of Jasmin: e.g., when looking up in an array, the index is always cast to an integer type. For the translation of function applications in expressions (additions, subtractions, etc.), we reused the semantics from Jasmin expressions, by transporting values back to Jasmin types, applying the operations, and then transporting back to SSS-Prove types. Note that this transport is only non-trivial for arrays. This simplifies the proof significantly, only requiring us to prove that all operations are invariant under this transport.

5.2.3 Instructions. The main difficulty in translating instructions is translating function calls; for calls to operations we could mostly use the same solution as for expressions and for for-loops we simply iterate the translated body. To be able to call functions, we choose to let our translation keep track of previously translated functions, and only allow these to be called; this avoids cyclic calls and recursion (which are always rejected by the Jasmin compiler). Furthermore, we make sure to call these translated functions with a fresh stack frame ID to avoid collisions between local variables.

Note that we currently do not translate Jasmin while loops, as they do not have a correspondent in SSS-Prove. This does not constitute a conceptual problem in practice, since for-loops are sufficient for most cryptographic routines.

5.2.4 Programs. We translate Jasmin programs, which map function names to function declarations (Section 3.2.1), to maps from function names to SSS-Prove functions taking an ID and a list of inputs to SSS-Prove code.

5.3 Unary Deterministic Judgments

SSS-Prove originally supported only relational judgments of the form \( \vdash \{ \phi \} c_0 \sim c_1 \{ \psi \} \), as presented in Section 3.3. For the sake of our correctness theorem, we want to relate a translated Jasmin term \( c_0 \) to the value \( v \) it evaluates to, i.e., \( c_1 \) is always of the form \( \text{ret } v \). Since Jasmin’s semantics is deterministic, we do not need the full power of a probabilistic judgment. We thus extend SSS-Prove and build a new unary judgment on top of the relational logic, to deal with the special case where we relate a raw code with a return value: 

\[ \vdash \{ \phi \} c \Downarrow v \{ \psi \} \]

Here \( \phi \) is a precondition on the initial state of \( c \), while \( \psi \) is a postcondition on the final state after running \( c \). The postcondition no longer mentions a final state or return value for the right hand side, instead the return value \( v \) is part of the judgment. We define \( \vdash \{ \phi \} c \Downarrow v \{ \psi \} \) as the following judgment relating \( c \) to \( \text{ret } v \):

\[ \vdash \{ (m_0, m_1), \phi m_0 \} c \sim \text{ret } v \{ (a_0, m'_0), (a_1, m'_1), \psi m'_0 \land a_0 = a_1 \land a_1 = v \} \]

The precondition only considers the memory of the left-hand side, while the postcondition also states that both sides must produce the value \( v \).

While this unary judgment is conceptually simpler than the relational logic, we have found it beneficial to reuse the existing theory instead of starting from scratch. An advantage of this is that we can easily leverage the rules of the relational programming logic and the tactics provided by SSS-Prove to prove unary judgments. Moreover, we establish a precise connection between the two logics by proving that whenever \( c \) is free of sampling operations, the judgment above is equivalent to saying that running \( c \) on any initial state \( m \) such that \( \phi m \) will yield return value \( v \) and final state \( m' \) such that \( \psi m' \). For instance, we obtain the expected rules for values, sequential composition, and writing to the heap.

\[ \forall m. \phi m \Rightarrow \psi m \land v = v' \]

\[ \vdash \{ \phi \} \text{ret } v \Downarrow v' \{ \psi \} \]

\[ \vdash \{ \phi \} c \Downarrow u \{ \xi \} \vdash \{ \xi \} k u \Downarrow v \{ \psi \} \]

\[ \vdash \{ \phi \} x \leftarrow c ; ; k x \Downarrow v \{ \psi \} \]

\[ \vdash \{ \lambda m. \exists m', \phi(m') \land m = m'[t \leftarrow v] \} r \Downarrow w \{ \psi \} \]

\[ \vdash \{ \phi \} \text{put } t v ; ; r \Downarrow w \{ \psi \} \]

Other rules can also be derived straightforwardly from the definition of the unary judgment as analogues of the relational rules, which are detailed by Haselwarter et al. [25].

