# The Impact of Reversibility on Parallel Pebbling

Jeremiah Blocki, Blake Holman, and Seunghoon Lee

Purdue University, West Lafayette, IN, 47906, USA {jblocki,holman14,lee2856}@purdue.edu

Abstract. The (parallel) classical black pebbling game is a helpful abstraction which allows us to analyze the resources (time, space, space-time, cumulative space) necessary to evaluate a function f with a static data-dependency graph G on a (parallel) computer. In particular, the parallel black pebbling game has been used as a tool to quantify the (in)security of Data-Independent Memory-Hard Functions (iMHFs). Recently Blocki et al. [BHL22] introduced the parallel reversible pebbling game as a tool to analyze resource requirements when we additionally require that computation is reversible. Intuitively, the parallel reversible pebbling game extends the classical parallel black pebbling game by imposing restrictions on when pebbles can be removed. By contrast, the classical black pebbling game imposes no restrictions on when pebbles can be removed to free up space. One of the primary motivations of the parallel reversible pebbling game is to provide a tool to analyze the full cost of quantum preimage attacks against an iMHF. However, while there is an extensive line of work analyzing pebbling complexity in the (parallel) black pebbling game, comparatively little is known about the parallel reversible pebbling game. Our first result is a lower bound of  $\Omega\left(N^{1+1/\sqrt{\log N}}\right)$  on the reversible cumulative pebbling cost for a line graph on N nodes. This yields a separation between classical and reversible pebbling costs demonstrating that the reversibility constraint can increase cumulative pebbling costs (and space-time costs) by a multiplicative factor of  $\Omega\left(N^{1/\sqrt{\log N}}\right)$  — the classical pebbling cost (space-time or cumulative) for a line graph is just  $\mathcal{O}(N)$ . On the positive side, we prove that any classical parallel pebbling can be transformed into a reversible pebbling strategy whilst increasing space-time (resp. cumulative memory) costs by a multiplicative factor of at most  $\mathcal{O}\left(N^{2/\sqrt{\log N}}\right)$  (resp.  $\mathcal{O}\left(N^{\mathcal{O}(1)/\sqrt[4]{\log N}}\right)$ ). We also analyze the impact of the reversibility constraint on the cumulative pebbling cost of depth-robust and depth-reducible DAGs exploiting reversibility to improve constant factors in a prior lower bound of Alwen et al. [ABP17]. For depth-reducible DAGs we show that the state-of-the-art recursive pebbling techniques of Alwen et al. [ABP17] can be converted into a recursive reversible pebbling attack without any asymptotic increases in pebbling costs. Finally, we extend a result of Blocki et al. [BLZ20] to show that it is Unique Games hard to approximate the reversible cumulative pebbling cost of a DAG G to within any constant factor.

 $\label{eq:Keywords: Parallel Reversible Pebbling \cdot Data-Independent Memory-Hard Function \cdot Quantum Preimage Attacks.$ 

# 1 Introduction

The classical black pebbling game is a powerful computational abstraction that is used to analyze the relationship between the space and time complexity needed to evaluate a function  $f_G$ , where the data-dependencies associated with f are encoded in some directed acyclic graph (DAG) G. For example, if  $f_G(x) = x \times y$ , then G would encode the dependencies  $x \to f(x)$  and  $y \to f(x)$ , and pebbling strategies for G correspond to cost-equivalent algorithms for  $f_G$ . Within the last decade, the *parallel* pebbling game has been used to analyze the security of *Data-Independent Memory-Hard Functions* (iMHFs), e.g., see [AS15, AB16, ABP17, BZ17]. iMHFs are side-channel resistant, making them an attractive tool to protect low-entropy secrets such as user passwords against brute-force attacks. The (classical) parallel pebbling game, however, is insufficient for analyzing the cost of a quantum preimage attack on iMHFs. Quantum adversaries can evaluate MHFs in superposition to guess passwords with quadratically fewer queries with Grover's algorithm [Gro96]. In addition to the number of iMHF queries, the full cost of a quantum preimage attack will also depend on the width and depth of a quantum circuit implementing the iMHF. Thus, Blocki, Holman, and Lee [BHL22] introduced the *parallel reversible pebbling game* as a tool to analyze the (amortized) cost of a quantum circuit evaluating an iMHF. While there has been an extensive body of work analyzing the space-time and cumulative memory costs of DAGs in the parallel black pebbling game (e.g., see [AS15, ABP17, ABP18, BHK<sup>+</sup>19, BZ17]), comparatively little is known about reversible pebbling game. Blocki et al. [BHL22] gave parallel reversible pebbling strategies for iMHFs such as Argon2 [BDK16] and DRSample [ABH17] with space-time costs  $\mathcal{O}\left(N^2/\sqrt[3]{\log N}\right)$  and  $\mathcal{O}\left(\frac{N^2 \log \log N}{\log N}\right)$  — a space-time improvement of factors of  $\sqrt[3]{\log N}$  and  $\frac{\sqrt{\log N}}{\log \log N}$ , respectively in comparison to the naïve reversible pebbling attack which has space-time cost  $\mathcal{O}\left(N^2)$ . They also showed that the line graph can be pebbled with space-time complexity  $\mathcal{O}\left(N \cdot 2^{2\sqrt{\log N}}\right)$ , whereas in the classical pebbling game the space-time complexity is simply N.

If we dropped the reversibility constraint it is natural to wonder whether or not would we be able to find parallel pebbling attacks with lower costs for graphs such as Argon2 [BDK16], DRSample [ABH17], or the line graph. This leads us to ask the following natural question:

#### Can we characterize impact of the reversibility constraint on pebbling costs?

More generally, what is the necessary overhead (in terms of space-time/amortized space-time complexity) to build a quantum circuit for a classical algorithm? If there is such an inherent penalty for reversibility, is there a systematic way to map classical algorithms to quantum circuits that never exceed this penalty? In this paper, we answer both questions in the affirmative in the parallel reversible pebbling model.

Review: Classical Parallel Pebblings and MHFs. We will review the parallel black pebbling game as it relates to Memory-Hard Functions. Let  $G = (V = \{1, \ldots, N\}, E)$  be a DAG with nodes labeled in topological order. A graph G along with a hash function  $H : \{0,1\}^* \to \{0,1\}^\lambda$  defines data-dependencies of the MHF  $f_{G,H}$ . Each node *i* corresponds to a label  $\ell_i$ . For an input *x*, we have  $\ell_0 = x$  and  $\ell_i = H$  (parents(*i*))) for  $i \ge 1$ . To compute  $f_G(x)$ , an algorithm must compute the label  $\ell_N = f_G(x)$  via *H* and the data dependencies *G*. A classical parallel pebbling  $P = (P_0, P_1, \ldots, P_t)$ of *G* begins with no pebbles on the graph  $(P_0 = \emptyset)$ . From round  $P_i$ , we can place a pebble on any nodes whose parents are already pebbled (parents  $(P_{i+1} \setminus P_i) \subseteq P_i)$  and then remove any pebble in  $P_i$  that can be removed. This corresponds to computing  $\ell_j$ , where the dependencies of  $\ell_j$  are already in memory, and then removing labels from memory to free up space. The pebbling *P* must satisfy  $N \in P_t$ , representing the fact that we computed the final output value  $\ell_N = f_G(x)$ . In the sequential black pebbling game, we additionally require that at most one new node is pebbled in each round (i.e.,  $|P_{i+1} \setminus P_i| \le 1$  for all i < t), while the parallel pebbling game imposes no such restrictions on the number of new pebbles in each round.

A result of Alwen and Serbinenko [AS15] implies that in the parallel random oracle model, the complexity of evaluating the function  $f_G$  is fully characterized by the parallel pebbling cost of G. Thus, classical parallel pebbling game has been used to analyze many prominent iMHFs via their underlying DAGs such as Argon2i [BDK15, BCS16, BDKJ16], the winner of the 2015 Password Hashing Competition, and DRSample [ABH17] which provides asymptotic improvements over Argon2i.

Review: parallel reversible pebbling. Quantum attackers can perform pre-image searches over a password database to crack user passwords, for example, in quadratically fewer queries using Grover's algorithm [Gro96]. Such attacks motivate the study of quantum circuit implementations of MHFs. Given an algorithm for evaluating an MHF f, one cannot immediately convert it into quantum circuit that computes f in superposition with similar cost. This is because quantum circuits are reversible. As a result, there is no unitary quantum circuit for deleting or resetting a register, unlike classical computation. This result is called the No-Deleting Theorem [KPB00]. So, while quantum algorithms generalize classical computation, the reversibility of quantum circuits imposes a restriction on evaluating a function in superposition as opposed to evaluating a function classically. Instead, quantum algorithms can free up memory by uncomputing. We will now consider an example of quantum uncomputation. Suppose a quantum algorithm is computing an MHF  $f_{G,H}$ . The algorithm has quantum query access to H, making queries of the form  $|x\rangle |b\rangle \rightarrow |x\rangle |b \oplus H(x)\rangle$ . If the algorithm has basis states of the form  $|x\rangle |H(x)\rangle |H(H(x))\rangle$ , it can remove the data in the register containing H by re-querying x:

$$|x\rangle |H(x)\rangle |H(H(x))\rangle \rightarrow |x\rangle |H(x) \oplus H(x)\rangle |H(H(x))\rangle = |x\rangle |0\rangle |H(H(x))\rangle$$

The classical parallel pebbling game fails to address the computational restrictions imposed by the No-Deleting Theorem, as pebbles can be deleted at any point in the pebbling. As a result, Blocki et al. [BHL22] introduced the *parallel reversible pebbling game*, imposing restrictions on how pebbles are removed. By reversibility, in a transition  $P_i \to P_{i+1}$ , we can no longer remove any pebbles from  $P_i$  that were used to place or remove a pebble in  $P_{i+1}$ . In other words,

$$parents(P_i \oplus P_{i+1}, G) \subseteq P_{i+1}$$

where  $P_i \oplus P_{i+1} \coloneqq (P_i \setminus P_{i+1}) \cup (P_{i+1} \setminus P_i)$ . The last rule introduced by the parallel reversible pebbling game is by the No-Deleting Theorem. A pebble on a node can only be removed if its parents were already pebbled in the prior round, i.e.,  $\mathsf{parents}(P_i \setminus P_{i+1}, G) \subseteq P_i$ .

Review: Measuring Pebbling Costs. Memory-Hard Functions protect against brute-force, offline password attackers by (ideally) requiring a large amount of space for the duration of the computation. While attackers have specialized hardware that lower their time cost (such as Application-Specific Integrated Circuits (ASICs), which can evaluate an MHF orders of magnitude times faster in parallel), memory cost stays relatively the same. Therefore, MHFs aim to minimize this hardware advantage by requiring high memory cost over time. Let  $P = (P_1, \ldots, P_t)$  be a pebbling for a DAG G = (V, E) for an underlying MHF  $f_G$ . Early works examined space-time complexity, the product of the space and time complexity of a pebbling, denoted by  $\prod_{st} (P) = t \cdot \max_{1 \le j \le t} |P_j|$ . However, for classical memory-hardness, the space-time complexity fails to capture the cost of evaluating a function multiple times in parallel [AS15], e.g., there exists graphs G with the property that spacetime cost of pebbling  $\sqrt{N}$  copies of G in parallel is asymptotically equivalent to the space-time cost of pebbling just a single instance of G!

Alwen and Serbinenko [AS15] introduced *cumulative complexity* (CC) to address these shortcomings and model the amortized space-time cost of evaluating the function multiple times. The cumulative (pebbling) cost of a pebbling P is defined as  $\Pi_{cc}(P) = \sum_{1 \le j \le t} |P_j|$ . One can easily show that the cumulative cost of pebbling m distinct copies of G in parallel is m times the cumulative cost of pebbling G once. Thus, cumulative pebbling cost is an appropriate metric to analyze the amortized space-time costs of an iMHF  $f_G$  and cumulative pebbling cost has become a standard cost-metric for analyzing memory-hardness, e.g., [AS15, AB16, ABP17, BZ17, BHK<sup>+</sup>19, ABH17, BZ18, BLZ20, AGK<sup>+</sup>18].

Prior to this work, almost all reversible pebbling results focused on space-time complexity instead of cumulative complexity. Blocki et al. [BHL22] argued that the reversible space-time cost of G is useful for analyzing the full cost (width × depth) of a single quantum preimage attack on our iMHF  $f_G$  using Grover's search. However, there are still many natural settings where we would want to consider the reversible cumulative pebbling cost of G. For example, consider an password attacker who wants to crack multiple different user passwords. Such an attacker would like to run multiple instances of Grover's search to recover multiple preimages of  $f_G$  in parallel. In this case, the attacker's amortized space-time cost would be captured reversible cumulative pebbling cost of G.

So far, we have discussed the (space-time and cumulative) complexity of pebblings. We can further discuss the complexity of graphs G that actually define the MHFs. When defining the cost of the graph, it is necessary to consider pebblings of the relevant kind (in terms of parallelism and reversibility, for example). When a type of pebbling is chosen from {sequential, parallel} × {irreversible, reversible}, the space-time and cumulative complexity of G is the minimum cost pebbling of G of that type. We denote  $\Pi_{st}^{\leftrightarrow,\parallel}(G)$  (resp.  $\Pi_{cc}^{\leftrightarrow,\parallel}(G)$ ) to be the *parallel reversible space-time* (resp. cumulative pebbling) cost of G, e.g.,  $\Pi_{st}^{\leftrightarrow,\parallel}(G)$  denote the minimum space-time cost achieved by any legal reversible pebbling of G. We denote  $\Pi_{st}^{\leftrightarrow,\parallel}(G)$  (resp.  $\Pi_{cc}^{\leftrightarrow}(G)$ ) to be the sequential reversible space-time (resp. cumulative pebbling) cost of G. Intuitively,  $\Pi_{st}^{\leftrightarrow,\parallel}(G)$  denotes the minimum space-time cost achieved by any sequential and reversible pebbling of G. See Definition 2 for the formal definition of  $\Pi_{st}^{\leftrightarrow,\parallel}(G)$ ,  $\Pi_{cc}^{\leftrightarrow,\parallel}(G)$ , and  $\Pi_{cc}^{\leftrightarrow,\parallel}(G)$ . We use the symbol  $\leftrightarrow$  (resp.  $\parallel$ ) in the superscript to indicate that are considering reversible (resp. parallel) pebblings. We can drop the  $\leftrightarrow$  symbol to denote pebbling cost in the classical black pebbling game, e.g.,  $\Pi_{st}^{\parallel}(G)$  denote the minimum space-time cost achieved by any legal parallel black pebbling of G.

