Abstract

In the context of fully-homomorphic-encryption, we consider the representation of large integers by their decomposition over a product of rings (through the Chinese Remainder Theorem) and introduce a new algorithm for the determination of the sign solely through the knowledge of ring-components. We then prove that our algorithm delivers a correct result with a very high probability.

1 Introduction

On top of the two elementary arithmetic operations (addition and multiplication) included by design in all fully-homomorphic-encryption (FHE) systems, many real-world applications require comparisons\(^1\). As a consequence, algorithms aimed at computing the sign\(^2\) of a message have been developed for the most prominent classes of FHE cryptosystems, that is to say FHEW/TFHE schemes for boolean circuits [22], Brakerski-Gentry-Vaikuntanathan (BGV), Brakerski/Fan-Vercauten (BFV) schemes for messages in finite fields [17, 25] and Cheon-Kim-Kim-Song (CKKS) scheme for real and complex messages [9, 19, 20]. We refer to [22] for an evaluation of the comparative merits of these various algorithms and for a description of what appears, up to our knowledge, as the most recent technique for the large-precision evaluation of the sign. However, none of the literature cited above is concerned with the sign evaluation of large-integers from its residues (encryptions thereof). It is precisely the objective of this work to introduce a method for determining the sign for a FHE crypto-system based on a residue number system (RNS).

Using the Chinese Remainder Theorem (CRT) in order to build a FHE library is indeed a well-known theoretical alternative to the binary representation of large numbers (say 32-bits or 64-bits) and their treatment by circuits (see for instance papers on the TFHE [11] and FHEW [14] protocols). The advantage of the representation of numbers of \(\mathbb{Z}/p\mathbb{Z}\) by their moduli in a product of rings of \(\mathbb{Z}/p_1\mathbb{Z} \times \cdots \times \mathbb{Z}/p_k\mathbb{Z}\) lies in the fact that each ring can be handled separately as far as additions and multiplications are concerned. In the companion paper [5] by the same authors, we indeed introduce a modification

\(^1\)This is in particular the case for training neural networks [2, 18] –or more generally statistical learning [10]– or requesting databases.

\(^2\)The comparison of two messages \(a\) and \(b\) boils down to the determination of the sign of \(a - b\).
of the bootstrap procedure which aims at allowing (without extra computational cost) larger values of the pairwise coprime integers \( p_i \)'s and thus values of \( p = \prod_{i=1}^{k} p_i \) up to \( 2^{64} \). However, as aforementioned, one key aspect of the manipulation of large sets of data is the necessity to order and sort them: at the core of all FHE-library, should lie the possibility to determine the sign of a single number. Until now, this has prevented the use of the CRT in the context of FHE as the homomorphic determination of the sign has long been considered as a difficult question.

In this paper, we present a solution of this problem in the context of FHEW/TFHE encryption protocols. The corresponding algorithm and associated devices have given rise to the patent [6]. More precisely, we show how to compute with the help of homomorphic operations and several functional bootstrappings, an encrypted value of the sign of any element of \( \mathbb{Z}/p\mathbb{Z} \) from the FHEW-encryptions of its residues in the \( \mathbb{Z}/p_i\mathbb{Z} \) for \( i = 1, \ldots, \kappa \).

To this aim, we introduce a new algorithm which computes a series of scalings of the original ciphertext, obtained in a standard way with the Bezout coefficients. We then show that among the consecutive magnifications of this message (again, in encrypted version), one allows to determine safely its sign. The result is then carried out through a cascade of linear combinations whose aim is to preserve the relevant information. The trick used here is to a large extent similar to the one used in [3, 4]. We prove rigorously the correctness of the algorithm with very high probability for appropriate parameters and we explain how to choose them.

2 Background

2.1 Notations and preliminaries on the Chinese remainder theorem

For all integer \( p \geq 2 \), the main representative of \( \mu \in \mathbb{R}/p\mathbb{Z} \), denoted by \( [\mu]_p \), will be taken in the interval \([-p/2, p/2]\), and the norm of \( \mu \) is \( |\mu| = |[\mu]_p| \). Throughout the paper, for all interval \( I \subset \mathbb{R} \) of length smaller than \( p \), for any \( \mu \in \mathbb{R}/p\mathbb{Z} \), we shall say that \( \mu \in I \) if there exists \( k \in \mathbb{Z} \) such that \( [\mu]_p - kp \in I \).

Consider an integer \( p \) of the form

\[
p = \prod_{i=1}^{k} p_i
\]

where the integers \( p_i \geq 3 \) are assumed to be odd and pairwise coprime, i.e.

\[
\forall 1 \leq i < j \leq k, \quad p_i \wedge p_j = 1.
\]

Any element \( \mu \) in the set \( \mathbb{Z}_p \) may be represented unambiguously (owing to the Chinese Remainder Theorem) by its coordinates

\[
(\mu_1, \ldots, \mu_k) \in \mathbb{Z}_{p_1} \times \cdots \times \mathbb{Z}_{p_k}
\]

with

\[
\mu_i = \mu \mod p_i, \quad i = 1, \ldots, k.
\]

The Chinese Remainder Theorem states that the map

\[
\Phi : \mathbb{Z}_p \to \mathbb{Z}_{p_1} \times \cdots \times \mathbb{Z}_{p_k},
\]

\[
\mu \mapsto (\mu_1, \ldots, \mu_k) = (\mu \mod p_1, \ldots, \mu \mod p_k)
\]
is an isomorphism with inverse
\[ \Phi^{-1} : \mathbb{Z}_{p_1} \times \cdots \times \mathbb{Z}_{p_k} \rightarrow \mathbb{Z}_p \]
\[ (\mu_1, \ldots, \mu_k) \mapsto \mu = \sum_{i=1}^{k} \tilde{p}_i^{-1} \tilde{p}_i \mu_i \mod p \]
where \( \tilde{p}_i = p/p_i \) and where \( \tilde{p}_i^{-1} \) denotes the inverse of \( \tilde{p}_i \) in \( \mathbb{Z}_{p_i} \), determined as a Bezout coefficient by Euclidean’s algorithm.

### 2.2 LWE encryption and Functional Bootstrapping

In this section we recall the definition of LWE ciphertexts [26], and the properties of the functional bootstrapping procedure needed by our algorithm. The LWE cryptosystem is parametrized by a plaintext modulus \( p_i \), a ciphertext modulus \( q \) and the secret dimension \( n \). As in the BFV, FHEW and TFHE schemes, we shall encrypt any message in \( \mathbb{Z}_{p_i} \) in the most significant digits of integers of \( \mathbb{Z}_q \). The LWE encryption of a message \( \mu_i \in \mathbb{Z}_{p_i} \) under (secret) key \( s \in \mathbb{Z}^n \) is a vector \( c = \text{LWE}^{n,q,p_i}_s(\mu_i) = (a,b) \in \mathbb{Z}^{n+1} \) such that
\[ b = \langle a, s \rangle + \lfloor q\mu_i/p_i \rfloor + e \mod q \]
where \( e \in \mathbb{Z}_q \) is the so-called noise, which is picked from a centered Gaussian distribution during secret-key encryption. For all ciphertext \( c = (a, b) = \text{LWE}^{n,q,p_i}_s(\mu_i) \), the so-called phase is the quantity
\[ \varphi_s(c) := b - \langle a, s \rangle \in \mathbb{Z}_q \]
and we shall denote the error term associated to \( c \) by
\[ \text{Err}(c) = \varphi_s(c) - q\mu_i/p_i. \]
Introducing the rounding error
\[ \delta_i := \lfloor q\mu_i/p_i \rfloor - q\mu_i/p_i, \]
we have \( \text{Err}(c) = e + \delta_i \in \mathbb{Q} \) with \( |\delta_i| \leq \frac{1}{2} \). The message \( \mu_i \) is recovered by first computing the approximate decryption function
\[ \varphi_s(c) = \lfloor q\mu_i/p_i \rfloor + e = q\mu_i/p_i + \text{Err}(c) \mod q \]
and then rounding its main representative to the closest multiple of \( q/p_i \). Decryption is correct if \( |\text{Err}(c)| < \frac{q}{2p_i} \). Now, if \( p = \prod_{i=1}^{k} p_i \) is as in the previous section, the encryption of any (possibly large) integer \( \mu \in \mathbb{Z}_p \) will be the set of encryptions \( \text{LWE}^{n,q,p_i}_s(\mu_i) \) of its components \( \mu_i \) for \( 1 \leq i \leq k \).