5.4 Correctness Theorem

We prove that our translation preserves the semantics of well-defined programs. To do this we define a relation between Jasmin memory states and SSS-Prove memory states. First, we relate the global Jasmin memory to the “global memory map” stored on the heap in SSS-Prove. We say that the global Jasmin state \( m \) is related to the heap \( h \) when, if one can successfully read a single byte at an address from the Jasmin memory, then one can look up the corresponding value in the “global memory map” stored at MEM on the SSS-Prove heap:

\[ m \sim h \Rightarrow \forall \rho. v. m[\rho] = v \Rightarrow h[\text{MEM}][\rho] = v \]

To relate the local memory of Jasmin and our encoding of local memory in SSS-Prove, we define a relation between a variable map \( \rho \) and a heap \( h \) relative to a stack frame ID \( i \). We write \( h[x]' \) for the lookup of the variable \( x \) on the heap relative to ID \( i \). A variable map \( \rho \) is related to the heap \( h \) w.r.t. \( i \) if successfully looking up a variable \( x \) in \( \rho \) implies that looking up \( x \) on \( h \) relative to \( i \) yields the same value:

\[ \rho \sim_i h \Rightarrow \forall x. v. \rho[x] = v \Rightarrow h[x]' = v \]

Now, the relation between a Jasmin memory pair \((m, \rho)\) (of global and local state) and an SSS-Prove heap is not just the conjunction over all these relations, since we need to know that a function can make an arbitrary number of function
We say that a stack frame ID \( \eta \) is fresh w.r.t. a heap \( h \) when \( \rho_0 \sim \eta \) holds, where \( \rho_0 \) is the empty variable map. We assume that we have a prefix order \( \leq \) on stack frame IDs and say that a stack frame ID \( s \) is valid w.r.t. a heap \( h \) when all strict successors of \( s \) are fresh w.r.t. \( h \), i.e., for all \( s' \succ s \), \( \rho_0 \sim \eta \). Furthermore, we say that two IDs \( s_1 \) and \( s_2 \) are disjoint, when there is no ID which both are a prefix of. Concretely, we require for all IDs \( s \) that \( s_1 \preceq s \) and \( s_2 \preceq s \) do not both hold simultaneously. We assume that storing at disjoint ID locations preserves values: if \( s_1 \) and \( s_2 \) are disjoint then \( \forall x, y, h[y \leftarrow v]^\sim s x^\eta = h[x]^\eta \).

For a variable map \( \rho \), two stack frame IDs \( (\rho, i, \sigma) \) (main and sub-ID) and a set \( I \) of IDs we say that the tuple \( (\rho, i, \sigma, I) \) is a stack frame. We say that a stack frame \( (\rho, i, \sigma, I) \) is valid w.r.t. a heap \( h \) when the following conditions hold: (1) \( \sigma \) is valid w.r.t. \( h \), (2) \( \rho \sim h \), (3) \( \sigma \not\in I \), (4) for all \( \sigma' \in I \), \( i < \sigma', \sigma' \) is disjoint from \( \sigma \) and \( \sigma' \) is valid w.r.t. \( h \), (5) for all \( \sigma', \sigma'' \in I \), \( \sigma' \) and \( \sigma'' \) are disjoint.

The intuition for a valid stack frame \( (\rho, i, \sigma, I) \) is that \( \rho \) should be related to the main stack frame ID \( i \), and the sub stack frame ID \( \sigma \) should be a valid ID from which the current function can spawn new functions with fresh memory; \( i \) is there to keep track of which IDs are currently in use and to which variable maps they relate. Note that the set \( I \) is only needed for the proof of correctness, and is not actually used in the translation of a given program.

A stack is then a list of stack frames. The empty stack is denoted by \( S_0 \). A stack frame \( (\rho, i, \sigma, I) \) is disjoint from a stack \( S \) when \( i \) is disjoint from all other stack frames and IDs occurring in sets of the stack frames on \( S \). A stack \( S \) is valid w.r.t. a heap \( h \) when either \( S \) is empty or \( S = F :: S' \) where \( S' \) is a valid stack and \( F \) is a valid stack frame disjoint from \( S' \).