Notation. For a positive integer N, we denote  $[N] \coloneqq \{1, \ldots, N\}$ . Similarly, for positive integers  $a \leq b$ , we define  $[a, b] \coloneqq \{a, \ldots, b\}$ . For simplicity, we let  $\log(\cdot)$  be a log with base 2, i.e.,  $\log x \coloneqq \log_2 x$ . The notation  $\stackrel{\$}{\leftarrow}$  denotes a uniformly random sampling, e.g., we say  $x \stackrel{\$}{\leftarrow} [N]$  when x is sampled uniformly at random from 1 to N.

Let G = (V, E) be a directed acyclic graph (DAG) with the set of nodes V and the set of edges E. Without loss of generality, we often times simply let V = [N] where N is the number of nodes in G. Throughout the paper, we will follow this notation convention (that V = [N]) unless specified differently. For  $v \in V$ , we define  $\mathsf{parents}(v, G)$  to be the *immediate parents* of node v in G, i.e.,  $\mathsf{parents}(v, G) \coloneqq \{u \in V : (u, v) \in E\}$ . Similarly, for a subset  $W \subseteq V$ , we say  $\mathsf{parents}(W, G) \coloneqq \bigcup_{w \in W} \{u : (u, w) \in E\}$  to be the *immediate parents* of the set W in G. We define  $\mathsf{ancestors}(v, G)$  to be the set of all  $\mathit{ancestors}$  of v in G, i.e.,  $\mathsf{ancestors}(v, G) \coloneqq \bigcup_{i \ge 1} \mathsf{parents}^i(v, G)$ , where  $\mathsf{parents}^i(v, G) = \mathsf{parents}^{i-1}(v, G), G$ . Similarly,  $\mathsf{ancestors}(W, G) \coloneqq \bigcup_{i \ge 1} \mathsf{parents}^i(W, G)$ , where  $\mathsf{parents}^i(W, G) = \mathsf{parents}(v, G)$  and  $\mathsf{parents}^i(W, G) = \mathsf{parents}(W, G)$  and  $\mathsf{recursively}$  define  $\mathsf{parents}^i(W, G) = \mathsf{parents}(\mathsf{parents}^{i-1}(W, G), G)$ . We say  $\mathsf{sinks}(G) \coloneqq \{v \in V : \nexists(v, u) \in E\}$  to be the set of all  $\mathit{sink} nodes$  of G. For  $v \in V$ ,  $\mathsf{depth}(v, G)$  denotes the number of nodes in the longest directed path in G ending at node v, and  $\mathsf{depth}(G) = \max_{v \in V} \mathsf{depth}(v, G)$  denotes the number of

nodes in the longest directed path in G. The indegree of a node  $v \in V$  is the number of incoming edges into v, i.e.,  $indeg(v, G) \coloneqq |parents(v, G)|$ , and the maximum indegree in G is defined by  $indeg(G) \coloneqq \max_{v \in V} indeg(v)$ . For a subset  $S \subseteq V$ , we define G - S to be the subgraph of G obtained by deleting all the nodes in S and all edges that are incident to S. For  $k \in [N]$ ,  $G_{\leq k} \coloneqq G - [k+1, N]$ and  $S_{\leq k} \coloneqq S \cap [k]$ . For sets S and R, we let  $S \oplus R = (S \setminus R) \cup (R \setminus S)$ .

We say that a DAG G = (V, E) is (e, d)-depth robust if for any subset  $S \subseteq V$  such that  $|S| \leq e$ we have depth $(G - S) \geq d$ . Otherwise, we say that G is (e, d)-reducible and call the subset S a depth-reducing set (which is of size at most e and yields depth(G - S) < d).

#### 1.1 Our Results

In this paper, we are concerned with characterizing the extent to which reversibility impacts pebbling costs. While we are primarily motivated by characterizing the post-quantum security of Memory-Hard Functions, we note that the reversible pebbling game is a general tool to analyze space-time trade-offs of reversible computation. Thus, our results will likely be of interest outside the field of cryptography e.g., quantum circuit compilation. At a high level, our main results show that

- (1) any procedure (captured by the parallel reversible pebbling game) for converting a classical algorithms running in time t into an equivalent quantum circuit must increase amortized space-time complexity (cumulative complexity) by a factor of at least  $2^{(\sqrt{2}-o(1))\sqrt{\log t}}$ , and
- (2) there exists a procedure for converting classical algorithms into quantum circuits that increases amortized space-time complexity by a factor of at most  $2^{\mathcal{O}(\log^{3/4} t)}$ .

1.1.1 A Separation between Reversible and Irreversible Pebbling. Bennett [Ben89] presented the first sequential reversible pebbling of the line graph, and it has remained open whether Bennett's original pebbling is optimal [FA17]. Blocki et al. [BHL22] provided slight modifications to Bennett's pebbling to show that the parallel reversible cumulative complexity of the line graph  $\mathcal{L}_N$ on N nodes is at most  $\Pi_{cc}^{\leftrightarrow,\parallel}(\mathcal{L}_N) = \mathcal{O}\left(N \cdot 2^{2\sqrt{\log N}}\right)$ . Prior work of Knill [Kni95] showed that for reversible sequential pebbling we have  $\Pi_{st}^{\leftrightarrow}(L_N) = \mathcal{O}\left(N \cdot 2^{2\sqrt{\log N}}\right)$ . However, proving lower bounds is substantially harder when we allow for parallel pebbling strategies and when we consider cumulative pebbling cost instead of space-time costs. We show that  $\Pi_{cc}^{\leftrightarrow,\parallel}(\mathcal{L}_N) = \mathcal{O}\left(N \cdot 2^{(\sqrt{2}-o(1))\sqrt{\log N}}\right)$ which immediately implies that  $\Pi_{st}^{\leftrightarrow,\parallel}(\mathcal{L}_N) = \mathcal{O}\left(N \cdot 2^{(\sqrt{2}-o(1))\sqrt{\log N}}\right)$  since  $\Pi_{cc}^{\leftarrow,\parallel}(P) \leq \Pi_{st}^{\leftarrow}(P)$ for any pebbling P (see Theorem 1).

This result immediately implies a multiplicative gap between the reversible and irreversible pebbling costs. In particular, we have  $\Pi_{cc}^{\parallel}(\mathcal{L}_N) = \Pi_{st}^{\parallel}(\mathcal{L}_N) = N$  for the line graph  $\mathcal{L}_N$ .<sup>1</sup> It follows that

$$\frac{\Pi_{st}^{\leftarrow,\parallel}(\mathcal{L}_N)}{\Pi_{st}^{\parallel}(\mathcal{L}_N)} = \Omega\left(2^{(\sqrt{2}-o(1))\sqrt{\log N}}\right), \text{ and } \frac{\Pi_{cc}^{\leftarrow,\parallel}(\mathcal{L}_N)}{\Pi_{cc}^{\parallel}(\mathcal{L}_N)} = \Omega\left(2^{(\sqrt{2}-o(1))\sqrt{\log N}}\right)$$

Our results also show that the attack of Blocki et al. [BHL22] is optimal within a subpolynomial factor  $o\left(N^{\frac{0.586}{\sqrt{\log N}}}\right)$ . See Section 3.1 for details.

<sup>&</sup>lt;sup>1</sup> The pebbling sequence  $P_1, \ldots, P_N$  with  $P_i = \{i\}$  where we simply walk a single pebble to the end of the graph is legal.

**1.1.2** Pebbling Attacks: Making Computation Reversible. In light of the previous result, it is natural to wonder if we can find a family of graphs  $G_N$  with a larger multiplicative gap between the reversible/classical pebbling costs than the line graph  $\mathcal{L}_N$ , specifically with respect to the stronger metric of cumulative complexity. In the sequential computation setting Bennet [Ben89] showed how to transform an irreversible pebbling into a reversible pebbling while preserving space-time complexity. We demonstrate that this transformation can be extended to the parallel setting. More specifically we show that an irreversible parallel pebbling  $P = (P_1, \ldots, P_t)$  of G can made reversible using a reversible line graph pebbling  $Q = (Q_1, \ldots, Q_{t'})$  of the line graph  $\mathcal{L}_t$ . In particular, we argue that the composed pebbling  $R = (R_1, \ldots, R_{t'})$  with  $R_i = \bigcup_{j \in Q_i} P_j$  for each  $i \leq t'$  is a legal reversible pebbling of G. Trivially, we have  $\max_i |R_i| \leq (\max_i |P_i|) (\max_j |Q_j|)$ , i.e., the maximum space usage for our reversible pebbling is the product of the maximum space usage of P and Q. We can use the reversible line graph pebbling from [BHL22] to instantiate our pebbling  $Q = (Q_1, \ldots, Q_{t'})$  and show that the irreversible space-time can never be too far from reversible space-time complexity.

**Theorem 2** (Classical vs. Reversible Space-Time Complexity). Let G = (V = [N], E) be a DAG. Then

$$\Pi_{st}^{\overleftarrow{\leftarrow},\parallel}(G) = \mathcal{O}\left(N^{\frac{2}{\sqrt{\log N}}}\right) \cdot \Pi_{st}^{\parallel}(G),$$

and

$$\Pi_{st}^{\longleftrightarrow}\left(G\right)=\mathcal{O}\left(N^{\frac{2}{\sqrt{\log N}}}\sqrt{\log N}\right)\cdot\Pi_{st}\left(G\right).$$

Unfortunately, the above strategy (generalized from Bennett) completely fails to preserve cumulative memory costs. Suppose for example that the pebbling  $P = (P_1, \ldots, P_t)$  of G has low  $\Pi_{cc}(P) = \sum_i |P_i|$ . It is possible that there is some round i where the space usage  $|P_i| \gg \Pi_{cc}(P)/t$  greatly exceeds the average space usage per round. Observe that for our composed pebbling we will have  $|R_j| \ge |P_i|$  for every round  $j \le t'$  such that  $i \in Q_j$ . If we get unlucky it could be that the reversible line graph pebbling  $Q = (Q_1, \ldots, Q_{t'})$  of  $\mathcal{L}_t$  keeps a pebble on node i in almost every round j so that  $\Pi_{cc}(R) \gg \Pi_{cc}(P)$ . We address this problem by introducing a weighted version of the reversible pebbling game where the cost of placing a pebbling on a node i is equal to its weight. Intuitively, we will set the weight of node i in  $\mathcal{L}_t$  to be  $|P_i|$ . We then design efficient reversible pebbling strategies for the weighted line graph to compose with such irreversible pebbling then we can compose this reversible pebbling with  $P = (P_1, \ldots, P_t)$  to obtain a composed pebbling  $R = (R_1, \ldots, R_{t'})$  such that  $\Pi_{cc}(R) \le \Pi_{cc}(P) \cdot \mathcal{O}\left(N^{\frac{\mathcal{O}(1)}{\frac{1}{\sqrt{\log N}}}}\right)$ . We stress that this is the primary technical challenge as adding weights to the nodes makes it substantially more challenging to develop an efficient reversible pebbling strategies.

**Theorem 3** (Classical vs. Reversible Cumulative Complexity). Let G = (V = [N], E) be a DAG. Then

$$\Pi_{cc}^{\longleftrightarrow,\parallel}(G) = \mathcal{O}\left(N^{\frac{\mathcal{O}(1)}{4\sqrt{\log N}}}\right) \cdot \Pi_{cc}^{\parallel}(G),$$

and

$$\Pi_{cc}^{\longleftrightarrow}\left(G\right) = \mathcal{O}\left(N^{\frac{\mathcal{O}(1)}{\frac{4}{\sqrt{\log N}}}}\right) \cdot \Pi_{cc}\left(G\right).$$

This means that to find an efficient reversible pebbling (up to these subpolynomial factors), it suffices to find an efficient classical pebbling. See Section 3.2 for details.

**1.1.3 Reversibility and Depth-Robust Graphs.** Classically, an important property of a pebbling graph is *depth robustness*. Alwen et al. [ABP17] showed that if G is (e, d)-depth robust then  $\Pi_{cc}^{\parallel}(G) \geq ed$ . While the same lower bound holds for the parallel *reversible* CC, it is natural to ask if one could achieve a better lower bound. We show that if G is (e, d)-depth robust then  $\Pi_{cc}^{\leftrightarrow,\parallel}(G) \geq e(2d-1)$ , and furthermore, if  $G - \operatorname{sinks}(G)$  is (e, d)-depth robust then  $\Pi_{cc}^{\leftrightarrow,\parallel}(G) \geq 2ed$  (see Theorem 9). Intuitively, the lower bound of Alwen et al. [ABP17] followed from the observation that given a pebbling  $P_1, \ldots, P_t$  of G such that for any  $i \leq d$  the set  $B_i = P_i \cup P_{i+d} \cup P_{i+2d} \ldots$  is a depth-reducing set, i.e.,  $G - B_i$  contains no path of length d. Intuitively, if  $G - B_i$  had a path  $v_1, \ldots, v_d$  of length d then we would *never* place a pebble on node  $v_d$  (It takes d steps to walk a pebble down the path, but every d rounds we are guaranteed to have no pebbles on the path). Our key observation is that for a reversible pebbling it would take at least 2d rounds to walk a pebble down to node  $v_d$  and then remove pebbles from every node in the path. Thus, we can increase our gap to 2d, define  $B_i = P_i \cup P_{i+2d} \cup P_{i+4d} \cup P_{i+6d} \ldots$ , and argue that  $G - \operatorname{sinks}(G) - B_i$  contains no path of length d.<sup>2</sup>

We also consider a parallel *relaxed* reversible pebbling where it is not required to remove pebbles from the intermediate nodes at the final round. In this setting, we cannot apply our new lower bound directly since we cannot assume that all pebbles on non-sink nodes are cleared by the end of the pebbling, e.g., it is possible during the last d pebbling rounds we pebble all of the nodes in the path  $v_1, \ldots, v_d$  and leave them. To lower bound the cost of a parallel relaxed reversible pebbling, it is helpful to define a graph  $G_{\mathsf{Trunc},d} \coloneqq G - [N - d + 1, N]$  where we truncate last d nodes and incident edges from the graph G. We show that if  $G_{\mathsf{Trunc},d}$  is (e, d)-depth robust then  $\widetilde{\Pi}_{cc}^{\leftrightarrow,\parallel}(G) \ge e(2d-1)$ (see Theorem 10), where  $\widetilde{\Pi}_{cc}^{\leftrightarrow,\parallel}(G)$  denotes the *parallel relaxed reversible CC* of G (see Definition 2 for a formal definition). This yields improvement by a multiplicative factor of  $\approx 1.885$  for the parallel relaxed reversible CC of DRSample [ABH17] with suitable parameters. See Section 5 for details.