Homomorphic arithmetic operations intrinsically increase the level of noise up to a point where the message can not decrypted. The bootstrapping procedure introduced by Gentry [16] and its generalisations to the evaluation of functions have been designed to re-encrypt a message with a lower noise without having to decrypt it beforehand. Ducas and Micciancio [14], and later on in a faster version, Chillotti et al. [11, 12], have introduced a very efficient bootstrapping based on the polynomial rings (see also [23, 21] for further

---

3When \( p_i = q \), the message \( \mu_i \in \mathbb{Z}_q \) is not rescaled and the corresponding \( \text{LWE}^{n,q,p_i}_s(\mu_i) \) ciphertext will be denoted shortly as \( \text{LWE}^{n,q}_s(\mu_i) \).
improvements), whose details we shall not give here\textsuperscript{4}. In the rest of this section, we nevertheless present its main properties for later use in the paper.

The FHEW/TFHE functional bootstrapping algorithm uses the polynomial ring

\[ \mathcal{R}_{N,p'} = \mathbb{Z}_{p'}[X]/(X^N + 1) \]

where \( N \) is a power-of-two, so that \( X^N + 1 \) is the \( 2N \)-th cyclotomic polynomial. The underlying idea of this method consists in the homomorphic implementation of a function

\[ f_v : \mu \in \mathbb{Z}_{2N} \mapsto f_v(\mu) = \text{coeff}_0 \left( X^\mu v(X) \mod (X^N + 1) \right) \in \mathbb{Z}_{p'} \quad (2.1) \]

where \( \text{coeff}_0 \) selects the constant term of a polynomial and where \( v \in \mathcal{R}_{N,p'} \) is the so-called test-polynomial, whose choice determines the characteristics of the functional bootstrapping. Note that this function \( f_v \) defined on \( \mathbb{Z}_{2N} \) satisfies the negacyclic constraint

\[ f_v(\mu + N) = -f_v(\mu). \quad (2.2) \]

**Proposition 2.1** Let \( c \) be a \( \text{LWE}_{n,q} \) ciphertext. For a given test-polynomial \( v \in \mathcal{R}_{N,p'} \), there exists an homomorphic evaluation of the function \( f_v \) (a so-called "blind rotation") that provides a ciphertext

\[ c' = \text{LWE}_{n',q',p'}(f_v(2N\varphi_s(c)/q + \delta(c))) \]

where the term \( \delta(c) \) comes from specific rounding approximations on the ciphertext \( c \) after a rescaling. In the special case where \( q|2N \), we have \( \delta(c) = 0 \). Moreover, the variance of the refreshed error associated to the ciphertext \( c' \) is constrained by security requirements only and does not depend on the error of the original ciphertext \( c \).

Owing to this result, the key feature of the functional bootstrapping is that, if \( p_i \) is odd and small enough, then for any target function \( F : \mathbb{Z}_{p_i} \mapsto \mathbb{Z}_{p'} \), it is possible to choose the test polynomial \( v(X) \) such that

\[ \forall \mu \in \mathbb{Z}_{p_i}, \quad f_v([2N\mu/p_i] + \varepsilon) = F(\mu) \]

as soon as \( \varepsilon \) is small enough. This enables to obtain a \( \text{LWE}_{n',q',p'}(F(\mu)) \) ciphertext from a \( \text{LWE}_{n,q,p_i}(\mu) \) ciphertext, with a refreshed error. In the special case where \( p' = p_i, q' = q \) and \( F \) is the identity function, this operation is a bootstrapping in the usual sense.

### 3 Setting of the problem

We define the sign of an element \( \mu \in \mathbb{Z}_p \) as the sign of its main representative. When \( p \) is odd, we have

\[
\text{sign}(\mu) = \begin{cases} 
-1 & \text{if } [\mu]_p \in \left\{-\frac{p-1}{2}, \ldots, -1\right\}, \\
0 & \text{if } [\mu]_p = 0, \\
+1 & \text{if } [\mu]_p \in \left\{1, \ldots, \frac{p-1}{2}\right\}. 
\end{cases}
\]

\textsuperscript{4}For a thorough description of the technique in the RNS context, we refer the reader to [5].
Now, the sign of $\mu \in \mathbb{Z}_p$ cannot be determined from the signs of its components $(\mu_1, \ldots, \mu_k)$. This can be easily seen on the following example with $k = 2$, $p_1 = 3$ and $p_2 = 5$: both $-1, 2 \in \mathbb{Z}_{15}$ and $7 \in \mathbb{Z}_{15}$ have positive signs, while their components are respectively $(-1, 2) \in \mathbb{Z}_3 \times \mathbb{Z}_5$ and $(1, 2) \in \mathbb{Z}_3 \times \mathbb{Z}_5$ with signs $(-1, 1)$ and $(1, 1)$ respectively. This shows that the value of $\mu$ has to some extent to be computed through $\Phi^{-1}$ in order to evaluate its sign. In the context of homomorphic encryption, the purpose of this paper is to reach the following

**Objective:** Find the encrypted value of the sign of an element of $\mathbb{Z}_p$ from the encrypted values of its components. More precisely, given the $k$ values $c_i = \text{LWE}_{s,q,p}(\mu_i) \in \mathbb{Z}_{n+1}^q$, $i = 1, \ldots, k$,

we aim at obtaining

$$\text{LWE}_{s,q,3}^n \left( \text{sign} \circ \Phi^{-1}(\mu_1, \ldots, \mu_k) \right),$$

where the sign $\in \{-1, 0, 1\}$ has been identified with an element of $\mathbb{Z}_3$.

We first note that, by linearity of LWE encryption, the ciphertext $c = \sum_{i=1}^{k} [p_i^{-1}] p_i c_i$ is an encrypted value of $\mu = \Phi^{-1}(\mu_1, \ldots, \mu_k)$, i.e. $c = \text{LWE}_{s,q,p}^n(\mu)$. As a matter of fact, denoting $c_i = (a_i, b_i)$ and $c = (a, b)$, we have

$$b - \langle a, s \rangle = \sum_{i=1}^{k} [p_i^{-1}] p_i b_i - \sum_{i=1}^{k} \langle [p_i^{-1}] p_i a_i, s \rangle = \sum_{i=1}^{k} [p_i^{-1}] p_i (b_i - \langle a_i, s \rangle)$$

$$= \sum_{i=1}^{k} [p_i^{-1}] p_i ((q/p_i) \mu_i + \text{Err}(c_i)) \mod q$$

$$= (q/p) \sum_{i=1}^{k} [p_i^{-1}] p_i \mu_i + \sum_{i=1}^{k} [p_i^{-1}] p_i \text{Err}(c_i) \mod q$$

$$= (q/p) \mu + \text{Err}(c) \mod q,$$

with

$$\text{Err}(c) = \sum_{i=1}^{k} [p_i^{-1}] p_i \text{Err}(c_i).$$

A crude upper-bound of this error is obtained, by considering that $|\text{Err}(c_i)| < \frac{q}{2p_i}$ for $i = 1, \ldots, k$, as

$$|\text{Err}(c)| \leq \frac{1}{2} \sum_{i=1}^{k} p_i |\text{Err}(c_i)| < \frac{kq}{4},$$

which is obviously far too large to hope for a correct decryption of $\mu$ in $\mathbb{Z}_p$. Note that the condition $|\text{Err}(c_i)| < \frac{1}{2p_i}$ is not coincidental: it ensures that $\mu_i$ is correctly decrypted from $c_i$ in $\mathbb{Z}_{p_i}$. Now, in practice, the errors $\text{Err}(c_i)$, for $i = 1, \ldots, k$, are the sum of a fixed
rational (the rounding error) and of a sub-gaussian random variable $e_i$ with parameter $\sigma(e_i)$, that is to say such that

$$\mathbb{E}(e^{\lambda e_i}) \leq e^{\frac{1}{2} \sigma^2(e_i) \lambda^2}.$$  

As a consequence, $\text{Err}(c)$ is also composed of the sum of a fixed term $\delta$ bounded by $\sum_i p_i/4$ and of a sub-gaussian variable $e$ with parameter

$$\sigma(e) = \sqrt{\left(\frac{1}{4p_1} \sigma^2(e_1)\right) + \ldots + \left(\frac{1}{4p_k} \sigma^2(e_k)\right)}$$

and from Markov’s inequality

$$\mathbb{P}(\left|e\right| \geq \lambda) \leq 2e^{-\lambda^2/(2\sigma^2(e))}.$$  

In particular, if all the errors $e_i$, $i = 1, \ldots, k$, are independent and Gaussian with parameters $\sigma(e_i)$, then we have

$$\mathbb{P}(\left|e\right| \leq \lambda) = \text{erf} \left( \frac{\lambda}{\sqrt{2\sigma(e)}} \right).$$