Using these constructions we can finally define our relation on Jasmin and SSProve states. A Jasmin state pair \( (m, \rho) \) is related to the heap \( h \) w.r.t. the stack \( S \), which we write \( (m, \rho) \sim_S h \), when the following conditions hold: (1) \( S \) is valid w.r.t. \( h \), (2) \( m \sim h \), (3) \( \rho \) is the variable map at the top of the stack, i.e., the top of the stack is of the form \( (\rho, i, \sigma, I) \). This relation satisfies two key lemmas, which are needed to prove the correctness of our translation.

Lemma 1 (Push empty stack frame). If \( (m, \rho_1) \sim_{(\rho_1, i_1, \sigma_1, I_1)} h \) and \( \sigma_1, \sigma_2 \) are two disjoint IDs with \( \sigma < \sigma_1, \sigma_2 \), then

\[
(m, \rho_0) \sim_{(\rho_0, \sigma_1, \sigma_2, 0)} (\rho_0, i_1, \sigma_1, I_1) \sim_S h.
\]

Lemma 2 (Pop stack frame). Let \( F_i = (\rho_0, i_1, \sigma_1, I_1) \), then if \( (m, \rho_2) \sim_{F_i :: F_i} h \) then \( (m, \rho_1) \sim_{F_i} h \).

These two lemmas correspond to (1) calling a function and assigning it a fresh region of memory for local state and (2) returning from a function call to its caller, accounting for the operational semantics of Jasmin function calls according to Figure 2. Note in Lemma 1 that the sub-ID of the calling stack frame, \( \sigma \), is updated to a fresh ID \( \sigma_2 \), and that we initialize the callee frame with the same main and sub ID \( \sigma_1 \), since when the frame gets pushed in a function call, the callee has not invoked any further functions yet.

Using this relation, we show how our translation of Jasmin code relates to its source. For example, if we consider the function \( \text{translate}_\text{pexpr} \), which translates Jasmin expressions to \text{raw_code}, we get the following correctness lemma.

Lemma 3. Let \( v \) be a value, \( e \) an expression, \( s \) a Jasmin state pair and \( S \) a stack. If \( (e \mid s) \}\exp v \) then

\[
\{ h, s \sim_S h \} \text{ translate}_\text{pexpr} S \{ e \} \| \text{translate}_\text{value} v \{ h, s \sim_S h \}
\]

As evaluating expressions does not have memory side effects, the relation between Jasmin and SSProve states is preserved under expression translation.

We now prove the main theorem, which establishes the connection between \textit{function calls} in Jasmin and in SSProve:

**Theorem 1.** Let \( P \) be a Jasmin program, \( (m, \rho) \) a Jasmin state-pair, \( f \) a function name, and \( v_1, \ldots, v_k \) values for \( i = 1, \ldots, k \). Furthermore, let \( \sigma_1, \sigma_2, \ldots, \sigma_n \) be IDs such that \( \sigma_1 \) and \( \sigma_2 \) are disjoint and strict successors of \( \sigma \). If \( P' \) is the result of translating \( P \) and \( (f(v_1, \ldots, v_k) \mid m) \} \| \text{call} (\langle v_1, \ldots, v_n \rangle \mid m') \) then

\[
\{ h, (m, \rho) \sim (\rho, i, \sigma_1, I) h \}
\]

\[
P' f \sigma_1 \| \text{translate}_\text{values} (v_1, \ldots, v_k)
\]

\[
\{ h, (m', \rho) \sim (\rho, i, \sigma_2, I) h \}
\]

The theorem states that if calling the function \( f \) in the Jasmin program \( P \) and global memory \( m \) with arguments \( \vec{v} \) results in the new global memory \( m' \) and returns the values \( \vec{w} \), then we can conclude two things:

1. Calling the function at a fresh ID \( \sigma_1 \) and with the translation of the arguments \( \vec{v} \) evaluates to the translation of the return values \( \vec{w} \).
2. After calling the translated function, the global memory \( m' \) is related to heap where we have updated the sub-ID to a fresh one (from \( \sigma \) to \( \sigma_2 \)).

This is the expected behavior: calling a function can change the global but not the local state. We have to update our sub-ID because the previous one is no longer fresh, as we might have stored local state inside the function call.