1.1.4 Reversible Recursive Pebbling Attack. Alwen and Blocki [AB16] gave a generic parallel pebbling attack on any (e, d)-reducible graph G with  $\Pi_{cc}^{\parallel}(G) \leq \mathcal{O}\left(eN + N\sqrt{Nd}\right)$ . While Blocki et al. [BHL22] gave a reversible version of the attacks from Alwen et al. [AB16], the stateof-the-art upper bounds on  $\Pi_{cc}^{\parallel}(G)$  for most depth-reducible graphs actually utilize the recursive depth-reducing attack of [ABP17] — a recursive extension of [AB16] for graphs that are  $(e_i, d_i)$ reducible for a set of points  $(e_0, d_0), (e_1, d_1), \ldots$  with decreasing depth parameters  $d_{i+1} < d_i$  and increasing size parameters  $e_i > e_{i-1}$ . We provide a reversible extension of the recursive depthreducing attack of [ABP17]. As an immediate corollary, we obtain upper bounds on  $\Pi_{cc}^{\leftrightarrow,\parallel}(G)$ which (asymptotically) match the best known classical pebbling upper bounds on  $\Pi_{cc}^{\parallel}(G)$  for several iMHF candidates including Argon2iA (an older version of Argon2i) and Argon2iB (the current version). See Section 4 for details.

**1.1.5** Approximation Hardness of the Parallel Reversible Cumulative Pebbling Cost. We establish the approximation hardness of  $\Pi_{cc}^{\leftrightarrow,\parallel}(G)$  for a constant-indegree DAG G within any constant factor in the worst-case analysis under the Unique Games Conjecture. Our result extends

<sup>&</sup>lt;sup>2</sup> We have to exclude sinks(G) because if the final node  $v_d$  in our path was a sink node then the pebbling may never remove a pebble from node d. In this case it may be possible to walk a pebble to node  $v_d$  and then remove pebbles from  $v_1, \ldots, v_{d-1}$  in just 2d - 1 steps.

the prior approximation hardness result by Blocki et al. [BLZ20] which demonstrates that given a constant-indegree DAG G, it is Unique Games hard to approximate  $\Pi_{cc}^{\parallel}(G)$  within any constant factor. A key part of the proof of [BLZ20] was finding more efficient parallel pebbling on a graph called the superconcentrator overlay  $\operatorname{superconc}(G)$  when the graph G is depth-reducible. Applying the generic depth-reducing pebbling attacks of Alwen and Blocki [AB16] in a blackbox manner was not efficient enough so Blocki et al. [BLZ20] optimized the attack to exploit particular structure in the graph  $\operatorname{superconc}(G)$ . We show how to modify the pebbling strategy of Blocki et al. [BLZ20] to obtain a reversible pebbling of  $\operatorname{superconc}(G)$  without asymptotically increasing the pebbling cost. The approximation hardness of  $\Pi_{cc}^{\leftrightarrow,\parallel}(G)$  immediately follows. See Section 6 for details.

## 1.2 Related Work

Reversible pebbling games [Ben89, Krá01, MSR<sup>+</sup>19, Kni95] were introduced to analyze the spacetime complexity of quantum algorithms in the context of the limitations imposed by reversibility and the Quantum No-Deletion Theorem. These pebbling games only model *sequential* computation, meaning only one pebble can be placed or removed each round. In contrast, quantum adversaries computing an MHF  $f_{G,H}$  can make quantum queries to H in parallel, making these sequential games insufficient for analyzing the security of MHFs. For this reason, Blocki et al. [BHL22] introduced the *parallel reversible pebbling game*, which extends the reversible pebbling game by allowing any number of legal placing and removing of pebbles in each round. The authors used the parallel reversible pebbling game to analyze the post-quantum security of iMHFs to provide reversible space-time cost upper bounds of  $\mathcal{O}\left(N \cdot 2^{2\sqrt{\log N}}\right)$  for line graphs and the first reversible space-time cost upper bound of  $\mathcal{O}\left(\frac{N^2 \log \log N}{\log N}\right)$  for Argon2i. They also designed a reversible depth-reducing attack with cumulative complexity asymptotically equivalent to its counterpart in [ABP17].

Kornerup et al. [KSS21] introduced the (sequential) spooky pebbling game which models measurementbased deletion. The goal of the spooky pebbling game is to save quantum memory by measuring, storing the result of the measurement in classical memory, and then later using the result to restore the original state. A disadvantage to the spooky pebbling game in the context of a preimage attack is that it requires a linear number of measurements for each query to  $f_{G,H}$ , making it unsuitable for our applications [BHL22, KSS21].

## 2 Preliminaries

**Definition 1 (Reversible Graph Pebbling, [BHL22]).** Let G = (V, E) be a DAG and let  $T \subseteq V$  be a target set of nodes to be pebbled. A pebbling configuration (of G) at round i is a subset  $P_i \subseteq V$ . Let  $P = (P_0, \ldots, P_t)$  be a sequence of pebbling configurations. Below are the following properties which define various aspects of reversible pebblings.

- (1) The pebbling should start with no pebbles  $(P_0 = \emptyset)$  and end with pebbles on all of the target nodes i.e.,  $T \subseteq P_t$ .
- (2) A pebble can be added only if all of its parents were pebbled at the end of the previous pebbling round, i.e.,  $\forall i \in [t] : x \in (P_i \setminus P_{i-1}) \Rightarrow \mathsf{parents}(x, G) \subseteq P_{i-1}$ .
- (3) (Quantum No-Deletion Property) A pebble can be deleted only if all of its parents were pebbled at the end of the previous pebbling round, i.e.,  $\forall i \in [t] : x \in (P_{i-1} \setminus P_i) \Rightarrow \mathsf{parents}(x, G) \subseteq P_{i-1}$ .

- (4) (Quantum Reversibility) If a pebble was required to generate new pebbles (or remove pebbles), then we must keep the corresponding pebble around, i.e.,  $\forall i \in [t] : x \in \mathsf{parents}(P_i \setminus P_{i-1}, G) \cup \mathsf{parents}(P_{i-1} \setminus P_i, G) \Rightarrow x \in P_i$ .
- (5) (Remove Excess Pebbles) We also consider an optional constraint that  $P_t = T$ . If a pebbling does not satisfy this optional constraint we call it a relaxed pebbling.
- (6) (Sequential pebbling only) At most one pebble is added or removed in each round, i.e.,  $\forall i \in [t] : |(P_i \cup P_{i-1}) \setminus (P_i \cap P_{i-1})| \le 1.$

Now we give pebbling definitions with respect to the above properties.

- A legal parallel reversible pebbling of T is a sequence  $P = (P_0, \ldots, P_t)$  of pebbling configurations of G where  $P_0 = \emptyset$  and which satisfies conditions (1), (2), (3), (4) and (5) above. If our pebbling additionally satisfies condition (6) then we say that it is a sequential pebbling. Similarly, if our pebbling does not satisfy condition (5) then we call our pebbling strategy a relaxed pebbling.
- A legal reversible pebbling sequence is a sequence of pebbling configurations  $(P_0, \ldots, P_t)$  which satisfies properties (2) and (3) and (4) without requiring  $P_0 = \{\}$ .

We denote  $\mathcal{P}_{G,T}^{\leftrightarrow,\parallel}$  the set of all legal parallel reversible pebblings of G with a target set T, respectively. We denote with  $\widetilde{\mathcal{P}}_{G,T}^{\leftrightarrow,\parallel}$  the set of all legal relaxed parallel reversible pebblings of G with target set T. We will mostly be interested in the case where  $T = \operatorname{sinks}(G)$  in which case we simply write  $\mathcal{P}_{G}^{\leftrightarrow,\parallel}$  or  $\widetilde{\mathcal{P}}_{G}^{\leftrightarrow,\parallel}$ .

**Definition 2 (Reversible Pebbling Complexity).** Given a DAG G = (V, E), we essentially use the same definitions for the reversible pebbling complexity as defined in the previous literature [AS15, ABP17, ABP18, BHL22]. That is, the standard notion of time, space, space-time and cumulative pebbling complexity (CC) of a reversible pebbling  $P = \{P_0, \ldots, P_t\} \in \mathcal{P}_G^{\leftrightarrow,\parallel}$  are also defined to be:

- (time complexity)  $\Pi_t(P) = t$ ,
- (space complexity)  $\Pi_s(P) = \max_{i \in [t]} |P_i|,$
- (space-time complexity)  $\Pi_{st}(P) = \Pi_t(P) \cdot \Pi_s(P)$ , and
- (cumulative pebbling complexity)  $\Pi_{cc}(P) = \sum_{i \in [t]} |P_i|$ .

For  $\alpha \in \{s, t, st, cc\}$  and a target set  $T \subseteq V$ , the (non-relaxed/relaxed) parallel reversible pebbling complexities of G are defined as

$$\Pi_{\alpha}^{\longleftrightarrow,\parallel}(G,T) = \min_{P \in \mathcal{P}_{G,T}^{\longleftrightarrow,\parallel}} \Pi_{\alpha}(P), \text{ and } \widetilde{\Pi}_{\alpha}^{\longleftrightarrow,\parallel}(G,T) = \min_{P \in \widetilde{\mathcal{P}}_{G,T}^{\longleftrightarrow,\parallel}} \Pi_{\alpha}(P),$$

respectively. When  $T = \operatorname{sinks}(G)$  we simplify notation and write  $\Pi_{\alpha}^{\longleftrightarrow,\parallel}(G)$ .

We define the time, space, space-time and cumulative pebbling complexity of a sequential reversible pebbling  $P = \{P_0, \ldots, P_t\} \in \mathcal{P}_G^{\leftrightarrow}$  in a similar manner:  $\Pi_t^{\leftrightarrow}(P) = t$ ,  $\Pi_s^{\leftrightarrow}(P) = \max_{i \in [t]} |P_i|$ ,  $\Pi_{st}^{\leftrightarrow}(P) = \Pi_t^{\leftrightarrow}(P) \cdot \Pi_s^{\leftrightarrow}(P)$ , and  $\Pi_{cc}^{\leftrightarrow}(P) = \sum_{i \in [t]} |P_i|$ . Similarly, for  $\alpha \in \{s, t, st, cc\}$  and a target set  $T \subseteq V$ , the sequential reversible pebbling complexities of G are defined as  $\Pi_{\alpha}^{\leftrightarrow}(G, T) = \min_{P \in \mathcal{P}_G^{\leftrightarrow}} \Pi_{\alpha}^{\leftrightarrow}(P)$ . When  $T = \operatorname{sinks}(G)$  we simplify notation as well and write  $\Pi_{\alpha}^{\leftrightarrow}(G)$ .

We also introduce a new complexity notion that will be useful in our efficient pebbling compositions. The toggle number of a node v in a pebbling P is the number of times it is pebbled or unpebbled. The toggle number of a pebbling is its maximum toggle number over all nodes. **Definition 3 (Toggle Number).** Let P be a pebbling for a DAG G = (V = [N], E) and  $v \in V$ . We let  $\mathsf{toggle}(P, v) \coloneqq |\{i \mid v \in P_i \oplus P_{i+1}\}|$ , and  $\mathsf{toggle}(P) \coloneqq \max_{v \in [N]} \mathsf{toggle}(P, v)$ .

As mentioned in the prior work [BHL22], when we compare the relaxed and non-relaxed pebbling of a DAG G, the space-time cost and the cumulative pebbling complexity of a relaxed/non-relaxed reversible pebbling is not fundamentally different. We note that compared to the relaxed reversible pebbling, the running time of a non-relaxed pebbling increases by a multiplicative factor of 2 and the space usage increases by an additive factor of  $|T| \leq |P_t|$  where T is the target set. Hence, the overall space-time costs increase by a multiplicative factor of 4 *at most* [BHL22] and so is the cumulative pebbling complexity since CC is always upper bounded by the space-time cost. In the remainder of the paper, when we write "legal reversible pebbling" we assume that the pebbling is parallel and non-relaxed by default.

## 3 The Cost of Reversibility on Pebbling

In this section, we discuss the extent to which the additional rules imposed by reversibility impact the space-time and cumulative complexity of pebbling graphs. We first show that any reversible pebbling for the line graph  $\mathcal{L}_N$  on N nodes has CC  $\Omega\left(N^{1+\frac{\sqrt{2}-o(1)}{\sqrt{\log N}}}\right)$ . Since cumulative complexity lower bounds space-time complexity, this also implies that the reversible space-time complexity of the line graph is  $\Omega\left(N^{1+\frac{\sqrt{2}-o(1)}{\sqrt{\log N}}}\right)$ . Since the classical space-time and cumulative complexity of the line graph is  $\mathcal{O}(N)$ , this result shows that, in general, we cannot hope to provide reversible pebblings with cost equivalent to the best classical pebblings. On the other hand, we also show that any sequential pebbling for a graph G can be converted to into a reversible pebbling for G with a space-time overhead of  $\mathcal{O}\left(N^{\frac{2}{\sqrt{\log N}}}\right)$  and a CC overhead of  $\mathcal{O}\left(N^{\frac{\mathcal{O}(1)}{\sqrt{\log N}}}\right)$ .