If we assume for simplicity that the contribution of the rounding errors $\delta$ is negligible, the decryption of $c$ in $\mathbb{Z}_p$ coincides with $\mu$ with probability

$$\text{erf} \left( \frac{q}{2\sqrt{2\sigma(e)p}} \right).$$

Assuming, for instance, that the parameters $\sigma(e_i) = \frac{q}{2\sqrt{2\theta}}$ have all been adjusted so as to ensure a correct decryption in $\mathbb{Z}_{p_i}$ with a given probability $\text{erf}(\theta)$, we then have

$$\sigma(e) = \frac{q}{2\sqrt{2\theta}} \left( \sum_{i=1}^{k} \left( \frac{1}{4p_i} \right) \right)^2$$

and we can obtain from the following inequalities, valid for for $x \geq 0$,

$$\text{erf}(x) = \frac{2}{\sqrt{\pi}} \int_{0}^{x} e^{-t^2} dt \geq 1 - \frac{1}{\sqrt{\pi}} \frac{e^{-x^2}}{x} \quad \text{and} \quad \text{erf}(x) \leq 1 - \frac{e}{2\pi} e^{-2x^2},$$

the estimates

$$\text{erf}(\theta) \geq 1 - \frac{e^{-\theta^2}}{\sqrt{\pi} \theta} \quad \text{and} \quad \text{erf} \left( \frac{q}{2\sqrt{2\sigma p}} \right) \leq 1 - \frac{e}{2\pi} e^{-\frac{2\theta^2}{\sigma p^2}}.$$  

Hence, the probability that the decryption of $\mu$ fails can be bounded from below by

$$1 - \text{erf} \left( \frac{q}{2\sqrt{2\sigma p}} \right) \geq \frac{e}{2\pi} \exp \left( -\frac{2\theta^2 p_{\max}^2}{p^2 \sum_{i=1}^{k} \left( \frac{1}{4p_i} \right)^2} \right) \geq \frac{e}{2\pi} \exp \left( -\frac{2\theta^2 p_{\max}^2}{kp^2} \right),$$

where $p_{\max} = \max_{i=1,\ldots,k} p_i$. Taking $k = 8$ with $(p_1, p_2, p_3, p_4, p_5, p_6, p_7, p_8) = (7, 11, 13, 17, 19, 23, 25, 27)$ for instance (which yields $p \approx 2^{32.225}$), and $\text{erf}(\theta) = 1 - 10^{-10}$ (that is to say $\theta = 4.572824967$), this means that a failed decryption of $\mu$ in $\mathbb{Z}_p$ occurs with a probability larger than 0.657 (note that the assumption that $\delta$ is negligible does not invalidate this estimate as a non-zero $\delta$ would lead to an even more pessimistic probability). This renders the determination of $\mu$ intractable as such and one should look for an algorithm to determine the sign of $\mu$ without knowing $\mu$ exactly.
4 The sign algorithm for plaintexts

To introduce our method, let us examine a toy problem where we want to determine the sign of an integer \( \mu \in \mathbb{Z}_p \), but instead of knowing its components \( \mu_i \), we only have in hand some noisy values \( \tilde{\mu}_i \in \mathbb{R} \) satisfying \( \tilde{\mu}_i = \mu_i + e_i \). We assume having an estimate on the error terms, more precisely \( |e_i| \leq \varepsilon / k \), for some \( 0 < \varepsilon \leq 1 / (2\bar{p} + 2) \), and where \( \bar{p} \geq 3 \) is an odd rescaling parameter whose role will be made precise further. Trying to reconstruct \( \mu \) from the noisy values yields the approximate value

\[
\tilde{\mu}^{[0]} := \Phi^{-1}(\tilde{\mu}_1, \ldots, \tilde{\mu}_k) = \sum_{i=1}^{k} [\tilde{\mu}_i - \varepsilon p, \tilde{\mu}_i + \varepsilon p] \mod p, \quad \text{with} \quad e^{[0]} = \sum_{i=1}^{k} [\tilde{\mu}_i - \varepsilon p, \tilde{\mu}_i + \varepsilon p].
\]

We have the estimate

\[
|\tilde{\mu}^{[0]} - \mu| = |e^{[0]}| \leq \frac{p}{2} \sum_{i=1}^{k} |e_i| \leq \frac{\varepsilon}{2} p. \quad (4.1)
\]

If \( \bar{p} \geq 1 \), the signs of \( \tilde{\mu}^{[0]} \) and \( \mu \) may be different and it is clear that knowing \( \tilde{\mu}^{[0]} \) may not be sufficient to determine the sign of \( \mu \).

The following function will be useful (the scaling by \( 2N \), unnatural here, prepares its use with ciphertexts in next section).

**Definition 4.1** Let \( 0 \leq \varepsilon \leq 1 \) and \( N \geq 1 \) an integer. We introduce the function \( g_\varepsilon \) on \( \mathbb{R} / (2N \mathbb{Z}) \) by

\[
g_\varepsilon(\mu) = \begin{cases} +1 & \text{if} \ \mu \in [\varepsilon N, N - \varepsilon N[, \\ -1 & \text{if} \ \mu \in [-N + \varepsilon N, -\varepsilon N[, \\ 0 & \text{otherwise}. \end{cases}
\]

Note that \( g_\varepsilon \) is odd and satisfies the negacyclic constraint (2.2).

Assume that \( g_\varepsilon(2N\tilde{\mu}^{[0]}/p) = +1 \). Then \( \tilde{\mu}^{[0]} \in [\frac{p}{2}, \frac{p}{2} - \frac{\varepsilon}{2} p] \) and, from (4.1), we deduce that \( \mu \in [0, \frac{p}{2}] \), i.e. \( \text{sign}(\mu) = +1 \). Similarly, if \( g_\varepsilon(2N\tilde{\mu}^{[0]}/p) = -1 \), then we have \( \text{sign}(\mu) = -1 \). Consequently, \( g_\varepsilon(2N\tilde{\mu}^{[0]}/p) \) is an estimator of the sign of \( \mu \) with no false positive (i.e. if this estimator gives a non zero value, it is the correct sign).