6 AES Example

As a larger case study of our framework, we verify the security of a Jasmin implementation of a PRF-based encryption scheme using AES and prove it equivalent to a Hacspec reference implementation. The Jasmin implementation and the general methodology for proving security are similar to the presentation in EasyCrypt [8], but we use our toolchain based on SSProve to conduct the formalization.

The workflow for proving security of our AES implementation is as follows:
We skip implementing the Jasmin code by reusing the im-
plementation from the EasyCrypt and Jasmin tutorial [8],
which relies on the Intel AES-NI hardware acceleration in-
structions [23]. Our reference implementation in Hacspec is
based on the NIST standard [20], and it successfully passes
the corresponding public test vectors [20, 23].

For the security analysis, we prove indistinguishability
under chosen plaintext attack (INd-CPA) of the AES imple-
mementation of the PRF-based symmetric encryption scheme
described below. Concretely, we prove that the advantage
of an adversary in distinguishing the encryption of a mes-
tage from the encryption of a random message is (linearly)
bounded by the advantage of the same adversary in distin-
guishing AES from a PRF. For details on the concrete bounds,
see the SSProve journal paper [25, §2.3].

As was the case in Section 2, we do not have to write a se-
curity proof of the abstract encryption scheme from scratch,
since such a proof, for an abstract PRF, is already present
in the SSProve library [25, §2.3]. To connect this with our
efficient implementation, we need to prove that an adversary
cannot distinguish between the efficient implementation and
the abstract implementation given in SSProve [25, §2.3] in-
stantiated with a Coq implementation of AES.

As in loc. cit., our definitions follow SSP methodology [17].
The PRF-based encryption scheme is given by the code:

\[ \text{Definition PRF\_ENC } f \ m \ := \]
\[ k\_val \leftarrow \text{kgen } ; ; \text{ enc } m \ k\_val. \]

Here, kgen is a key generation code that uniformly samples
a key on its first invocation and returns a fixed key on sub-
sequent calls. The enc function is given by the code:

\[ \text{Definition enc } m \ k \ := \]
\[ r \leftarrow \text{sample uniform } N ; ; \]
\[ \text{let pad } := \ f \ r \ k \ \text{in let c } := \ m \ \oplus \ \text{pad in }\]
\[ \text{ret } (r, c). \]

Here \( f \) is the function which we assume to be a PRF and
which we will instantiate with AES. The PRF is used to gen-
erate a pad from a uniformly sampled nonce \( r \); the ciphertext
is computed as the xor of the message and the pad. For all
functions \( f : \text{word } \rightarrow \text{word } \rightarrow \text{word } \) we denote the game
consisting of the single export PRF\_ENC \( f \) by PRF\_real \( f \).

We reuse the SSProve proof [1, §2.3] by showing that
PRF\_real aes is perfectly indistinguishable from the same
scheme with \( \text{enc } \) replaced by the translated Jasmin code.

The high-level structure of the security analysis of the
implementation is as follows:

1. Write an intermediate imperative implementation di-
rectly in SSProve code.
2. Write a functional implementation directly in Coq.
3. Prove the equivalence between the intermediate im-
plementation and the functional implementation.
4. Prove the equivalence between the translated imple-
mentation and the intermediate implementation.
5. Connect the equivalences to the existing security proof
of the abstract encryption scheme.

Steps (1) and (2) can also be copied almost verbatim from
the EasyCrypt development: the syntactic similarities of the
EasyCrypt and SSProve codes make the translation very
straightforward. For the proofs in steps (3) and (4) we can
reuse some parts, e.g., the loop invariants, but in general the
differences in the programming languages and the underly-

6.1 Translation

As mentioned in Section 2, we start by printing the Coq
ASTs of all the involved functions during Jasmin compilation.
Then we use the translation described in Section 5 to obtain
SSProve code for each function used in the implementation.

6.2 Specification

Next, we write intermediate specifications for the Jasmin
functions. Compared to the example in Section 2, these cor-
respond to the pure Coq XOR function. As mentioned, we
take inspiration from the specifications in the EasyCrypt and
Jasmin tutorial [8]. This step removes translation artefacts
(e.g., compiler-generated memory locations) and allows us
to focus on proving the underlying logical statements.