## 3.1 A Separation between General and Reversible Pebbling

In this section, we show that line graphs are witnesses to among the greatest asymptotic separations between general and reversible pebblings. In particular, Theorem 1 shows that, in terms of cumulative complexity, the pebbling in Theorem 5 is tight and the composition in Corollary 1 is tight up to a factor of  $N^{\frac{1}{\sqrt{\log N}}}$ .

**Theorem 1 (Line Graphs Cumulative Complexity Lower Bound).** The cumulative complexity of the line graph  $\mathcal{L}_N$  on N nodes is

$$\Pi_{cc}^{\longleftrightarrow,\parallel}(\mathcal{L}_N) = \Omega\left(N^{1+\frac{\sqrt{2}-o(1)}{\sqrt{\log N}}}\right).$$

The idea of the lower bound for reversibly pebbling line graphs is as follows. Let  $C(N) = \Pi_{cc}^{\leftrightarrow,\parallel}(\mathcal{L}_N)$ . Any pebbling for  $\mathcal{L}_N$  first pebbles the sub-line graph  $\mathcal{L}_{k(N)}$  for some increasing function  $k(N) \leq N$ , incurring cost C(k(N)). Now, to pebble the rest of  $\mathcal{L}_N$  (incurring cost at least C(N - k(N))), the pebbling must at some point either unpebble [k(N)] (with cost C(k(N))) or must keep a pebble on [k(N)] (with cost at least N - k(N), the time required to finish pebbling  $\mathcal{L}_N$ ). This leads to Lemma 1.

**Lemma 1.** Let  $C(N) = \prod_{cc}^{\longleftrightarrow, \parallel} (\mathcal{L}_N)$ . Then for any 1 < k(N) < N we have

$$C(N) \ge C(k(N)) + C(N - k(N)) + \min\{C(k(N)), N - k(N)\}.$$

We will choose k(N) such that  $C(k(N)) \leq N - k(N)$ , meaning we only need to bound  $C(N) \geq 2C(k(N)) + C(N - k(N))$ . Using this relation, we show that  $C(N) = \Omega\left(N^{1+\frac{\sqrt{2}-o(n)}{\sqrt{\log N}}}\right)$ . We choose  $k(N) = N \cdot 2^{-c\sqrt{\log N}} = N^{1-\frac{c}{\sqrt{\log N}}}$  for any  $0 < c < \sqrt{2}$  and let  $f(N) = N \cdot 2^{c\sqrt{\log N}} = N^{1+\frac{c}{\sqrt{\log N}}}$ . By induction, we show that  $C(N) \geq c'f(N)$  for some constant c' > 0. To prove this, we first show that  $2f(k(N)) + f(N - k(N)) \geq f(N)$  for all sufficiently large N. The proof is left to Appendix B.

**Lemma 2.** Define functions h, f, and g such that for any  $0 < c < \sqrt{2}$ ,  $h(N) = 2^{c\sqrt{\log N}}$ ,  $f(N) = N \cdot h(N)$ , and  $g(N) = 2f\left(\frac{N}{h(N)}\right) + f\left(N - \frac{N}{h(N)}\right)$ . There exists  $N_0 \ge 1$  such that  $f(N) \le g(N)$  for all  $N \ge N_0$ .

Putting it all together, we lower bound the reversible cumulative complexity of line graphs.

Proof of Theorem 1. Let  $C(N) = \prod_{cc}^{\leftrightarrow, \parallel}(\mathcal{L}_N)$ . Define h, f, and g as in Lemma 2 (for any constant  $0 < c < \sqrt{2}$ , setting k(N) = N/h(N). Then by Lemma 1, we have that

$$C(N) \ge C(k(N)) + C(N - k(N)) + \min\{C(k(N)), N - k(N)\}.$$

We'll prove that  $C(N) = \Omega(f(N))$  via induction. Define f and g as in Lemma 2. Fix  $N_0$  large enough for 1) Lemma 2 to hold and 2)  $f(N/h(N)) \leq N - N/h(N)$  for all  $N \geq N_0$ .

Now pick a sufficiently small constant c' > 0 so that  $C(N_0) \ge cf(N_0)$ . And suppose for all  $N_0 \le N' < N$ , that  $C(N') \ge cf(N')$ . We have

$$C(N) \ge C(k(N)) + C(N - k(N))$$

$$+ \min \{C(k(N)), N - k(N)\}$$

$$= 2 \cdot C(k(N)) + C(N - k(N))$$

$$\ge 2c'f(k(N)) + c'f(N - k(N))$$
inductive hypothesis
$$= c'g(N)$$

$$\ge c'f(N)$$
Lemma 2

by Lemma 2. Since this holds for every  $0 < c < \sqrt{2}$ , it follows that  $C(N) = \Omega\left(N^{1+\frac{\sqrt{2}-o(1)}{\sqrt{\log N}}}\right)$ .  $\Box$ 

#### **3.2** Efficient Transformations from Classical to Reversible Pebblings

In this section, we discuss the extent to which it is possible to "convert" parallel irreversible pebblings into parallel reversible pebblings while minimizing the overhead in terms of space-time and cumulative complexity. The main idea is to consider an irreversible pebbling  $P = (P_1, \ldots, P_t)$  of some graph G. Since P is irreversible, it is possible that in some transition  $P_i \to P_{i+1}$ , some node j was deleted without having its parents pebbled or placed while deleting one of its parents. So, we can simulate  $P_i \to P_{i+1}$  by keeping around any pebbles that make this step irreversible. Now suppose our pebbling state contains  $P_i \cup P_{i+1} \cup P_{i+2}$ . Then we can free up space by removing all pebbles in  $P_{i+1} \setminus (P_i \cup P_{i+2})$ . This is reversible because  $\mathsf{parents}(P_i \setminus P_{i+1}, G)$  and  $\mathsf{parents}(P_{i+1} \setminus P_i, G)$  are contained in  $P_i$  by the (irreversible) legality of the pebbling P. More generally, we can instead focus on reversibly pebbling the line graph  $\mathcal{L}_t$ , where each node  $i \in [t]$  of  $\mathcal{L}_t$  represents the pebbling configuration  $P_i$ . By the reversibility of the pebbling of  $\mathcal{L}_t$ , the resulting pebbling steps of the graph G will be reversible. This is the intuition behind pebbling composition.

**Definition 4 (Pebbling Composition).** Let  $P = (P_1, \ldots, P_t)$  be a pebbling for a graph G and and  $L = (L_1, \ldots, L_{t'})$  be a pebbling of the line graph  $\mathcal{L}_t$ . The composition of L with P is the pebbling  $Q = L \circ P$ , defined by  $Q_i := \bigcup_{i \in L_i} P_j$  for  $i \in [t']$ .

Using pebbling composition, we show that classical and reversible space-time and cumulative complexity of graphs are within subpolynomial factors in N of each other.

**Theorem 2** (Classical vs. Reversible Space-Time Complexity). Let G = (V = [N], E) be a DAG. Then

$$\Pi_{st}^{\longleftrightarrow,\parallel}\left(G\right) = \mathcal{O}\left(N^{\frac{2}{\sqrt{\log N}}}\right) \cdot \Pi_{st}^{\parallel}\left(G\right),$$

and

$$\Pi_{st}^{\longleftrightarrow}(G) = \mathcal{O}\left(N^{\frac{2}{\sqrt{\log N}}}\sqrt{\log N}\right) \cdot \Pi_{st}(G).$$

As a brief application of this result, we obtain a new upper bound on the parallel reversible space-time complexity of the bit-reversal graph, underlying MHFs such as Catena [FLW13]. Alwen and Serbinenko [AS15] show that the parallel space-time complexity of the bit-reversal graph is  $\mathcal{O}(N^{1.5})$ . Applying Theorem 2, we see that the parallel reversible space-time complexity of the bit-reversal graph is  $\mathcal{O}(N^{1.5+\frac{2}{\sqrt{\log N}}})$ .

**Theorem 3 (Classical vs. Reversible Cumulative Complexity).** Let G = (V = [N], E) be a DAG. Then

$$\Pi_{cc}^{\longleftrightarrow,\parallel}(G) = \mathcal{O}\left(N^{\frac{\mathcal{O}(1)}{4\sqrt{\log N}}}\right) \cdot \Pi_{cc}^{\parallel}(G),$$

and

$$\Pi_{cc}^{\longleftrightarrow}(G) = \mathcal{O}\left(N^{\frac{\mathcal{O}(1)}{\frac{4}{\sqrt{\log N}}}}\right) \cdot \Pi_{cc}(G).$$

Before these results, there were large gaps between the known upper and lower bounds of the reversible cumulative complexity of graphs underlying prominent MHFs such as Argon2i, Balloon Hash, and Catena, whereas their classical cumulative complexity is well understood. Applying Theorem 3, we immediately obtain reversible pebblings which match the best classical pebblings up to this subpolynomial factor. In future sections, we will show how we can match the classical upper bounds for these particular functions within a constant factor.

**3.2.1** Reversible Space-Time Complexity. Let  $P = (P_1, \ldots, P_t)$  be a pebbling or a graph G = (V = [N], E) and  $L = (L_1, \ldots, L_t)$  be a reversible pebbling for the line graph  $\mathcal{L}_t$ . We first show that  $Q = L \circ P$  is a legal reversible pebbling. Notice that since P starts as an empty pebbling, so does Q. Likewise,  $L_{t'} = t$ , so  $Q_{t'} = P_t$ , meaning the end conditions are also satisfied.

Now we want to show that Q satisfies Property 3, no deletion. In other words, for a transition  $Q_i \to Q_{i+1}$ , we want to show that

parents 
$$(Q_i \setminus Q_{i+1}, G) \subseteq Q_i$$
.

Since  $Q_i = \bigcup_{k \in L_i} P_k$ , we have that any deleted pebble  $v \in Q_i \setminus Q_{i+1}$  must also be contained in

$$\bigcup_{j \in L_{i+1} \setminus L_i} P_j \setminus P_{j-1} = \bigcup_{j \in L_i \setminus L_{i+1}} P_j \setminus \bigcup_{k \in L_{i+1}} P_k.$$

If v is added in round i+1 from some configuration  $P_j$ , it must be the case that j was unpebbled in L at round i. By the no-deletion property of L, it must be the case that  $parents(j, L) = \{j - 1\} \subseteq L_i$ . Therefore,

$$Q_i \setminus Q_{i+1} \subseteq \bigcup_{j \in L_i \setminus L_{i+1}} P_j \setminus P_{j-1}$$

and

parents 
$$(Q_i \setminus Q_{i+1}, G) \subseteq \bigcup_{j \in L_i \setminus L_{i+1}} \text{ parents } (P_j \setminus P_{j-1}, G)$$
.

Again, by the no deletion property of L if  $j \in L_{i+1} \setminus L_i$ , then the parents of j-1 is contained in  $L_i$ , so

$$\bigcup_{j \in L_i \setminus L_{i+1}} \operatorname{parents} \left( P_j \setminus P_{j-1}, G \right) \subseteq \bigcup_{j \in L_i \setminus L_{i+1}} P_{j-1}.$$

Applying the no-deletion property of L once more, notice that

$$\bigcup_{j \in L_i \setminus L_{i+1}} P_{j-1} = \bigcup_{k \in \mathsf{parents}(L_i \setminus L_{i+1}, \mathcal{L}_{t'})} P_k$$

and

$$\bigcup_{k \in \mathsf{parents}(L_i \setminus L_{i+1}, \mathcal{L}_{t'})} P_k \subseteq \bigcup_{k \in L_i} P_k = Q_i$$

Thus, Q satisfies Property 3. The proof that Q satisfies the rest of the properties follows from similarly careful analysis, which is formalized in Appendix B.

Now we analyze the space-time complexity of Q. At any step i,  $Q_i$  contains at most  $\Pi_s(L)$  configurations of P. Thus,  $\Pi_s(Q) \leq \Pi_s(L) \cdot \Pi_s(P)$ . Likewise,  $\Pi_t(Q) = \Pi_t(L)$ , leading to Theorem 4.

**Theorem 4 (Reversible Composition Pebbling).** Let  $P = (P_1, \ldots, P_t)$  be a (possibly irreversible) pebbling for a DAG G, and  $L = (L_1, \ldots, L_{t'})$  be a reversible pebbling for  $\mathcal{L}_N$ . Then the composition  $L \circ P$  is a legal reversible pebbling of G satisfying  $\Pi_{st}(Q) \leq \Pi_s(P) \cdot \Pi_{st}(L)$ .

At a high level, Theorem 4 says that we can combine any pebbling for an arbitrary DAG G with a reversible pebbling of a line graph to obtain a reversible pebbling of G with comparable space-time complexity. We will use the reversible pebbling from [BHL22].

**Theorem 5 (Reversible Line Graph Pebbling** [BHL22]). There exist a family of sequential pebblings  $L_N$  and a family of parallel reversible pebblings  $L_N^{\parallel}$  for line graphs  $\mathcal{L}_N$  such that

(1) 
$$\Pi_t(L_N) = \mathcal{O}\left(N^{1+\frac{1}{\sqrt{\log N}}}\right), \Pi_s(L_N) = \mathcal{O}\left(N^{\frac{1}{\sqrt{\log N}}}\sqrt{\log N}\right), \Pi_{st}(L_N), \Pi_{cc}(L_N) = \mathcal{O}\left(N^{1+\frac{2}{\sqrt{\log N}}}\sqrt{\log N}\right),$$
  
and  $\operatorname{toggle}(L_N) = \mathcal{O}\left(N^{\frac{1}{\sqrt{\log N}}}\right), and$ 

$$(2) \ \Pi_t \left( L_N^{\parallel} \right) = \mathcal{O}(N), \ \Pi_s \left( L_N^{\parallel} \right)' = \mathcal{O}\left( N^{\frac{2}{\sqrt{\log N}}} \right), \ \Pi_{st} \left( L_N^{\parallel} \right), \Pi_{cc} \left( L_N^{\parallel} \right) = \mathcal{O}\left( N^{1 + \frac{2}{\sqrt{\log N}}} \right), \ and \\ \operatorname{toggle}(L_N^{\parallel}) = \mathcal{O}\left( N^{\frac{1}{\sqrt{\log N}}} \right).$$

Some of these results are unproven or implicit in the work of [BHL22], so for completeness, we provide proof of Theorem 5 in Appendix B.