Assume now that \( g_\varepsilon(2N\tilde{\mu}^{[0]}/p) = 0 \) and consider the rescaled value \( \bar{\mu} \). We first claim that, under this assumption \( g_\varepsilon(2N\bar{\mu}^{[0]}/p) = 0 \), necessarily \( \bar{\mu} \) and \( \mu \) have the same sign. Of course, if \( \mu = 0 \), then \( \bar{\mu} = 0 \). Next, assume that \( \mu > 0 \). Using again (4.1), we deduce from \( g_\varepsilon(2N\bar{\mu}^{[0]}/p) = 0 \) that \( \mu \in [0, \varepsilon p] \cup [\frac{p}{2} - \varepsilon p, \frac{p}{2}] \). In the case \( \mu \in [0, \varepsilon p] \), we have

\[
0 < \bar{\mu} \leq \frac{\varepsilon p}{2p + 1} \leq \frac{p}{2} - \varepsilon p, \quad (4.2)
\]

and in the other case \( \mu \in [\frac{p}{2} - \varepsilon p, \frac{p}{2}] \), we have \( \frac{p}{2} - \mu \in [0, \varepsilon p] \) and similarly we get

\[
0 < \bar{\mu}(\frac{p}{2} - \mu) \leq \frac{p}{2} - \varepsilon p,
\]

which is equivalent to

\[
\varepsilon p \leq \bar{\mu}(\frac{p}{2} - \mu) < \frac{p}{2}.
\]
We recall that $\bar{p}$ is odd, so $\frac{p-1}{2}$ is an integer, which yields $\bar{p} \mu \in [\varepsilon p, \frac{p}{2}]$. Consequently, in both cases, we have $\text{sign}(\bar{p} \mu) = +1 = \text{sign}(\mu)$. If $\mu < 0$, by considering $-\mu < 0$ we get that $\text{sign}(\bar{p} \mu) = -1 = \text{sign}(\mu)$. The claim is proved.

We now consider the following approximation of $\bar{p} \mu$:

$$\tilde{\mu}^{[1]} := \sum_{i=1}^{k} [\bar{p}\hat{\mu}_i] p\hat{\mu}_i = \bar{p} \mu + e^{[1]} \mod p,$$

with $e^{[1]} = \sum_{i=1}^{k} [\bar{p}\hat{\mu}_i] p\hat{\mu}_i$.

Since we have the same estimate

$$|\tilde{\mu}^{[1]} - \bar{p} \mu| = |e^{[1]}| \leq \frac{p}{2} \sum_{i=1}^{k} |e_i| \leq \frac{\varepsilon}{2} p,$$  \hspace{1cm} (4.3)

the same reasoning as above leads to the fact that if $g_\varepsilon(2N\tilde{\mu}^{[1]}/p) = +1$ (resp. $= -1$) then $\text{sign}(\bar{p} \mu) = \text{sign}(\mu) = +1$ (resp. $= -1$). In other words, in the case $g_\varepsilon(2N\tilde{\mu}^{[0]}/p) = 0$, the quantity $g_\varepsilon(2N\tilde{\mu}^{[1]}/p)$ is an estimator of the sign of $\mu$ with no false positive.

One can iterate on this method, considering all the rescalings

$$\tilde{\mu}^{[r]} := \sum_{i=1}^{k} [\bar{p}^r\hat{\mu}_i] p\hat{\mu}_i = \bar{p}^r \mu + e^{[r]} \mod p,$$

with $e^{[r]} = \sum_{i=1}^{k} [\bar{p}^r\hat{\mu}_i] p\hat{\mu}_i$, \hspace{1cm} (4.4)

for $r \in \mathbb{N}$. By an induction argument, one can easily generalize the above proof and show that, if $g_\varepsilon(2N\tilde{\mu}^{[r]}/p) = \ldots = g_\varepsilon(2N\tilde{\mu}^{[r-1]}/p) = 0$, then all the terms $\bar{p}^r \mu$, $\bar{p}^{r-1} \mu$, $\ldots$, $\bar{p} \mu$ and $\mu$ have the same sign and, moreover, if $g_\varepsilon(2N\tilde{\mu}^{[r]}/p) = +1$ (resp. $= -1$) then $\text{sign}(\mu) = +1$ (resp. $= -1$).

In fact, the list of rescalings can be taken finite. To see this point, we state a technical Lemma.

**Lemma 4.2** Let $3 \leq \bar{p} < p$ be odd integers, let $0 < \varepsilon \leq \frac{1}{2(p+1)}$ and let $\mu \in \left[\frac{(p-1)}{2}, \frac{(p-1)}{2}\right]$, an integer. Consider the sequence $(\bar{p}^r \mu)_{r \geq 0}$. The following statements hold true.

(i) If $\mu \in [0, \varepsilon p]$, then there exists $r^* \in \mathbb{N}^*$ such that for all $0 \leq r < r^*$, one has $\bar{p}^r \mu \in [0, \varepsilon p]$ and $\bar{p}^{r-1} \mu \in [\varepsilon p, \frac{p}{2} - \varepsilon p]$.

(ii) If $\mu \in \left[\frac{p}{2} - \varepsilon p, \frac{p}{2}\right]$, then there exists $r^* \in \mathbb{N}^*$ such that for all $0 \leq r < r^*$, one has $\bar{p}^r \mu \in \left[\frac{p}{2} - \varepsilon p, \frac{p}{2}\right]$ and $\bar{p}^{r-1} \mu \in \left[\varepsilon p, \frac{p}{2} - \varepsilon p\right]$.

(iii) If $\mu \in \left[-\varepsilon p, 0\right]$, then there exists $r^* \in \mathbb{N}^*$ such that for all $0 \leq r < r^*$, one has $\bar{p}^r \mu \in [-\varepsilon p, 0]$ and $\bar{p}^{r-1} \mu \in \left[-\frac{p}{2} + \varepsilon p, -\varepsilon p\right]$.

(iv) If $\mu \in \left[-\frac{p}{2}, -\frac{p}{2} + \varepsilon p\right]$, then there exists $r^* \in \mathbb{N}^*$ such that for all $0 \leq r < r^*$, one has $\bar{p}^r \mu \in \left[-\frac{p}{2}, -\frac{p}{2} + \varepsilon p\right]$ and $\bar{p}^{r-1} \mu \in \left[-\frac{p}{2} + \varepsilon p, -\frac{p}{2}\right]$.

**Proof.** Items (iii) and (iv) can be directly deduced from (i) and (ii) by $\mu \rightarrow \frac{p}{2} + \mu$. Note indeed that, $\bar{p}$ being odd, we have $\bar{p}^r \frac{p}{2} = \frac{p}{2} \mod p$ for all $r \geq 0$.

Let us prove (i). We thus assume that $\mu \in [0, \varepsilon p]$. Let $r^* \geq 1$ be the largest integer such that $\bar{p}^r \mu \in [0, \varepsilon p]$ for all $0 \leq r \leq r^* - 1$ (such an integer exists given that $\bar{p}^0 \mu \in [0, \varepsilon p]$.

\[ \frac{1}{2} \leq \bar{p}^{r^*} \mu < \frac{3}{2} \implies \frac{1}{2} \leq \frac{1}{2} \bar{p}^r \mu \leq \frac{3}{2} \implies \frac{1}{2} \leq \frac{1}{2} \bar{p}^r \mu \leq \frac{3}{2} \]
and that \( \bar{p}^r \mu \to +\infty \) when \( r \to +\infty \). By construction, we have \( \bar{p}^{r-1} \mu \leq \varepsilon p < \bar{p}^r \mu \), which yields

\[
\begin{align*}
    r^* &= 1 + \left\lfloor \frac{\log_{\bar{p}} \left( \frac{\varepsilon p}{\mu} \right)}{p} \right\rfloor .
\end{align*}
\]

Moreover, replacing \( \mu \) by \( \bar{p}^{r-1} \mu \in [0, \varepsilon p] \) in (4.2), we obtain \( \bar{p}^r \mu \leq \frac{p}{2} - \varepsilon p \). We have proved (i).