6.3 Equivalences for Intermediate Code

Then we prove that our intermediate implementations are
equivalent to functional (stateless) Coq functions. The state-
ments we prove are generally of the form:

\[ \vdash \{(m_0, m_1), \phi (m_0, m_1)\} \ c i \sim \]
\[ \text{ret } (f i) \{(a_0, m_0'), (a_1, m_1'). \phi (m_0', m_1') \land a_0 = a_1\} \]

where \( i \) is arbitrary input, \( c \) is the intermediate SSProve code
and \( f \) is the pure Coq function. Note that we also prove
that these equivalences preserve the precondition \( \phi \); for the
equivalences to hold we usually have to assume that \( \phi \) is
stable w.r.t. memory locations used by \( c \).

Even though \( f \) is usually stateless, we have to keep the
heap of the right-hand side in mind, since it might be relevant
in certain contexts; otherwise we could have used the unary
judgments of Section 5.3.

1. Implement the encryption scheme in Hacspec and
Jasmin.
2. Translate the two implementations to SSProve code.
3. Prove the two translations equivalent and prove security
properties of the Jasmin translation.\(^6\)

\(^6\)Here we deviate slightly from the intended workflow from Section 2 by
doing the security proof on the implementation instead of the specification.
The reason for this is simply that parts of security proof about the Jasmin
implementation were already completed when the Hacspec specification
was added to the project.
6.4 Equivalences for Translated Code

When reasoning about the code generated by our translation from Jasmin to SSProve, we have to prove equivalences of the following form:

\[ \vdash \{ (m_0, m_1), (m_0, m_1) \} \quad P' F id i \sim c i \{ (a_0, m_0'), (a_1, m_1'), \phi (m_0', m_1') \land a_0 = a_1 \} \]

where \( P' \) is the translated Jasmin program, \( i \) is an arbitrary input, \( id \) is a stack frame ID, \( F \) is the function name in the Jasmin program and \( c \) is the intermediate code.

Once we have proven such an equivalence, we can reuse it in proofs where \( F \) appears as a called function. It is therefore important that the equivalences are parametric in \( id \). We also want to preserve the precondition \( \phi \) and again we have to assume that \( \phi \) is stable w.r.t. the locations of \( F \) and \( c \).

Regarding our advantage theorem, we require that \( \phi \) is stable w.r.t. all possible locations used by \( \phi \), i.e., locations stored using an \( id \) with prefix \( id \) (\( id \neq id' \)). This turns out to be a sufficient and reasonably manageable invariant to preserve.

6.5 Connecting AES to the PRF Security Proof

The encryption function of which we want to prove the security can be implemented in Jasmin as:

```jasmin
fn enc(reg u128 n, reg u128 k, reg u128 p) -> reg u128 {
  reg u128 mask, c;
  mask = aes(n, k);
  c = xor(mask, p);
  return(c);
}
```

We translate it into SSProve as \( JENC \) and use it in the following security game, supplying the random nonce \( r \):

```
Definition JPRF_real id0 m :=
  k_val ← kgen ;;
  r ← sample uniform N ;;
  res ← JENC id0 k_val r m ;;
  ret (r, res)
```

We then prove it perfectly indistinguishability from a similar scheme \( CPRF \) which uses an intermediate, simplified SSProve encryption function, \( ENC \), in place of \( JENC \).

We establish the indistinguishability by applying Theorem 1 of the SSProve paper [1]. We thus have to find a stable invariant that is preserved by a run of each of these schemes and prove that they return equal values. We prove a slight generalization of the version that theorem. Before, the invariant was required to be stable w.r.t. the finite sets of locations used by the program. Moreover, these sets were assumed to be disjoint from the state of the adversary. We now only require the invariant to be stable w.r.t. some arbitrary sets of locations assumed to be disjoint from the state of the adversary. In particular, the sets can be infinite.

Thanks to this generalization we can apply the theorem when one of the programs is the output of our translation, since we do not have to provide the concrete set of locations used by the program, but instead we can use an infinite over-approximation. We thus obtain the following.

**Theorem JPRF_perf_ind id : JPRF_real id ≈_0 CPRF_real.**

We prove that \( CPRF_real \) is perfectly indistinguishable from \( PRF_real aes \) using the original SSProve Theorem 1 as we have better control over which locations are used.