**Corollary 1.** Let G be a DAG on N nodes. Then  $\Pi_{st}^{\longleftrightarrow,\parallel}(G) = \mathcal{O}\left(N^{\frac{1}{\sqrt{\log N}}} \cdot \Pi_{st}^{\parallel}(G)\right)$ .

*Proof.* Let  $P = (P_1, \ldots, P_t)$  be a pebbling of G and  $L = (L_1, \ldots, L_{t'})$  of  $\mathcal{L}_t$  from Theorem 5. If Q is the pebbling derived as in Theorem 4, then

$$\begin{aligned} \Pi_{st}(P) &\leq \frac{\Pi_{st}(P) \cdot \Pi_{s}(L) \cdot \Pi_{t}(L)}{\Pi_{t}(P)} \\ &= \mathcal{O}\left(\Pi_{st}(P) \cdot \Pi_{s}(L)\right) \qquad \quad \triangleleft \text{Theorem 4} \\ &= \mathcal{O}\left(2^{2\sqrt{\log N}} \cdot \Pi_{st}(P)\right). \end{aligned}$$

Next, we see that composing a sequential reversible pebbling of a line graph with a sequential pebbling of a graph G results in a reversible sequential pebbling for G. The proof is included in Appendix B.

**Corollary 2.** If  $P = (P_1, \ldots, P_t)$  is a sequential pebbling of a DAG G and L is a reversible sequential pebbling of  $\mathcal{L}_t$ , then  $L \circ P$  is a reversible sequential pebbling of G.

**3.2.2** Reversible Cumulative Complexity. In this section, we'll give a transformation that maps irreversible pebblings  $P = (P_1, \ldots, P_t)$  of a graph G = (V = [N], E) to reversible pebblings  $Q = (Q_1, \ldots, Q_{t'})$  at the cost of just a subpolynomial factor in cumulative complexity. As with space-time complexity, the mapping will involve reversibly pebbling the line graph  $\mathcal{L}_t$  associated with the given irreversible pebbling P of G. However, the method is much different. To see why the pebbling from Theorem 4 fails to preserve cumulative complexity, consider the reversible pebbling L of  $\mathcal{L}_t$ . The node  $i'_{k-1}$  in  $I'_k$  is kept for  $\Omega(t)$  steps. It could be the case that the pebbling configuration  $P_{i'_{k-1}}$  could be large (as large as  $\Omega(N)$ ) as well. If this large space usage happens for a small amount of time in P, then  $\Pi_{st}(P) \gg \Pi_{cc}(P)$  yet  $\Pi_{cc}(Q)$  is of similar magnitude to  $\Pi_{st}(Q) \gg \Pi_{cc}(P)$ .

For this transformation, we will still be providing a reversible pebbling for  $\mathcal{L}_t$ , but we will have to avoid keeping pebbles on nodes *i* associated with large configurations  $P_i$ . For this reason, it will be useful to instead consider pebblings on weighted graphs. This way, we can describe pebbling strategies for  $\mathcal{L}_t$ , where the "weight" of node *i* is wt<sub>i</sub> =  $|P_i|$ .

**Definition 5 (Weighted Graph Pebbling).** Let G = (V, E) be a graph with weights  $wt_v$  for  $v \in V$ . For a pebbling  $P = (P_1, \ldots, P_t)$  of G, the weighted cumulative complexity of P is

$$\Pi_{wcc}(P) = \sum_{i \in [t]} \sum_{v \in P_i} \mathsf{wt}_v,$$

and the weighted cumulative complexity of G is

$$\Pi_{wcc}(G) = \min_{P \in \mathcal{P}(G)} \Pi_{wcc}(P).$$

Consider a weighted line graph on N nodes. Our high-level goal is to minimize the number of pebbling rounds where we have pebbles on nodes with high weight. So, we construct a series of weight buckets  $S_0, \ldots, S_\ell$ , where  $S_0$  are the lightest nodes and  $S_\ell$  are the heaviest. In an ideal world, we would like to "ignore" heavier buckets and only pebble the nodes in  $S_0$  pretending that these nodes form a line graph of length  $|S_0|$ . However, this strategy would yield an illegal pebbling of the entire graph as we are skipping over heavier nodes. We fix the issue recursively. In particular, consider nodes  $u, v \in S_0$  and suppose that u is the predecessor of v in  $S_0$  (i.e., any intermediate node w with u < w < v has higher weight and is not in  $S_0$ ). Now suppose that our pebble of  $S_0$  illegally places (or removes) a pebble from node  $v \in S_0$  skipping over all of the intermediate nodes between u and v. We can patch the pebbling by recursively pebbling the weighted subgraph induced by nodes [u+1, v-1] and injecting these pebbling steps in between our pebbling of  $S_0$  i.e., we recursively place a pebble on v-1, then place a pebble on v, then reverse the recursive pebbling to clear pebbles from the interval [u+1, v-1]. The number of times that we have to recursively pebble/unpebble this interval [u+1, v-1] is upper bounded by the togqle number of our original pebbling of the line graph on  $|S_0|$  nodes, which is the maximum number of times that a node is pebbled/unpebbled. In particular, this recursive call is made at most twice the toggle number of the pebbling of the line graph on  $|S_0|$  nodes.

Fig. 1: An illustrative example of WRevLinePeb([14], wt, S, 0, L). Given a line graph  $\mathcal{L}_{14}$  with 14 nodes, based on the weight wt = (wt<sub>1</sub>,...,wt<sub>14</sub>) that is shown above each node, we construct subgraphs  $\mathcal{L}_{S_0}, \ldots, \mathcal{L}_{S_3}$ . In each subgraph, a solid edge means it is legal to pebble next node, and a dashed edge means it is illegal to proceed pebbling and we would need to make a recursive call. For example, in  $\mathcal{L}_{S_0}$ , it is illegal to place a pebble on node 10 from node 3, so we need to run WRevLinePeb([4, 9], wt, S, 1, L) recursively to place a pebble on node 9 and then proceed to node 10. One important observation here is that even though the number of recursive calls grows exponentially with the level of recursion, the size of the nodes in each level is decreasing even faster. This makes our reversible weighted pebbling CC-efficient. See Theorem 6 for the details.

Now we describe in more detail the CC-efficient reversible, weighted line graph pebbling WRevLinePeb<sup>||</sup>. In particular, we consider a line graph  $\mathcal{L}_N$  with weights wt<sub>i</sub> on node *i* satisfying  $\sum_i wt_i \leq N^2$ . Note that without loss of generality, we can always take  $wt_1 = wt_N = 1$ , so assume this to be the case. recall that to keep the cumulative cost low, we will aim to keep pebbles on "heavy" nodes for as little time as possible, placing pebbles on the heaviest nodes only when necessary. We first partition nodes according to their weight such that  $S = (S_0, \ldots, S_\ell)$ . Later, we will take care in assigning nodes to buckets to ensure that 1) there aren't too many nodes in heavier buckets, and 2)  $\ell$  is small, meaning there aren't to many buckets overall.

Fix some family of line graph pebblings L(i) for  $\mathcal{L}_i$  for  $1 \leq i \leq N$ . A set  $S \subseteq [N]$  induces a line graph  $\mathcal{L}_S$ , where the *i*th node of  $\mathcal{L}_S$  is the *i*th smallest value in S. We similarly let L(S) denote the pebbling corresponding to L(|S|). As L is a family of pebblings, recall that  $L(i)_j$  is the *j*th pebbling configuration of the pebbling of the line graph  $\mathcal{L}_i$ . For

- a set of weights  $\mathsf{wt} = (\mathsf{wt}_1, \ldots, \mathsf{wt}_N),$
- set of buckets  $\mathcal{S} = (S_1, \ldots, S_\ell)$ , and
- an interval  $I = [a, b] \subseteq [N]^3$  and integer  $i \in [0, \ell]$  such that  $I \subseteq S_{\geq i} := \bigcup_{j \geq i} S_j$ ,

the weighted line graph pebbling WRevLinePeb(I, wt, S, i, L) of  $\mathcal{L}_I$  with weights defined by wt is defined in Algorithm 1. See Figure 1 for an illustrative example.

Algorithm 1: WRevLinePeb $  (I = [a, b], wt, S = (S_0, \dots, S_\ell), i, L)$	
1 if $i = \ell + 1$ or $I = \emptyset$ then	
2 return	
3 f	$pr \ j = 1, \dots,  L(I \cap S_i)  - 1;$ // done in parallel
4 (	do
5	${f for} \ v\in L(S_i\cap I)_j\oplus L(S_i\cap I)_{j+1};$ // $v$ to be pebbled or unpebbled
6	do
7	Let $u = \max\{a-1\} \cup (I \cap S_i \cap [v-1]);$ // v's predecessor
8	Let $I' = [u+1, v-1]$
9	Pebble $I'$ using WRevLinePeb $  (I', wt, S, i+1, L) $
10	if $v \in L(S_i \cap I)_{j+1}$ then
11	Pebble $v$ ; // as $v-1$ is pebbled
<b>12</b>	else
13	Unpebble $v$
14	Unpebble $I'$ by reversing WRevLinePeb $  (I', wt, S, i+1, L) $

To analyze the weighted cumulative complexity of our pebbling we'll need to know the maximum number of times we place or remove pebbles on any particular node. Recall that the toggle number for a node v in a pebbling P is  $\mathsf{toggle}(v, P) = |\{i \mid v \in P_i \oplus P_{i+1}\}|$ , and  $\mathsf{toggle}(P) = \max_v \mathsf{toggle}(v, P)$ . The toggle number of our non-weighted reversible line graph pebbling will help us upper bound the number of times we will end up pebbling nodes in  $S_i$ .

Consider the pebbling WRevLinePeb([N], wt,  $S = (S_0, \ldots, S_\ell), 0, L$ ) of the weighted line graph on N nodes and weights wt. The analysis consists of two components for each  $i \in [\ell]$ : 1) T(i), the number of steps that at least one pebble is contained in  $S_i$ , and 2) M(i), the greatest number of

<sup>&</sup>lt;sup>3</sup> Recall that if a > b then  $[a, b] = \emptyset$  and  $[a, a] = \{a\}$ 

pebbles contained in  $S_i$  at any step. This way,

$$\Pi_{wcc}\left(\mathsf{WRevLinePeb}([N],\mathsf{wt},\mathcal{S},0,L)\right) \leq \sum_{0 \leq i \leq \ell} T(i)M(i) \max_{j \in S_i} \mathsf{wt}_j.$$

First we bound T(i). For now, assume  $\Pi_t(L(N)) \leq cN$  for some constant c. If we have sub-intervals  $I_1, \ldots, I_k \subseteq [N]$ , then the time it takes to pebble each interval individually is at most  $c\sum_i |I_i|$ . Now consider the number of steps in which there's a pebble in  $S_\ell$ . Every time we pebble/unpebble a node in the  $S_0$  pebbling, we call a pebbling in  $S_1$ . This happens at most  $\tau := 2 \operatorname{toggle}(L(N))$  times (to pebble then unpebble). Therefore, throughout the pebbling of  $S_0$ , we (re)pebble nodes in  $S_\ell$  at most  $2^\ell \tau^\ell$  times, and the total number of steps with a pebble in  $S_\ell$  is at most  $T(\ell) \leq c 2^\ell \tau^\ell |S_\ell|$ . Now consider  $S_{\ell-1}$ . We similarly see that we repebble  $S_{\ell-1}$  at most  $2^{\ell-1} \tau^{\ell-1}$ times, but now we may also have pebbles in  $S_{\ell-1}$  while we're waiting for pebblings of subsets of  $S_\ell$ to complete. Thus,  $T(\ell-1) \leq c 2^{\ell-1} \tau^{\ell-1} |S_{\ell-1}| + c 2^\ell \tau^\ell |S_\ell|$ . More generally we have

$$T(i) \le c \sum_{i \le j \le \ell} 2^j \tau^j |S_j| \le c(\ell+1) 2^\ell \tau^\ell |S_i|,$$

under the assumption that the sizes of the buckets  $S_i$  are decreasing with respect to *i*. While this bound may seem crude, we will assign the buckets S such that  $2^{\ell}$  and  $\tau^{\ell}$  are small, subpolynomial terms, meaning T(i) isn't too much larger than  $|S_i|$  in general.

Now we bound M(i). By the construction of L,  $M(0) \leq \Pi_s(L(S_0))$ . Notice that the pebbling L cannot pebble/repebble more than  $\Pi_s(L(S_0))$  nodes in a single step. Then for  $S_1$ , there are at most  $\Pi_s(L(S_0))$  calls in a single step to intervals containing nodes in  $S_1$ . For each of these calls, there are at most  $\Pi_s(L(S_1))$  pebbles on the graph in  $S_1$ . So,  $M(1) \leq \Pi_s(L(S_1)) \cdot \Pi_s(L(S_0))$ . More generally, we see that

$$M(i) \le \prod_{0 \le j \le i} \Pi_s(L(S_j)) \le \Pi_s(N)^{i+1}.$$

Here, we rely on the fact that both  $\ell$  and  $\Pi_s(i)$  are relatively small. We'll see shortly that  $\Pi_s(i)^{\ell}$  is still subpolynomial.