In order to prove (ii), we now assume that \( \mu \in \left[ \frac{p}{2} - \varepsilon p, \frac{p}{2} \right] \). Then \( \frac{p}{2} - \mu \leq \varepsilon p \) so Item (i) can be applied to \( \frac{p}{2} - \mu \). Setting \( r^* = 1 + \left\lfloor \frac{\log_{\bar{p}} \left( \frac{\varepsilon p}{p/2 - \mu} \right)}{p} \right\rfloor \), one has

\[
\forall 0 < r \leq r^* - 1, \quad \bar{p}^r \left( \frac{p}{2} - \mu \right) \in [0, \varepsilon p] \quad \text{and} \quad \bar{p}^{r*} \left( \frac{p}{2} - \mu \right) \in [\varepsilon p, \frac{p}{2} - \varepsilon p].
\]

By substracting \( p/2 \), this yields

\[
\forall 0 < r \leq r^* - 1, \quad \bar{p}^r \mu - \bar{p}^{r-1} \frac{p}{2} \in \left[ \frac{p}{2} - \varepsilon p, \frac{p}{2} \right] \quad \text{and} \quad \bar{p}^{r*} \mu - \bar{p}^{r-1} \frac{p}{2} \in \left[ \varepsilon p, \frac{p}{2} - \varepsilon p \right].
\]

Since \( \bar{p}^{r-1} \) is an integer for all \( r > 0 \), the proof of (ii) is complete. \( \square \)

**Remark 4.3** By considering the smallest and largest positive values in \( \mathbb{Z}_p \), that is to say \( \mu = 1 \) and \( \mu = \frac{p-1}{2} \), with \( \varepsilon \leq \frac{1}{2(p+1)} \), we can bound from above \( r^* \) by

\[
\begin{align*}
    r^* &\leq r_{\max} = 1 + \left\lfloor \log_{\bar{p}} \left( \frac{p}{p+1} \right) \right\rfloor .
\end{align*}
\]

In order to prepare the adaptation of this algorithm to ciphertexts, we summarize in the following proposition the result that we have proved.

**Proposition 4.4** Let \( 3 \leq \bar{p} < p \) be odd integers and let \( 0 < \varepsilon \leq \frac{1}{2(p+1)} \). Let \( \mu \in \mathbb{Z}_p \) and consider a sequence of real numbers \( \mu^{[r]} \) defined for \( r = 0, 1, \ldots, r_{\max} = 1 + \left\lfloor \log_{\bar{p}} \left( \frac{p}{p+1} \right) \right\rfloor \) and satisfying

\[
|\mu^{[r]} - 2N\bar{p}^r \mu/p| \leq \varepsilon N.
\]  

Then, there exists \( r^* \geq 0 \) such that

1. if \( \mu > 0 \) then \( g_\varepsilon(\mu^{[r]}^{[1]}) = 1 \) and for all \( 0 \leq r < r^* \), \( g_\varepsilon(\mu^{[r]}) = 0 \);
2. if \( \mu < 0 \) then \( g_\varepsilon(\mu^{[r]}^{[1]}) = -1 \) and for all \( 0 \leq r < r^* \), \( g_\varepsilon(\mu^{[r]}) = 0 \);
3. if \( \mu = 0 \) then \( g_\varepsilon(\mu^{[r]}) = 0 \) for all \( r \geq 0 \),

where the function \( g_\varepsilon \) was introduced in Definition 4.1.

As a direct application of this proposition, one can directly determine the sign of \( \mu \) by a lexicographic comparison of \( (g_\varepsilon(2N\tilde{\mu}^{[0]}/p), g_\varepsilon(2N\tilde{\mu}^{[1]}/p), \ldots, g_\varepsilon(2N\tilde{\mu}^{[r_{\max}]/p})/p \) with \( (0, 0, \ldots, 0) \). Equivalently, we can state the
Proposition 4.4. Let $3 \leq \bar{p} < p$ be odd integers, let $0 < \varepsilon \leq \frac{1}{2(\bar{p}+1)}$ and let $\mu \in \mathbb{Z}_p$. Denote $\mu_i = \mu \mod p_i$ and let $g_\varepsilon$ be the function given in Definition 4.1. If for $0 \leq r \leq r_{\text{max}} = 1 + \left\lfloor \log_{\bar{p}} \left( \frac{p}{\bar{p}+1} \right) \right\rfloor$, we define $\tilde{\mu}^{[r]}$ by (4.4), where the noisy values $\tilde{\mu}_i \in \mathbb{R}/p_i\mathbb{Z}$ satisfy $|\tilde{\mu}_i - \mu_i| \leq \varepsilon/k$, then we have

$$\text{sign}(\mu) = \text{sign} \left( \sum_{r=0}^{r_{\text{max}}} 2^{r_{\text{max}}-r} g_\varepsilon(2N\tilde{\mu}^{[r]/p}) \right). \quad (4.6)$$

As a matter of fact, either all values $g_\varepsilon(2N\tilde{\mu}^{[r]/p})$ remain null, and the sum accordingly, or the first non-vanishing value (either 1 or −1) dominates the sum (owing to the scaling factors $2^{r_{\text{max}}-r}$).

5 The homomorphic sign algorithm

With the notations introduced in Section 2, we consider a plaintext $\mu \in \mathbb{Z}_p$ encoded by its CRT components $\mu_i$, $1 \leq i \leq k$, which are encrypted as $c_i = \text{LWE}^{n,q,p}_s(\mu_i)$, with errors $\text{Err}(c_i)$. Our aim is to obtain an encrypted value of sign($\mu$). Three steps are necessary to adapt the above algorithm from plaintexts to ciphertexts.

5.1 Rescaling ciphertexts

The first step consists in rescaling the ciphertexts $c_i$ by factors $\bar{p}^r$. The following result is an adaptation of Proposition 4.4.

Proposition 5.1. Let $3 \leq \bar{p} < p$ be odd integers and let $0 < \varepsilon \leq \frac{1}{2(\bar{p}+1)}$. Consider the sequence

$$c^{[r]} = \sum_{i=1}^{k} [\bar{p}^{r-1}p_i] c_i, \quad r = 0, \ldots, r_{\text{max}} = 1 + \left\lfloor \log_{\bar{p}} \left( \frac{p}{\bar{p}+1} \right) \right\rfloor \quad (5.1)$$

of encrypted values $\text{LWE}^{n,q,p}_s(\bar{p}^r \mu)$ and denote, for all $\text{LWE}^{n,q}_s$ ciphertext $c$,

$$\tilde{\varphi}_s(c) := 2N\varphi_s(c)/q + \delta(c) \in \mathbb{Z}_2N, \quad (5.2)$$

where $\delta(c)$ was defined in Proposition 2.1. Suppose that, for all $r$, we have the estimate

$$\left| 2N\text{Err}(c^{[r]}/q + \delta(c^{[r]})) \right| \leq \varepsilon N. \quad (5.3)$$

Then, there exists $r^* \in \{0, \ldots, r_{\text{max}}\}$ such that

1. if $\mu > 0$ then $g_\varepsilon(\tilde{\varphi}_s(c^{[r^*]})) = 1$ and for all $0 \leq r < r^*$, $g_\varepsilon(\tilde{\varphi}_s(c^{[r]})) = 0$;

2. if $\mu < 0$ then $g_\varepsilon(\tilde{\varphi}_s(c^{[r^*]})) = -1$ and for all $0 \leq r < r^*$, $g_\varepsilon(\tilde{\varphi}_s(c^{[r]})) = 0$;

3. if $\mu = 0$ then $g_\varepsilon(\tilde{\varphi}_s(c^{[r^*]})) = 0$ for all $r \geq 0$,

where the function $g_\varepsilon$ was defined in Definition 4.1.

Proof. This result if a direct application of Proposition 4.4, setting $\mu^{[r]} = \tilde{\varphi}_s(c^{[r]})$. Indeed, (5.3) yields, for all $r$,

$$|\mu^{[r]} - 2\bar{p}^r \mu/p| = \left| \tilde{\varphi}_s(c^{[r]}) - 2N\bar{p}^r \mu/p \right| \leq \varepsilon N,$$

which enables to apply this proposition. \qed
Remark 5.2 Piecewise constant functions may also be obtained through an elaboration of the same technique as for the sign. To this aim, it is sufficient to notice (i), that the Heaviside function \( H(\mu) \) can be emulated through the same procedure by attributing the value 0 instead of \(-1\) to all torus-elements in \([-\frac{p}{2} + \frac{\varepsilon}{2}p, -\frac{\varepsilon}{2}p]\) in the definition of \( g_\varepsilon \) and (ii), that all piecewise constant functions \( f \) on the discrete torus \([-\frac{p}{4}, \frac{p}{4}]\) are linear combinations of translated Heaviside functions \( f(x) = \sum \alpha_i H(x - \beta_i) \) where the \( \alpha_i \)'s are integers and the \( \beta_i \)'s elements of \([-\frac{p}{4}, \frac{p}{4}]\).