**Theorem CPRF_perf_ind id : CPRF_real ≈_0 PRF_real aes.**

Combining these two theorems, we get the following: the advantage of any adversary, which uses locations disjoint from \( JENC \) and from the intermediate encryption schemes, in distinguishing between \( JPRF_real \) and \( PRF_ENC \) is 0. This we can then combine with the result from the SSProve paper [1, Section 2.3] which states that \( PRF_ENC \) is IND-CPA secure up to the advantage of an adversary against \( aes \) as a PRF.

7 Related Work

The use of formal verification for cryptography has been intensely investigated, and Barbosa et al. [7] give an overview. More narrowly, work related to SSProve can be found in the extended version of the SSProve paper [25]. In this section, we survey the closest related work to ours in this space.

CertiCrypt [11] is the earliest framework for reasoning about cryptographic code in Coq, but is no longer maintained. FCF [32] is a more recent foundational Coq framework for cryptographic proofs. It was used together with VST to verify the C implementations of HMAC in OpenSSL [14] and mbedTLS [41]. Our work is similar in that we prove the security and correctness of the Jasmin implementation of AES. While FCF could have been a reasonable option for us, we chose SSProve because it is under active development, uses the well-developed mathcomp [30] and mathcomp-analysis libraries [3], and supports modular proofs.

EasyCrypt [9, 10] is a proof assistant and verification tool specifically designed for game-based cryptographic proofs. Its good integration with automatic theorem provers (e.g., SMT solvers) is helpful for large proofs, even though it comes at a cost in terms of trusted computing base. The program logics of CertiCrypt and EasyCrypt come with native support for reasoning about function calls. This was not available in SSProve before and addressing this is one of the contributions of the present work (see Section 5.1).

In the fundamental 'Last Mile' paper [5] Jasmin programs are given semantics in Coq and the correctness of the Jasmin compiler is proved in Coq with respect to this semantics. As a realistic case study, they use EasyCrypt to prove the security and correctness of a Jasmin implementation of SHA3, relying on an unverified translation from Jasmin to EasyCrypt. In the present work, we bridge this gap by providing a verified translation from Jasmin to SSProve.
CryptHOL [12] is a foundational framework for game-based proofs that uses the theory of relational parametricity to achieve automation in Isabelle/HOL. However, unlike FCF and EasyCrypt, CryptHOL has so far not been used for the verification of efficient programs, as far as we are aware.

Schwabe et al. [37] prove the correctness of the C implementation of X25519 in TweetNaCl using VST. Prozzenko et al. [34] verify an impressive library of cryptographic code in F*. Fiat-Crypto [21] is a foundational tool that can generate verified efficient implementations of finite field arithmetic. These works are focused on correctness though and do not consider cryptographic security.

Currently, there is no formal specification for the complete Rust language. The Hacspec semantics can be seen as a precise semantics for a non-controversial subset of Rust. Similar proposals, but for much larger subsets of Rust, include those of Ho and Prozenko [26] and Denis et al. [18].

8 Future Work

Jasminify [40] is a python tool that simplifies the process of calling Jasmin code from Rust. After compiling a program, the Rust object file is replaced with the Jasmin object file. However, Jasminify does not come with any correctness guarantees. We have shown how to prove the equivalence of a Rust (Hacspec) implementation for AES with a Jasmin program. Hacspec is expressive enough to implement high-level cryptographic protocols. For such protocols, we now have a safe way to replace its cryptographic primitives by optimized Jasmin ones, as we know that their source-level semantics agree. As future work, one could try to test this toolchain, by using Jasminify, proving equivalence between the Hacspec and Jasmin implementations and then benchmarking to see what kind of performance gains one can achieve.

In concurrent work, libcrux [27] provides a library of verified implementations from different frameworks; and combines them with a safe Rust API. For example, it starts with a Hacspec reference implementation of HMAC and HKDH, and replaces their hash functions with optimized Jasmin implementations. It was proved [5] in EasyCrypt that the SHA3 implementation indeed implements a hash-function, but a formal connection with Hacspec is still missing. It would be exciting to use our framework to formally verify some of the replacements done in libcrux.

The Jasmin language is still under active development. In the present work, we devised a verified translation for the published version of the language [4]. It would be interesting to extend our work with language features that were added to Jasmin concurrently to our work.