Putting it all together, we get

$$\begin{split} \Pi_{wcc} \left( \mathsf{WRevLinePeb}([N],\mathsf{wt},\mathcal{S},0,L) \right) &\leq \sum_{0 \leq i \leq \ell} T(i)M(i) \max_{j \in S_i} \mathsf{wt}_j \\ &\leq c(\ell+1) 2^\ell \tau^\ell \sum_i |S_j| \cdot \Pi_s(L(N))^i \max_{j \in S_i} \mathsf{wt}_i \end{split}$$

Now fix  $L = \mathsf{RevLinePeb}^{\parallel}$ . All that is left is to define the buckets. Let  $\mathsf{wt}_{\mathsf{avg}}$  be the average weight in wt and  $S_i = \{j \mid \tau^{\alpha i} \mathsf{wt}_{\mathsf{avg}} \leq \mathsf{wt}_j \leq \tau^{\alpha(i+1)} \mathsf{wt}_{\mathsf{avg}}\}$ , where  $\tau = \mathsf{toggle}(L(S_0)) = \Theta\left(N^{\frac{1}{\sqrt{\log N}}}\right)$  and  $\alpha = \sqrt[4]{\log N}$ . This implies that the number of weight buckets is  $\ell \leq \frac{\log N}{\alpha \log \tau} = \mathcal{O}\left(\sqrt[4]{\log N}\right)$ . Now, we know that  $|S_i| \leq \frac{\sum_j \mathsf{wt}_j}{\tau^{\alpha i} \mathsf{wt}_{\mathsf{avg}}} = \frac{N}{\tau^{\alpha i}}$ . Thus, the sizes of the sets  $S_i$  shrink fairly quickly with respect to *i*. So much so, that the summand

$$T(0)M(0)\max_{j\in S_0}\mathsf{wt}_j = N^{\frac{\mathcal{O}(1)}{4\sqrt{\log N}}} \cdot N^{1+\frac{1}{\sqrt{\log N}}} = N^{1+\frac{\mathcal{O}(1)}{4\sqrt{\log N}}}$$

dominates the entire WCC sum above. This results in Theorem 6.

**Theorem 6** (Reversible Cumulative Complexity of Weighted Line Graphs). Given a weighted line graph  $\mathcal{L}_N$  with weights  $\mathsf{wt}_i \leq N$  for nodes  $i \in N$ . Then there exists a parallel reversible pebbling P and sequential pebbling S for  $\mathcal{L}_N$  with

$$\begin{split} \Pi_t(P) &= \mathcal{O}\left(N\right), & \Pi_{wcc}\left(P\right) = N^{\frac{\mathcal{O}(1)}{\sqrt[4]{\log N}}} \cdot \sum_i \mathsf{wt}_i, \text{ and} \\ \Pi_t(S) &= \mathcal{O}\left(N^{1 + \frac{\mathcal{O}(1)}{\sqrt[4]{\log N}}}\right), & \Pi_{wcc}\left(S\right) = N^{\frac{\mathcal{O}(1)}{\sqrt[4]{\log N}}} \cdot \sum_i \mathsf{wt}_i. \end{split}$$

*Proof.* Consider the pebbling  $P = \mathsf{WRevLinePeb}^{\parallel}([N], \mathsf{wt}, \mathcal{S}, 0, L = \mathsf{RevLinePeb}^{\parallel})$  as defined in the discussion above. First, we have that  $|S_i| \leq \frac{\sum_j \mathsf{wt}_j}{\tau^{\alpha i} \mathsf{wt}_{avg}} \leq \frac{N}{\tau^{\alpha i}}$ . Next  $\Pi_s(N)^i \leq c' N^{\frac{2i}{\sqrt{\log N}}}$  for some constant c' > 0. Finally,  $\max_{j \in S_i} \mathsf{wt}_j \leq \tau^{\alpha(i+1)} \mathsf{wt}_{avg}$ . So, the weighted cumulative complexity is at most

$$\begin{split} \Pi_{wcc}(P) &\leq \sum_{i} T(i)M(i) \max_{j \in S_{i}} \mathsf{wt}_{j} \\ &\leq c(\ell+1)2^{\ell}\tau^{\ell} \sum_{0 \leq i \leq \ell} |S_{i}| \cdot \Pi_{s}(L(N))^{i} \max_{j \in S_{i}} \mathsf{wt}_{i} \\ &\leq cc'(\ell+1)2^{\ell}\tau^{\ell+\alpha} N\mathsf{wt}_{\mathsf{avg}} \sum_{0 \leq i \leq \ell} N^{\frac{2i}{\sqrt{\log N}}} \\ &\leq cc'(\ell+1)^{2}2^{\ell}\tau^{\ell+\alpha} N^{\frac{2\ell}{\sqrt{\log N}}} \cdot N\mathsf{wt}_{\mathsf{avg}} \\ &\leq cc'(\ell+1)^{2}2^{\ell}\tau^{\ell+\alpha} N^{\frac{2\ell}{\sqrt{\log N}}} \cdot \sum_{j \in [N]} \mathsf{wt}_{j}. \end{split}$$

Now we need to analyze the coefficient on  $\sum_{j} \operatorname{wt}_{j}$ . Since  $\ell = O(\sqrt[4]{\log N})$  and  $\alpha = O(\sqrt[4]{\log N})$ , it follows that  $2^{\ell} = N^{\frac{O(1)}{\log^{3/4} N}}$  and  $\tau^{\ell+\alpha} = N^{\frac{O(\frac{4}{\sqrt{\log N}})}{\sqrt{\log N}}} = N^{\frac{O(1)}{\sqrt{\log N}}}$ . Putting it all together, we get

$$\Pi_{wcc}(P) = N^{\frac{O(1)}{\sqrt[4]{\log N}}} \sum_{j \in [N]} \mathsf{wt}_j.$$

Since we assume nodes  $1, N \in S_0$ , the time complexity of P at most

$$\begin{split} \Pi_t(P) &\leq T(0) \leq c \sum_{0 \leq j \leq \ell} 2^j \tau^j |S_j| \\ &\leq c |S_0| + c \sum_{1 \leq j \leq \ell} 2^j \frac{N}{\tau^{j(\alpha-1)}} \\ &\leq c N + 2c \ell \frac{N}{\tau^{\alpha-1}} \qquad \text{sum is decreasing in } j \\ &\leq 3c N \qquad \qquad \ell = o(\tau^{\alpha-1}). \end{split}$$

To finish up, we need a sequential weighted pebbling Q. Note that we can sequentially simulate P by executing the pebble placing/removing one at a time per step. There are at most 2(P)

pebbles placed or removed in a pebbling step of P. Then  $\Pi_t(Q) \leq \Pi_t(P) \cdot 2\Pi_s(P)$ . Likewise,  $\Pi_s(Q) \leq 2\Pi_s(P)$ . The number of steps spent with a pebble in  $S_i$  increases by at most a factor of  $\Pi_s(P)$ . We have that  $\Pi_s(P) \leq \ell \tau^\ell N^{\frac{2}{\sqrt{\log N}}} = N^{\frac{O(1)}{\sqrt{\log N}}}$ , so

$$\begin{split} \Pi_{wcc}(Q) &= N^{\frac{O(1)}{\sqrt[4]{\log N}}} \Pi_{wcc}(P) \\ &= N^{\frac{O(1)}{\sqrt[4]{\log N}}} \cdot N^{\frac{O(1)}{\sqrt[4]{\log N}}} \cdot \sum_{j \in [N]} \mathsf{wt}_j \\ &= N^{\frac{O(1)}{\sqrt[4]{\log N}}} \cdot \sum_{j \in [N]} \mathsf{wt}_j. \end{split}$$

## 4 Reversible Recursive Pebbling Attack

In the last section, we showed that the reversible cumulative complexity of a graph is always within a factor of  $N^{\frac{O(1)}{\sqrt[4]{\log N}}}$  of the classical cumulative complexity. In this section, we show for classes of graphs that satisfy certain depth-reducibility properties, there are reversible pebblings which match the best known classical pebblings in cumulative complexity. Blocki et al. [BHL22] introduced a reversible pebbling attack for (e, d)-reducible graphs G = (V = [N], E), based on the classical depth-reducing attack of [ABP17].

**Theorem 7 (Reversible Depth-Reducing Pebbling Strategy).** For any (e, d)-depth reducible graph G = (V = [N], E), target set T, and parameter  $g \in [d, N]$ , there exists a reversible parallel pebbling  $P = (P_1, \ldots, P_{2N}) = \mathsf{RGenPeb}(G)$  with  $P_{2N} = T$  such that

$$\Pi_{cc}(P) \le 2N\left(\frac{2Nd}{g} + e + (\delta + 1)g + |T|\right) + N + \frac{2Nd}{g}.$$

We construct a more general reversible pebbling attack based on the recursive attack of [ABP17]. As a result, we obtain asymptotically stronger reversible CC upper bounds for several iMHFs.

**Review of Algorithm in Theorem 7:** Let G = (V = [N], E) be an (e, d)-depth robust graph with depth reducing set  $S \subseteq [N]$  of size at most  $e_1$ . The pebbling RGenPeb(G) is composed of a sequence of alternating phase: *light phases* and *balloon phases*. Each light phase lasts 2g rounds. The goal of the  $c^{th}$  light phase is to pebble the nodes  $I_c = [(c-1)g+1, cg]$  one at a time with low space usage. To achieve this, we will enforce the light phase precondition on the pebbling configuration  $P_j$ , the step before the start of the  $c^{th}$  light phase. In particular, it must be the case that

$$LightReq_0^c = S_{\subset (c-1)g+1} \cup parents(I_c) \setminus I_c.$$

If this condition is satisfied, then we can simply place a pebble on node (c-1)g+k in  $P_{j+k}$  for all  $k \in [g]$ . The end condition for the  $c^{th}$  light phase is then  $P_{j+g} = S_{\leq cg} \cup I_c \cup \mathsf{parents}(I_c)$ . We then reverse the light phase, while keeping pebbles only on  $S_{\leq cg}$ , so  $\mathsf{LightReq}_{g+j}^c = \mathsf{LightReq}_{g-j}^c \cup S_{\leq cg}$ . However, this leaves us unprepared for the  $(c+1)^{th}$  light phase. To fix this, we can simply start a balloon phase with the goal of pebbling  $\mathsf{LightReq}_0^{c+1}$ . The pebbling attack of  $[\mathsf{BHL22}]$  accomplishes this by simply applying a greedy pebbling strategy. In particular, if  $\mathsf{BalloonReq}_{2g-2d-1}^c$  is the step before the balloon

phase begins, we must have pebbles on  $S_{\leq cg}$ . Then  $\mathsf{BalloonReq}_{2g+j}^c$  pebbles any node that can be legally pebbled from  $\mathsf{BalloonReq}_{2g+j-1}^c$ . In *d* rounds, nodes [cg] will be pebbled. Then we can reverse both the light phase and the balloon phase, keeping pebbles only on  $S_{\leq cq} \cup \mathsf{parents}(I_{c+1}) \setminus I_{c+1}$ .

Now we can describe the reversible recursive attack RRGenPeb. The main difference is that we replace the greedy balloon phases with more efficient algorithms when G is  $(e_i, d_i)$ -depth reducible along multiple points *i*. The proof is similar to that of [ABP17], but special consideration is needed to account for reversibility.

#### 4.1 Reversible Recursive Pebbling Strategy

Let G = (V = [N], E) be an  $(e_1, d_1)$ -depth reducible graph of depth  $d_1 \leq d_0$ , satisfying  $2d_1N \leq e_1d_0$ . Our goal is to pebble some target set  $T \subseteq V$ . The light phases will be pebbling intervals of length  $g = \left\lfloor \frac{e_1d_0}{N} \right\rfloor \geq 2d_1$ . These light phases are slightly different than in RGenPeb. Since we know that the depth of G is  $d_0 \leq N$ , we can instead pebble all nodes of the same depth each step, meaning the pebbling time will be at most  $2d_0$ . More formally we define sets  $D_1, \ldots D_{2d_1}$  such that parents $(D_1) = \emptyset$ , parents $(D_{i+1}) \subseteq \bigcup_{j \leq i} D_j$ , and each  $|D_i| \leq \frac{N}{d_0}$ . Analogously to before, we let  $I_c = \bigcup_{1 \leq j \leq cg} D_j$ . Likewise, for any set R, we let  $R_{\leq i} = R \cap \bigcup_{i \leq j \leq i} D_j$ . So, for  $0 \leq i \leq g$ , the  $i^{th}$  step of the  $c^{th}$  light phase will maintain

$$\mathsf{LightReq}_i^c = S_{\preceq (c-1)g+i} \cup T_{\preceq (c-1)g+i} \cup \bigcup_{(c-1)g \le j \le \min\{(c-1)g+i,N\}} D_j.$$

As before, we'll let LightReq<sup>c</sup><sub>cg+i</sub> = LightReq<sup>c</sup><sub>cg-i</sub>  $\cup S_{\leq cg} \cup T_{\leq cg}$  for  $0 \leq i \leq \min \{g, N - cg\}$ . Now, for some G' with depth at most d, let B(G', T', t) be a pebbling of G' with target set T' that terminates in at most  $t \geq 2d$  steps. Then we can let

BalloonReq<sup>c</sup> = 
$$B(G_{\leq cg} - S_{\leq cg}, \text{parents}(I_{c+1}) \setminus I_{c+1}, 2d_1)$$
.

There are technicalities we must account for with these new balloon phases:

- (Before Start) We let BalloonReq<sub>i</sub><sup>c</sup> =  $\emptyset$  for  $1 \le j \le cg 2d_1$ .
- (Early Termination) If BalloonReq terminates in less than  $t \leq 2d_1$  rounds, then we'll let

$$\mathsf{BalloonReq}^c_{cg-2d_1+t+j} = \mathsf{BalloonReq}^c_t$$

for  $1 \le j \le 2d_1 - t$ .

The pebbling, excluding clean-up, is

$$P' \coloneqq \mathsf{LightReq}^1 \cup \mathsf{BalloonReq}^1 + \dots + \mathsf{LightReq}^{\lceil 2d_0/g \rceil - 1} \cup \mathsf{BalloonReq}^{\lceil 2d_0/g \rceil - 1} + \mathsf{LightReq}^{\lceil 2d_0/g \rceil}$$

The final pebbling  $P = \mathsf{RRGenPeb}(G, \{(e_1, d_1, S_1)\}, B)$  is obtained by then reversing P' while keeping nodes on the target set T. More formally, for all  $1 \le j \le |P'|$ ,

$$P_{|P'|+j} = P'_{|P'|-j} \cup T.$$

Showing that P is a legal reversible pebbling is straightforward, and the proof is left to the Appendix C.