5.2 Emulating \( g_\varepsilon \) through bootstrapping

Having computed the rescaled ciphertexts \( c^{[r]} \) for \( 0 \leq r \leq r_{\text{max}} \) by formula (5.1), the second step of the sign algorithm consists in a functional bootstrapping of each \( c^{[r]} \) in order to compute an encrypted version of \( g_\varepsilon(\tilde{\varphi}_s(c^{[r]})) \). To this aim, we have to define a suitable test-polynomial \( v(x) \).

More precisely, we aim in this subsection at constructing a test-polynomial \( v^\kappa(X) \in \mathcal{R}_{N,2N} \) such that the associated function defined by (2.1) satisfies

\[
\forall \mu \in \mathbb{Z}_{2N}, \quad f_{v^\kappa}(\mu) = 2^\kappa g_\varepsilon(\mu),
\]

where \( 0 \leq \kappa \leq \log N \) is a scaling factor so as to emulate the function \( g_\varepsilon \), rescaled, in an encrypted form through a bootstrapping procedure (according to Proposition 2.1).

Let

\[
\varepsilon = \frac{1}{2N} + \frac{\alpha}{N}
\]

where \( \alpha \) is an integer satisfying

\[
0 \leq \alpha \leq \left\lfloor \frac{N}{2(p + 1)} - \frac{1}{2} \right\rfloor.
\]

It is readily seen that the constraint

\[
0 < \varepsilon \leq \frac{1}{2(p + 1)}
\]

is fulfilled.

A key feature of functional bootstrapping based on blind rotation is that for any function \( F \) defined from \( \mathbb{Z}_{2N} \) to \( \mathbb{Z} \) and such that

\[
\forall j \in \mathbb{Z}_{2N}, \quad F(j + N) = -F(j),
\]

there exists a unique polynomial \( v \in \mathbb{Z}[X]/(X^N + 1) \) such that the function \( f_v \) defined by (2.1) satisfies

\[
\forall j \in \mathbb{Z}_{2N}, \quad f_v(j) = F(j).
\]

Its coefficients \( v_j \) are given by \( v_j = F(-j), \ j = 0, \ldots, N - 1 \).

For a given \( \alpha \) in (5.5), it is thus enough to define \( F \) on \( \{0, \ldots, N - 1\} \) as follows:

\[
\forall 0 \leq j \leq \alpha, \quad F(j) = 0,
\]

\[
\forall \alpha + 1 \leq j \leq N - \alpha - 1, \quad F(j) = 2^\kappa,
\]

\[
\forall N - \alpha \leq j \leq N - 1, \quad F(j) = 0,
\]
so that
\[ v_j^\kappa := F(-j), \quad j = 0, \ldots, N - 1, \]
that is to say
\[ v_0^\kappa = \ldots = v_a^\kappa = 0, \quad v_{a+1}^\kappa = \ldots = v_{N-a-1}^\kappa = -2^\kappa, \quad v_{N-a}^\kappa = \ldots = v_{N-1}^\kappa = 0. \quad (5.7) \]
For these specific choices of \( \varepsilon \) and \( v^\kappa \), the equality (5.4) is satisfied.

5.3 Implementing the homomorphic lexicographic comparison

Arguing as for Corollary 4.5, it is clear from Proposition 5.1 that the sign of \( \mu \in \mathbb{Z}_p \) can be obtained from the expression
\[ r_{\max} \sum_{r=0}^{r_{\max}} 2^{r_{\max}-r} g_{\varepsilon}(\tilde{\phi}_s(c^{[r]})). \quad (5.8) \]
Assuming for a while that \( 2^{r_{\max}} \leq N \) and using that the addition is homomorphic, an encryption of (5.8) is
\[ \sum_{r=0}^{r_{\max}} \text{LWE}_{\tilde{\phi}_s}^{n,q,2N} \left( 2^{r_{\max}-r} g_{\varepsilon}(\tilde{\phi}_s(c^{[r]})) \right) = \sum_{r=0}^{r_{\max}} \text{LWE}_{\tilde{\phi}_s}^{n,q,2N} \left( f_{v^{r_{\max}-r}}(\tilde{\phi}_s(c^{[r]})) \right). \quad (5.9) \]
According to Subsection 2.2, we can bootstrap directly \( c^{[r]} \) onto the encryption of \( f_{v^{r_{\max}-r}}(\tilde{\phi}_s(c^{[r]})) \), by using the test-polynomial \( v^{r_{\max}-r}(X) \), and sum up homomorphically to obtained the desired ciphertext (5.9).

However, the noise in (5.9) is determined by the output noise of the bootstrapping procedure. This may render the decryption of (5.9) incorrect, as soon as the noise is non zero (indeed, the smallest non zero value in (5.8) may be \( \pm 1 \)). In order to overcome this difficulty, we first decompose the sum (5.8) into sub-sums of \( m \) terms as follows, where we have supposed, for the sake of simplicity, that \( r_{\max} + 1 = m^\ell \), where by definition \( \ell = \log_m(r_{\max} + 1) \). We suppose also that \( 2^{m+1} \leq N \). Let \( \bar{\varepsilon} \) be defined by
\[ \bar{\varepsilon} = \frac{1}{2N} + \frac{\tilde{\alpha}}{N}, \quad \text{with} \quad \tilde{\alpha} = \frac{N}{2^{m+1}}, \quad (5.10) \]
and consider
\[ g_{\bar{\varepsilon}} \left( \sum_{r_0=0}^{\log N-r_0-1} g_{\bar{\varepsilon}} \left( \sum_{r_1=0}^{\log N-r_1-1} g_{\bar{\varepsilon}} \left( \ldots \sum_{r_{\ell-1}=0}^{\log N-r_{\ell-1}-1} g_{\varepsilon}(\tilde{\phi}_s(c^{[j_\ell]})) \right) \right) \right) \]
\[ = \sum_{i=0}^{\ell-1} r_i m^{\ell-1-i}, \quad r = (r_0, \ldots, r_{\ell-1}). \quad (5.11) \]
Now, the smallest non zero values in this new sum is larger than \( 2^{\log N-m} \geq 1 \), which authorizes some noise in the encrypted form of (5.11). Note that the innermost loop involves \( g_{\varepsilon} \), while all other loops resort to \( g_{\bar{\varepsilon}} \). It is easy to check that, by Proposition 5.1 and as formula (5.8), this new expression also gives the sign of \( \mu \). Using once again the
homomorphy of the addition and the bootstrapped version of \( g_e \), we obtain an encryption of the sign of \( \mu \) from the sequence of ciphertexts \( c_{[k]}^{[k]} \) through the expression

\[
\hat{F} \left( \sum_{r_0=0}^{m-1} \tilde{F}_{r_0} \left( \sum_{r_1=0}^{m-1} \tilde{F}_{r_1} \left( \ldots \sum_{r_{\ell-1}=0}^{m-1} F_{r_{\ell-1}} (c_{[r]}^{[r]}) \right) \right) \right)
\]

where we have denoted, for any LWE ciphertext \( c \),

\[
F_j(c) := LWE_{s,q,2N}^{n,q} (f_{\log N-j-1} (\tilde{\phi}_s(c))) , \quad \tilde{F}_j(c) := LWE_{s,q,2N}^{n,q} (f_{\log N-j-1} (\tilde{\phi}_s(c)))
\]

and

\[
\hat{F}(c) := LWE_{s,q,3}^{n,q} (f_{\hat{v}}(\tilde{\phi}_s(c)))
\]

with \( \hat{v}^\alpha \) and \( \hat{v} \) obtained from the following adaptations of Formula (5.7):

\[
\begin{align*}
\tilde{v}_0^\kappa &= \ldots = \tilde{v}_0^\kappa = 0, \quad \tilde{v}_\alpha^\kappa = \ldots = \tilde{v}_{N-\alpha-1}^\kappa = -2^\kappa, \quad \tilde{v}_{N-\alpha}^\kappa = \ldots = \tilde{v}^\kappa_{N-1} = 0, \quad (5.12) \\
\hat{v}_0 &= \ldots = \hat{v}_\alpha = 0, \quad \hat{v}_{\alpha+1} = \ldots = \hat{v}_{N-\alpha-1} = -1, \quad \hat{v}_{N-\alpha} = \ldots = \hat{v}_{N-1} = 0. \quad (5.13)
\end{align*}
\]

The corresponding algorithm is the following Algorithm 1 and is illustrated in Figure 1, in a special case.

---

**Algorithm 1** Homomorphic determination of the sign

For \( r = 0, \ldots, m^\ell-1 \) do

\[
c^{[r]} = \sum_{i=1}^{k} [\hat{F}^r_{\hat{p}^i_{r-1}}]_{s_i}, \quad \text{with } c_i \in \mathbb{Z}_{2^N}^{n+1}
\]

End

\( S_0 = 0 \)

For \( r_0 = 0, \ldots, m-1 \) do

\( S_1 = 0 \)

For \( r_1 = 0, \ldots, m-1 \) do

\[
\ldots
\]

\( S_{\ell-2} = 0 \)

For \( r_{\ell-2} = 0, \ldots, m-1 \) do

\( S_{\ell-1} = 0 \)

For \( r_{\ell-1} = 0, \ldots, m-1 \) do

\[
r = r_{\ell-1} + m r_{\ell-2} + \ldots + m^{\ell-2} r_1 + m^{\ell-1} r_0
\]

\( S_{\ell-1} = S_{\ell-1} + F_{r_{\ell-1}} (c^{[r]}) \)

End

\( S_{\ell-2} = S_{\ell-2} + \tilde{F}_{r_{\ell-2}} (S_{\ell-1}) \)

\[
\ldots
\]

\( S_1 = S_1 + \tilde{F}_{r_1} (S_2) \)

End

\( S_0 = S_0 + \tilde{F}_{r_0} (S_1) \)

End

Return \( \hat{F}(S_0) \)
Remark 5.3 Note that the factors $2^j$ used here could be replaced by other choices. This one is optimal in the context of the sign but is not compatible with some other piecewise constant functions.

\[ c_0, c_1 \downarrow \downarrow = F_0(c_0) + F_1(c_1) \]
\[ c_2, c_3 \downarrow \downarrow = F_0(c_2) + F_1(c_3) \]
\[ c_4, c_5 \downarrow \downarrow = F_0(c_4) + F_1(c_5) \]
\[ c_6, c_7 \downarrow \downarrow = F_0(c_6) + F_1(c_7) \]
\[ \downarrow \downarrow \downarrow \downarrow = S_0 \]
\[ \downarrow \downarrow \downarrow \downarrow = S_1 \]
\[ \downarrow \downarrow \downarrow \downarrow = \tilde{S}_0 \]
\[ \downarrow \downarrow \downarrow \downarrow = \tilde{S}_1 \]
\[ \downarrow \downarrow \downarrow \downarrow = \tilde{S}_2 \]
\[ \downarrow \downarrow \downarrow \downarrow = \tilde{S}_3 \]
\[ \tilde{F}_0(\tilde{S}_2) + \tilde{F}_1(\tilde{S}_2) = S_0 \]
\[ \tilde{F}_0(\tilde{S}_1) + \tilde{F}_1(\tilde{S}_1) = S_1 \]
\[ \tilde{F}_0(\tilde{S}_0) = S_2 \]

Figure 1: Computation of the sign function for $m = 2$ and $\ell = 3$: each arrow represents a bootstrap.

The following proposition states the conditions under which our algorithm works.

Proposition 5.4 Let $3 \leq \bar{p} < p$ be odd integers and let $\varepsilon$ be given by (5.5), where the integer $\alpha$ satisfies (5.6). Let $\mu \in \mathbb{Z}_p$ and consider encryptions of its CRT components $c_i = \text{LWE}_n^{q,p_i}(\mu_i)$. Consider the sequence $c^{[r]}$, for $r = 0, \ldots, r_{\text{max}} = 1 + \left\lceil \log_p \left( \frac{p}{p+1} \right) \right\rceil$ defined by (5.1). Assume that (5.3) is satisfied for all $r$ and that each LWE ciphertext $S_i$ defined in Algorithm 1 as an argument of a function $\tilde{F}_j$ or of $\hat{F}$ satisfies the estimate

$$|2N\text{Err}(S_i)/q + \delta(S_i)| \leq N/2^{m+1} - 1.$$ (5.14)

Then Algorithm 1 provides an LWE$_n^{q,3}(\text{sign}(\mu))$ ciphertext with an error bounded independently of the $c_i$’s.

Proof. Thanks to Propositions 2.1 and 5.1, and by (5.4), we already know that the innermost loop, the only one that involves $g_\varepsilon$, is correct. Moreover, each $S_i$ to be bootstrapped in the next steps with the function $g_\varepsilon$ is an LWE$_n^{q,2N}(\Sigma_i)$ ciphertext, where $\Sigma_i$ is under the form

$$\Sigma_i = \sum_{j=0}^{m-1} 2^{\log N - j - 1} \xi_j \quad \text{with} \quad \xi_j \in \{-1, 0, 1\}.$$
These values belong to the set
\[
\frac{N}{2^m} \mathbb{Z}_{2^m+1} = \{0, \pm N/2^m, \pm 2N/2^m, \pm 3N/2^m, \ldots, \pm (2^m-1)N/2^m\}.
\]

Hence, owing to the formulae (5.12) or (5.13) of the test-polynomials \(v(X)\) used in this bootstrap, only three cases have to be examined:

- if \(\Sigma_i = 0\), then \(\tilde{F}_j(S_j)\) is a correct bootstrap if \(|\tilde{\varphi}_s(S_i)| \leq \tilde{\alpha}\);
- if \(\Sigma_i > 0\), then \(\tilde{F}_j(S_j)\) is a correct bootstrap if \(\tilde{\alpha} + 1 \leq \tilde{\varphi}_s(S_i) \leq N - \tilde{\alpha} - 1\);
- if \(\Sigma_i < 0\), then \(\tilde{F}_j(S_j)\) is a correct bootstrap if \(-N + \tilde{\alpha} + 1 \leq \tilde{\varphi}_s(S_i) \leq -\tilde{\alpha} - 1\).

Since \(\tilde{\alpha} = N/2^{m+1}\), it can be observed that each of these three conditions is satisfied when (5.14) is fulfilled. □

### 5.4 Correctness of the associated sign function for a specific implementation of bootstrap

In this subsection, we show that our method is of practical interest by estimating its probability of success in a typical implementation. We shall consider the TFHE bootstrapping introduced in [11, 12], extended to messages in the discrete tori \(T_{p_i} = \frac{1}{p_i} \mathbb{Z}_{p_i}\). In order to make our Proposition 2.1 more precise, let us make a few assumptions. We refer to [12] (see e.g. Algorithm 1 in this paper) for the definition of the parameters \(B_g\) and \(\ell_g\) involved in the gadget decomposition (and, also, we only consider the case where the associated \(k_g = 1\)). Moreover, the keys are binary and, for simplicity we only consider the case where no keyswitch is used in the bootstrap (although this restriction is far from optimal). If \(\mathbb{B}\) denotes the set \(\{0, 1\}\), the vectorial secret keys for LWE ciphertexts belong to \(\mathbb{B}^N\) and the polynomial secret keys for RLWE ciphertexts belong to \(\mathbb{B}[X]/(X^N + 1)\), where we recall that \(N\) is a power-of-two.