**Lemma 3.** For any  $(e_1, d_1)$ -depth reducible DAG G = (V = [N], E) of depth  $d_0$ , target set  $T' \subseteq [N]$ , and family of pebblings B(G', T', t') for all DAGs G' = (V', E'), target sets  $T' \subseteq V'$ , and  $t' \ge 2 \cdot \operatorname{depth}(G')$ , the pebbling

$$P = \mathsf{RRGenPeb}(G, d_0, \{(e_1, d_1, S_1)\}, B)$$

is a legal parallel reversible pebbling of G, where  $S_1$  is a depth-reducing set of size  $e_1$ .

Now we bound the CC of P. The argument is a straightforward accounting of 1) the CC contributions of the light phases and 2) the CC of the B called  $\frac{2e_1}{N}$  times. The proof is left to Appendix C.

**Lemma 4.** For any  $(e_1, d_1)$ -depth reducible DAG G = (V = [N], E) of depth  $d_0$ , target set  $T' \subseteq [N]$ , and family of pebblings B(G', T', t') for all DAGs G' = (V', E'), target sets  $T' \subseteq V'$ , and  $t' \geq 2 \cdot \operatorname{depth}(G')$ ,

$$\begin{split} \Pi_{cc} \left( \mathsf{RRGenPeb}(G, d_0, \{(e_1, d_1, S_1)\}, B) \right) \\ & \leq 4d_0(\delta + 2)e_1 + 4d_0|T| + \frac{2e_1}{N} \cdot \max_{|T'| \leq \delta e_1} \Pi_{cc} \left( B \left( G - S, T', 2d_1 \right) \right), \end{split}$$

where  $S_1$  is a depth-reducing set of size  $e_1$ .

By replacing B with a CC-optimal pebblings, we obtain Theorem 8.

**Theorem 8.** Let G = (V = [N], E) be an  $(e_1, d_1)$ -depth robust graph with depth  $d_0$ , then

$$\Pi_{cc}^{\leftrightarrow,\parallel}(G,T,4d_0) \le 4d_0(\delta+2)e_1 + 4d_0|T| + \frac{2e_1}{N} \cdot \max_{|T'| \le \delta e_1} \Pi_{cc} \left(G - S, T', 2d_1\right)$$

Now we will apply our theorem on graphs that are  $(e_i, d_i)$ -depth reducible for more than two values of *i*. It will be useful to employ a more general notion of depth-reducibility.

**Definition 6** (*f*-reducibility, [ABP17]). Let G = (V, E) be a DAG with N nodes and let  $f : \mathbb{N} \to \mathbb{N}$  be a function. We say that G is *f*-reducible if for every positive integer  $0 < d \leq N$ , G is (f(d), d)-depth reducible.

Next, we show that if g is f-reducible and decreasing slowly enough in d, then we can apply Theorem 8 recursively to obtain better Reversible CC upper bounds. The proof of this lemma follows almost exactly as the analogous theorem in [ABP17], so the proof is left in Appendix B.

**Lemma 5.** Let G be an f-reducible DAG of depth on N nodes then if  $f(d) = \widetilde{\mathcal{O}}\left(\frac{N}{d^b}\right)$  for some constant  $0 < b \leq 2/3$  and let  $a = \frac{1-2b+\sqrt{1+4b^2}}{2}$ . Then for any constant  $\varepsilon > 0$ ,  $\Pi_{cc}^{\leftrightarrow,\parallel}(G) \leq \mathcal{O}\left(\delta N^{1+a+\epsilon}\right)$ .

It turns out that many graphs of interest are f-reducible as required in the above lemma. In particular, we examine:

(1) Argon2i won the 2015 Password Hashing Competition. We use Argon2iB to refer to the current version and we use Argon2iA is Argon2's original edge distribution (uniform) and Argon2iB to refer to the current (non-uniform) edge distribution [BDK16].

- (2) Balloon Hash is a prominent memory-hard function introduced by [BCS16]. We examine the single buffer (SB) graph  $SB_N$  and the double buffer and linear graphs  $Lin_{\tau}^{\sigma}$  on  $N = \sigma \cdot \tau$  nodes as defined in [ABP17].
- (3) Catena was a finalist in the 2015 Password Hashing Competition [FLW13]. We examine Catena graphs  $\mathsf{DFG}_{\lambda}^{N}$  and  $\mathsf{BFG}_{\lambda}^{N}$  as defined in [ABP17].

Lemma 6 ([ABP17], [BZ17]). Let  $f_b(d) = \widetilde{\mathcal{O}}\left(\frac{N}{d^b}\right)$ , then

- (1) With high probability, Argon2i-A<sub>N</sub> is  $f_{0.5}$ -reducible.
- (2) With high probability, Argon2i-B<sub>N</sub> is  $f_{1/3}$ -reducible.
- (3) With high probability,  $SB_N$  is  $f_{0.5}$ -reducible.
- (4) The Balloon Hashing (Linear and Double Buffer (DB)) graph  $\operatorname{Lin}_{\tau}^{\sigma}$  is  $f_1$ -reducible for  $\tau = \mathcal{O}(\operatorname{polylog}(N))$ .
- (5) The Catena Double Butter are both  $f_1$ -reducible for  $\lambda = \mathcal{O}(\operatorname{polylog}(N))$ .

Now we can put these results together to upper bound the reversible CC of graph underlying MHFs.

**Corollary 3.** We have the following:

 $\begin{array}{ll} (1) & \Pi_{cc}^{\leftrightarrow,\parallel}(\operatorname{Argon2i-A}_{N}) = \mathcal{O}\left(N^{1.708}\right), \\ (2) & \Pi_{cc}^{\leftrightarrow,\parallel}(\operatorname{Argon2i-B}_{N}) = \mathcal{O}\left(N^{1.768}\right), \\ (3) & \Pi_{cc}^{\leftrightarrow,\parallel}(\operatorname{SB}_{N}) = \mathcal{O}\left(N^{1.708}\right), \\ (4) & \Pi_{cc}^{\leftrightarrow,\parallel}\left(\operatorname{Lin}_{\tau}^{\sigma}\right) = \widetilde{\mathcal{O}}\left(N^{\frac{13}{8}}\right) = \widetilde{\mathcal{O}}\left(N^{1.625}\right), \text{ where the number of vertices is } N = \sigma\tau, \text{ and} \\ (5) & \Pi_{cc}^{\leftrightarrow,\parallel}(\operatorname{DFG}_{\lambda}^{N}), \Pi_{cc}^{\leftrightarrow,\parallel}\left(\operatorname{BFG}_{\lambda}^{N}\right) = \widetilde{\mathcal{O}}\left(N^{\frac{13}{8}}\right) = \widetilde{\mathcal{O}}\left(N^{1.625}\right). \end{array}$ 

# 5 Depth Robustness and Reversible CC

In this section, we improve the lower bound of reversible CC for a depth-robust DAGs. Alwen et al. [ABP17] proved the lower bound of classical CC of a DAG G given its depth-robustness. In particular, they showed that if G is (e, d)-depth robust then  $\Pi_{cc}^{\parallel}(G) \geq ed$ . This immediately implies the same lower bound for reversible CC as well since for any DAG G we have  $\Pi_{cc}^{\leftrightarrow,\parallel}(G) \geq$  $\Pi_{cc}^{\parallel}(G)$ . However, it was not known if there is a tighter lower bound for reversible CC in terms of depth-robustness. We provide a constant-factor (factor of  $\approx 2$ ) improvement on the lower bound of reversible CC when a DAG is depth-robust. Our main results are stated in Theorem 9 and Theorem 10.

We first consider a *non-relaxed* reversible pebbling, where we would require the condition that in the final round we have pebbles only on the sink nodes and pebbles from all of the intermediate nodes have been removed. Since removing pebbles is not free in a reversible pebbling and needs reversible pebbling steps, we can get a better lower bound for a reversible CC than a classical CC.

**Theorem 9.** If G is (e,d)-depth-robust DAG then  $\Pi_{cc}^{\leftrightarrow,\parallel}(G) \ge e(2d-1)$ . Furthermore, if G-sinks(G) is (e,d)-depth-robust then  $\Pi_{cc}^{\leftrightarrow,\parallel}(G) \ge 2ed$ .

*Proof.* Let  $P = (P_1, \ldots, P_t)$  be a parallel reversible pebbling for G such that  $\Pi_{cc}(P) = \Pi_{cc}^{\langle i \rangle, \parallel}(G)$ . We first consider the case that G is (e, d)-depth-robust.

We will show that there exists a set  $B \leq \frac{\prod_{cc}^{\leftrightarrow,\parallel}(G)}{2d-1}$  such that there is no path of length d in G - B, meaning G isn't  $\left(\frac{\prod_{cc}^{\leftrightarrow,\parallel}(G)}{2d-1}, d\right)$ -depth robust. If G is (e, d)-depth robust for some e, then it must be the case that  $e \leq \frac{\prod_{cc}^{\leftrightarrow,\parallel}(G)}{2d-1}$ , implying  $e(2d-1) \leq \prod_{cc}^{\leftrightarrow,\parallel}(G)$ . Let  $B_i = P_i \cup P_{i+2d-1} \cup P_{i+2(2d-1)} \cup \dots$  for  $i \in [2d-1]$  (defining  $P_j = \emptyset$  for j > t). Since

Let  $B_i = P_i \cup P_{i+2d-1} \cup P_{i+2(2d-1)} \cup \ldots$  for  $i \in [2d-1]$  (defining  $P_j = \emptyset$  for j > t). Since  $\sum_i |B_i| \leq \sum_j |P_j| = \prod_{cc}^{\leftrightarrow, \parallel}(G)$ , there exists some  $B \coloneqq B_i$  in which  $|B_i| \leq \frac{\prod_{cc}^{\leftrightarrow, \parallel}(G)}{2d-1}$ . Now we will show there is no path of length d in G - B. Let  $v_1, \ldots, v_d$  be a path in G and let

Now we will show there is no path of length d in G - B. Let  $v_1, \ldots, v_d$  be a path in G and let  $p(v_d)$  be the first step in which node  $v_d$  is pebbled. Let  $k < p(v_d)$  denote the last round before  $p(v_d)$  when we had no pebble on the entire path  $\{v_1, \ldots, v_d\}$ . Let  $p(v_i)$  denote the first step after round k where we place a pebble on node  $v_i$  (because  $v_1$  is the first node in our path we have  $p(v_1) = k + 1$ ). Then  $p(v_1) < p(v_2) < \cdots < p(v_d)$  by Item 2 of Definition 1. Now let  $u(v_i)$  denote the first round after round  $p(v_d)$  where we remove a pebble from node  $v_i$ . Observe we always have at least one pebble on our path  $v_1, \ldots, v_d$  in between rounds  $p(v_1)$  and  $u(v_1)$  inclusive. If  $v_d$  is a sink node that it is possible that  $u(v_d) = \infty$ . However, we are guaranteed that  $u(v_1) > u(v_2) > \cdots > u(v_{d-1})$  by Item 4 of Definition 1 and we also know that  $u(v_{d-1}) > p(v_d)$  since we needed to have a pebble on node  $v_{d-1}$  in round  $p(v_d) - 1$  and we are not allowed to simultaneously remove the pebble from node  $v_{d-1}$  while we are placing a pebble on node  $v_d$ .

This means that  $|\{i: p(v_1) \leq i \leq u(v_1)\}| \geq 2d - 1$ . It follows that there is some j such that  $p(v_1) \leq i + j(2d - 1) \leq u(v_1)$ . Since,  $|P_j \cap \{v_1, \ldots, v_d\}| \geq 1$  it follows that  $B_i$  contains at least one node on our path. Since every path of length d intersects with B, G is not  $\left(\frac{\prod_{cc}^{i \to i} |(G)|}{2d - 1}, d\right)$ -depth robust.

The argument is similar when we assume  $G - \operatorname{sinks}(G)$  is (e, d)-depth robust. We now define  $B_i = P_i \cup P_{i+2d} \cup P_{i+2(2d)} \cup P_{i+3(2d)} \dots$  for  $i \in [2d]$  (defining  $P_j = \emptyset$  for j > t). Similar to our above argument there exists some  $B = B_i$  such that  $|B_i| \leq \frac{\prod_{cc}^{\leftrightarrow,\parallel}(G)}{2d}$ . Now if  $v_1, \dots, v_d$  is a path of length d in  $G - \operatorname{sinks}(G)$  then  $v_d$  cannot be a sink node (by definition). We therefore have  $p(v_d) < u(v_d) < u(v_{d-1})$  and it follows that  $|\{i: p(v_1) \leq i \leq u(v_1)\}| \geq 2d$  since  $p(v_1) < p(v_2) < \dots p(v_d) < u(v_d) < \dots < u(v_1)$ . Therefore,  $B_i$  contains at least one node on our path since there exists some j such that  $p(v_1) \leq i + 2jd \leq u(v_1)$ . Since every path of length d in  $G - \operatorname{sinks}(G)$  intersects with B it follows that  $G - \operatorname{sinks}(G)$  is not  $\left(\frac{\prod_{cc}^{\leftrightarrow,\parallel}(G)}{2d}, d\right)$ -depth robust. Since  $G - \operatorname{sinks}(G)$  is (e, d)-depth robust it follows that  $\prod_{cc}^{\leftarrow,\parallel}(G) \geq 2ed$ .