First, the deviation term \(\delta(c)\) in Proposition 2.1 comes from rounding the mask \((a_i)_{i=1}^N\) of the LWE\(_{N,q}\) ciphertext \(c = (a, b)\) at the beginning of the blind rotate process. More precisely, an instantiation of blind rotation leads to\(^5\)

\[
2N\varphi_s(c)/q + \delta(c) = \left[2Nb/q - \frac{1}{2}\sum_{i=1}^N \delta_i \right] - \sum_{i=1}^N \left[2Na_i/q \right] s_i,
\]

where we have denoted \(\delta_i = 2Na_i/q - [2Na_i/q]\). Since \(b = \sum_i a_i s_i + \varphi_s(c)\), we compute

\[
\delta(c) = \left[\sum_{i=1}^N (s_i - 1/2)\delta_i + 2N\varphi_s(c)/q \right] - 2N\varphi_s(c)/q,
\]

and denoting \(\gamma = -\sum_{i=1}^N (s_i - 1/2)\delta_i - 2N\varphi_s(c)/q\), this yields

\[
\delta(c) = \sum_{i=1}^N (s_i - 1/2)\delta_i + \gamma - \lceil \gamma \rceil.
\]

\(^5\)The trick of substracting the term \(\frac{1}{2} \sum_{i=1}^N \delta_i\) to \(2Nb/q\) before rounding improves the total rounding error.
Since we have assumed that $s_i \in \{0,1\}$ for all $i$, we finally get the estimate

$$|\delta(c)| \leq \frac{1}{2} \left(1 + \sum_{i=1}^{N} |2Na_i/q - |2Na_i/q|| \right). \quad (5.15)$$

Moreover, following [5], the variance of the refreshed error of the output $c' = \text{LWE}_{s}^{N,q,p'}$ (we take $q' = q$) can be computed as

$$\sigma_{out}^2 := \text{Var}(\text{Err}(c')) = N \left(1 + \frac{N}{2}\right) q^2 B_g^{-2\ell_g} + 2N^2 \epsilon_g B_g^2 + 2 \frac{1}{12} \sigma_{BK}^2,$$

where $\sigma_{BK}$ is the standard deviation for the noise sampled to generate the RGSW bootstrap keys. Finally, we shall make the standard assumption [24, 13] that the Central Limit Theorem applies and that the output error $\text{Err}(c')$ can be well approximated by a gaussian random variable.

A very conservative estimate of the correctness of the sign function can be obtained by computing the probability that all the bootstraps involved in Algorithm 1 are correct. Assuming that all the $e_i = \text{Err}(c_i)$ associated to the $c_i$’s involved in formula (5.1) are independent sub-gaussian random variables with parameters $\sigma(e_i)$, and that the terms in the sum in the right-hand side of (5.15) are uniformly distributed independent random variables and as such sub-gaussian with parameter $1/(2\sqrt{3})$, we may obtain the following upper bound of the probability of getting an incorrect sign by computing the probability that at least one condition on the errors in Proposition 5.4 is not satisfied. In other terms, we have

$$P_{\text{fail}} \leq P_{\text{fr}} + P_{\text{or}} \quad (5.16)$$

where $P_{\text{fr}}$ is the probability that one of the bootstrap of the innermost loop of Algorithm 1 fails and $P_{\text{or}}$ is the probability that one of the bootstrap of the outer loops of Algorithm 1 fails.

**Lemma 5.5** Assuming that all the $e_i = \text{Err}(c_i), i = 1, \ldots, k$ are independent sub-gaussian random variables with parameters $\sigma(e_i)$, and that each rounding error term in (5.15) is sub-gaussian with parameter $1/(2\sqrt{3})$, we have

$$P_{\text{fr}} \leq 2 \sum_{r=0}^{r_{\text{max}}} \exp \left(-\left(\varepsilon - 1/(2N)\right)^2/(8\sigma_r^2)\right) \quad (5.17)$$

where

$$\sigma_r^2 = \sum_{i=1}^{k} [p_i^{-1}]_{p_i} (\sigma(e_i)/q)^2 + 1/(192N), \quad r = 0, \ldots, r_{\text{max}}. \quad (5.18)$$

Moreover, assuming that the sums obtained in the outer loops of Algorithm 1 and used as input of further bootstraps are LWE ciphertext whose errors are independent sub-gaussian variables with common parameter $\sqrt{m} \sigma_{out}$, we have

$$P_{\text{or}} \leq \frac{2r_{\text{max}}}{m-1} \exp \left(-\left(1/2^m - 1/N\right)^2/(32\tilde{\sigma}_{r}^2)\right) \quad (5.19)$$

where

$$\tilde{\sigma}_{r}^2 = m\sigma_{out}^2/q^2 + 1/(192N).$$

We assume here that $B_g$ is even.
Proof. The first statement (5.17) follows from the upper-bound
\[ P_{fr} \leq \sum_{r=0}^{r_{max}} P\left(\left|\text{Err}(c^{[r]})/q + \delta(c^{[r]})/(2N)\right| \geq \varepsilon/2\right) \]
and from Markov’s inequality. For the second statement, we have to estimate from above the probability \( P_{incbo} \) that one bootstrap \( \tilde{F}_{r_i}(S_i), r_i \in \{0, \ldots, m-1\} \), of a sum \( S_i \) involved in the outer loops of Algorithm 1 is incorrect. Recall that each \( S_i \) is of the form
\[ S_i = e + \sum_{j=0}^{m-1} 2^{\log N-j-1} \xi_j, \]
where the \( \xi_j \)’s take their values in \( \{\pm 1, 0\} \) and \( e \) is a sub-gaussian variable with parameter \( \sqrt{m\sigma_{out}} \). According to Proposition 5.4, we have
\[ P_{incbo} \leq P\left(|e/q + \delta(S_i)/(2N)| \geq 1/2m + 2\right) \]
and using again Markov’s inequality yields (5.19). Note that the number of such bootstraps is
\[ m^{\ell-1} + m^{\ell-2} + \ldots + m^1 + m^0 = \frac{r_{max}}{m-1}. \]
\[ \square \]

An example
For instance, consider the situation where
\[ p = 7 \times 11 \times 13 \times 17 \times 19 \times 23 \times 25 \times 27 = 5019589575 > 2^{32} \]
and \( \bar{p} = 13 \). We take \( m = 3 \), \( \ell = 2 \) and compute \( r_{max} = 8 \). Maximizing (5.6), we obtain \( \alpha = 36 \).

We compute successively the Bezout coefficients associated with \( (p_i, \bar{p}/p_i) \) for \( i = 1, \ldots, 8 \) and the growth factors in (5.18). We have the following table:

<table>
<thead>
<tr>
<th>( p_j )</th>
<th>7</th>

</tr>
</tbody>
</table>

As cryptographic parameters, let us take the following values, corresponding to a security\(^7\) of \( \lambda = 80 \) bits.

<table>
<thead>
<tr>
<th>( N )</th>
<th>( q )</th>
<th>( \sigma_{\text{BK}} )</th>
<th>( B_g )</th>
<th>( \ell_g )</th>
</tr>
</thead>
<tbody>
<tr>
<td>1024</td>
<td>( 2^{64} )</td>
<td>( 1.5 \times 10^7 )</td>
<td>( 2^{13} )</td>
<td>2</td>
</tr>
</tbody>
</table>

\(^7\)According to the lattice estimator https://github.com/malb/lattice-estimator
We assume moreover that the ciphertexts \( c_i \) have been obtained by a bootstrap with the same parameters, i.e. for \( i = 1, \ldots, k \), we take \( \sigma(e_i) = \sigma_{\text{out}} \). This set of parameters yields

\[
\frac{\sigma_{\text{out}}^2}{q^2} = 2.14 \times 10^{-11}, \quad \bar{\sigma}_r = 5.09 \times 10^{-6}, \quad \mathbb{P}_{fr} \leq 1.19 \times 10^{-12} \quad \mathbb{P}_{or} \leq 7.25 \times 10^{-41}
\]

so, finally,

\[
\mathbb{P}_{\text{fail}} \leq 1.2 \times 10^{-12}.
\]

This proves the efficiency of our method. Note that the number of bootstraps involved in one homomorphic evaluation of the sign is \( r_{\max} + 1 + \frac{r_{\max}}{m-1} = 13 \) here, which is less than an homomorphic multiplication (which can be done with \( 2k = 16 \) bootstraps).