On the other hand, Theorem 9 is not directly applicable to the relaxed reversible pebbling since it is not necessary to unpebble intermediate nodes. Considering that unpebbling is the reverse of pebbling, it is tempting to suggest that the reversible CC of relaxed pebbling might be approximately half that of non-relaxed pebbling. However, we can indeed derive a similar lower bound to the non-relaxed setting for depth-robust graphs. Oversimplifying a bit, a main bottleneck why the proof of Theorem 9 does not apply to the relaxed reversible pebbling is that there might be a possibility of having a path of length longer than d in G - B if  $N \equiv s \mod 2d$  with s > d where N is the number of nodes in G. We can resolve this issue by truncating last d nodes from the graph. Given a DAG G = (V = [N], E), we define  $G_{\text{Trunc},d} \coloneqq G - [N - d + 1, N]$  to be a DAG which truncates last d nodes and incident edges from G. Then we have the following theorem. The proof of Theorem 10 and analysis of the relaxed reversible CC of DRSample [ABH17] can be found in Appendix D.

**Theorem 10.** Let G = (V = [N], E) be a DAG such that  $(i, i+1) \in E$  for all i < N and the graph  $G_{\mathsf{Trunc},d}$  is (e, d)-depth robust. Then  $\widetilde{\Pi}_{cc}^{\longleftrightarrow,\parallel}(G) \ge e(2d-1)$ .

## 6 Approximation Hardness of Reversible CC

In this section, we establish the Unique Games Hardness of approximating  $\Pi_{cc}^{\leftrightarrow,\parallel}(G)$  within any constant factor in the worst-case scenario. Our main result is stated in Theorem 11.

**Theorem 11.** Given a DAG G with constant indegree, it is Unique Games hard to approximate  $\Pi_{cc}^{\leftrightarrow,\parallel}(G)$  within any constant factor.

Our findings extend the previously demonstrated approximation hardness result for classical cumulative pebbling complexity by Blocki et al. [BLZ20] who showed that given a DAG G with constant indegree, it is Unique Games hard to approximate  $\Pi_{cc}^{\parallel}(G)$  within any constant factor. To prove this Blocki et al. [BLZ20] first extended a result of Svensson [Sve12] to show that given a constant indegree DAG G it is unique games hard to distinguish between the case where (1) G is  $(e_1, d_1)$ -reducible with  $e_1 = N^{1/(1+2\varepsilon)}/k$  and  $d_1 = kN^{2\varepsilon/(1+2\varepsilon)}$  (i.e., depth-reducible with relatively small  $e_1$  and  $d_1$ ), and (2) G is  $(d_2, e_2)$ -depth robust with  $e_2 = (1 - \varepsilon)N^{1/(1+2\varepsilon)}$  and  $d_2 = 0.9N^{(1+\varepsilon)/(1+2\varepsilon)}$ , for any constant  $\varepsilon > 0$  (i.e., depth-robust with even large  $e_2$  and  $d_2$  when  $\varepsilon$  is small)<sup>4</sup> To establish the Unique Games Hardness of  $\Pi_{cc}^{\parallel}(G)$  Blocki et al. [BLZ20] introduced the notion of a superconcentrator overlay superconc(G) constructed by overlaying G on the sources of a superconcentrator and overlaying a line graph on the sinks. They proved that if G was  $(e_2, d_2)$ -depth robust that  $\Pi_{cc}^{\parallel}(G) \geq \min\{\frac{e_2N}{8}, \frac{d_2N}{8}\} \geq \frac{e_2N}{8} = \frac{1-\varepsilon}{8}N^{\frac{2+2\varepsilon}{1+2\varepsilon}}$  and that if G was  $(e_1, d_1)$ -depth robust that  $\Pi_{cc}^{\parallel}(G) \leq 7e_1N = \frac{7}{k}N^{\frac{2+2\varepsilon}{1+2\varepsilon}}$ . Since we instantiate k with any constant value it follows that it is unique games hard to approximate  $\Pi_{cc}^{\parallel}(G)$  even for a constant indegree DAG G.

Since any reversible pebbling of G is also a legal black pebbling of G the lower bound  $\Pi_{cc}^{\parallel}(G) \geq \frac{1-\varepsilon}{8}N^{\frac{2+2\varepsilon}{1+2\varepsilon}}$  immediately extends to reversible pebbling. Our contribution is to verify that the pebbling attack of [BLZ20] on superconc(G) for an  $(e_1, d_1)$ -reducible DAG G can be converted into a reversible pebbling attack without a significant cost increase. The pebbling attack of Blocki et al. [BLZ20] is similar in spirit to the depth-reducing pebbling attacks of [AB16] with several optimizations specific to the supercontrator overlay superconc(G). If they had used the pebbling attacks of [AB16] in a black-box manner then we would have been able to immediately apply the reversible version of these attacks from [BHL22] to obtain a similar upper bound in the reversible setting. Unfortunately, the optimizations specific to superconc(G) were necessary to obtain a gap to establish unique games hardness. Thus, we still need to outline the reversible version of the optimized pebbling attack for superconc(G). See Appendix A for details.

<sup>&</sup>lt;sup>4</sup> [Sve12] proved that it is unique games hard to distinguish a DAG G that is  $(e_1, d_1)$ -reducible and  $(e_2, d_2)$ -depth robust for parameters  $d_1 \ll d_2$  and  $e_1 \gg e_2$ . However, the graph he constructed in his reduction did not have constant indegree. Blocki et al. [BLZ20] provided a gadget to reduce the indegree while preserving unique games hardness.

# A Approximation Hardness of Reversible CC

We begin by reviewing the approximation hardness of classical CC and subsequently delve into the challenges of extending this result to reversible CC in a black-box manner. We then provide a technique to overcome the challenge by extending the reversible pebbling strategy from previous work [BHL22].

#### A.1 Review: Approximation Hardness of Classical CC

Blocki et al. [BLZ20] showed that given a DAG G with constant indegree, it is Unique Games hard to approximate  $\Pi_{cc}^{\parallel}(G)$  within any constant factor. Basically, the intuition is that the depth-robustness of G is both necessary [AB16] and sufficient [ABP17] condition for computing  $\Pi_{cc}^{\parallel}(G)$  as the upper and lower bound of  $\Pi_{cc}^{\parallel}(G)$  are given as follows: for any (e, d)-reducible DAG G with N nodes and indegree indeg(G),  $\Pi_{cc}^{\parallel}(G) \leq \min_{g \geq d}(eN + gN \cdot \text{indeg}(G) + N^2 d/g)$  [AB16], and for any (e, d)-depth robust DAG G,  $\Pi_{cc}^{\parallel}(G) \geq ed$  [ABP17]. Then they showed that assuming that the Unique Games Conjecture is that to distinguish between the cases where (1) G is  $(e_1, d_1)$ -reducible with  $e_1 = N^{1/(1+2\varepsilon)}/k$  and  $d_1 = kN^{2\varepsilon/(1+2\varepsilon)}$  (i.e., depth-reducible with relatively small  $e_1$  and  $d_1$ ), and (2) G is  $(d_2, e_2)$ -depth robust with  $e_2 = (1-\varepsilon)N^{1/(1+2\varepsilon)}$  and  $d_2 = 0.9N^{(1+\varepsilon)/(1+2\varepsilon)}$ , for any constant  $\varepsilon > 0$  (i.e., depth-robust with even large  $e_2$  and  $d_2$  when  $\varepsilon$  is small). The approximation hardness of  $\Pi_{cc}^{\parallel}(G)$  can be proved by showing that there is a gap between the upper and lower bound of the classical pebbling complexity between the cases above.

To prove the argument, they presented the following technical ingredients:

- (1) The first technical ingredient is Svensson's result [Sve12]. Svensson showed that it is Unique Games hard to distinguish between the cases where a (layered) DAG G with N nodes is  $(e_1, d_1)$ reducible with  $e_1 = N/k$  and  $d_1 = k$  and G is  $(e_2, d_2)$ -depth robust with  $e_2 = N(1 - 1/k)$  and  $d_2 = \Omega(N^{1-\varepsilon})$ . But scrutinizing further, Svensson's graph has high indegree, i.e., indeg $(G) = \mathcal{O}(N)$ , whereas we want to have constant indegree. Furthermore, we cannot directly apply Svensson's result to get the approximation hardness of  $\Pi_{cc}^{\parallel}(G)$  as there is no gap between the upper and lower bound of  $\Pi_{cc}^{\parallel}(G)$  when G is a Svensson's graph.
- (2) Therefore, we need to reduce the indegree of the graph, but we also want to not lose the connectivity of Svensson's graph between each layer too much as we still want to have the Unique Games hardness result to distinguish between depth-reducible and depth-robust cases. This is where a  $\gamma$ -extreme depth-robust graph comes into play. A DAG G is said to be  $\gamma$ -extreme depth-robust if it is (e, d)-depth robust for any e, d > 0 such that  $e + d \leq (1 \gamma)N$ . By overlaying Svensson's graph on a  $\gamma$ -extreme depth-robust graph, i.e., only keeping edges from layer i to layer j in Svensson's graph if there is an edge from node i to j in the  $\gamma$ -extreme depth-robust graph, we can reduce the indegree from  $\mathcal{O}(N)$  to  $\mathcal{O}(N^{\varepsilon} \log^2 N)$ . Furthermore, by applying indegree reduction gadget from Blocki et al. [ABP17], they proved that it is Unique Games hard to distinguish between the cases where a constant-indegree DAG G is  $(e_1, d_1)$ -reducible with  $e_1 = N^{1/(1+2\varepsilon)}/k$  and  $d_1 = kN^{2\varepsilon/(1+2\varepsilon)}$  and  $(e_2, d_2)$ -depth robust with  $e_2 = (1-\varepsilon)N^{1/(1+2\varepsilon)}$  and  $d_2 = 0.9N^{(1+\varepsilon)/(1+2\varepsilon)}$ . However, there is still no gap between the classical pebbling complexity of the two cases.
- (3) To remedy the no-gap situation above, they used the superconcentrator overlay that was introduced by Blocki et al. [BHK<sup>+</sup>19], which is a graph denoted by superconc(G) that can be

constructed by overlaying a DAG G with N nodes with a superconcentrator [Pip77] with N input/output nodes. It gives a stronger lower bound  $\Pi_{cc}^{\parallel}(\operatorname{superconc}(G)) \geq \max\{eN, dN\}/8$  for CC and an improved pebbling strategy gives an improved upper bound, through which we can finally yield a gap between the upper and lower bound of the classical pebbling complexity of the superconcentrator overlay graph.

To summarize, Blocki et al. [BLZ20] made the worst-case analysis for the approximation hardness of the classical pebbling complexity by constructing a graph — the superconcentrator overlay of an indegree-reduced version (with  $\gamma$ -extreme depth-robust overlay) of Svensson's graph — that has a gap between the upper and lower bound of the classical pebbling complexity. The main result of the work can be presented as the following theorem.

**Theorem 12** ([BLZ20]). Given a DAG G with constant indegree, it is Unique Games hard to c-approximate  $\prod_{cc}^{\parallel}(G)$  for any constant c > 1.

# A.2 Computing Reversible CC is Also Unique Games Hard

A natural follow-up question is whether we can have the same approximation hardness result for *reversible* cumulative pebbling complexity. It is not a trivial black-box application of the prior work [BLZ20] since some of the pebbling strategies that were used in the prior analysis are inherently irreversible. For example, the improved strategy in Blocki et al. [BLZ20] when analyzing the upper bound of CC of the superconcentrator overlay graph, it runs multiple light and balloon phases [AB16]. At the end of each balloon phase, we discard all the unnecessary pebbles at once before running the next light phase, which is an irreversible pebbling transition.

Blocki et al. [BHL22] gave a reversible pebbling strategy which takes a light phase-balloon phase pebbling attack by Alwen and Blocki [AB16] and made it reversible. In particular, they showed the upper bound of  $\Pi_{cc}^{\leftrightarrow,\parallel}(G)$  when G is (e, d)-reducible.

**Theorem 13** ([BHL22, Theorem 4]). For any (e, d)-reducible DAG G with N nodes,

$$\Pi_{cc}^{\Longleftrightarrow,\parallel}(G) \leq \min_{g \geq d} \left\{ 2N\left(\frac{2Nd}{g} + e + 3g\right) + N + \frac{2Nd}{g} \right\}.$$

One might be tempted to adopt this strategy in a black-box manner and apply this upper bound with  $\operatorname{superconc}(G)$  to create a gap between the upper and lower bound of  $\Pi_{cc}^{\leftrightarrow,\parallel}(\operatorname{superconc}(G))$ . However, we cannot directly apply Theorem 13 to yield a gap between the upper and lower bound of  $\Pi_{cc}^{\leftrightarrow,\parallel}(\operatorname{superconc}(G))$ . First, we observe that  $\operatorname{superconc}(G)$  is  $(e + N/d, 2d + 4\log N)$ -reducible whenever G is (e, d)-reducible. This implies that  $\Pi_{cc}^{\leftrightarrow,\parallel}(\operatorname{superconc}(G)) = \mathcal{O}\left(N^{\frac{2+3\varepsilon}{1+2\varepsilon}}\right)$  when we apply Theorem 13 with an (e', d')-reducible DAG  $\operatorname{superconc}(G)$  where  $e' = e + N/d, d' = 2d + 4\log N$  and  $e = \frac{1}{k}N^{\frac{1}{1+2\varepsilon}}, d = kN^{\frac{2\varepsilon}{1+2\varepsilon}}$ . If we apply the lower bound  $\Pi_{cc}^{\leftrightarrow,\parallel}(\operatorname{superconc}(G)) \ge \min\left\{\frac{e'N}{8}, \frac{d'N}{8}\right\}$  [BHK<sup>+</sup>19, Theorem 9] as the same lower bound carries over to the reversible CC, we have that  $\Pi_{cc}^{\leftarrow,\parallel}(\operatorname{superconc}(G)) \ge \Omega(N^{\frac{2+2\varepsilon}{1+2\varepsilon}})$ , which implies that there is no gap between the upper and lower bound of  $\Pi_{cc}^{\leftarrow,\parallel}(\operatorname{superconc}(G))$ .

Therefore, we should open the black box and update the improved pebbling strategy from the prior work [BLZ20]. This can be done by substituting the classical pebbling strategy [AB16] to pebble all the input nodes with the reversible one [BLZ20]. We remark that this replacement would additionally require updating the light and balloon phases accordingly.

**Lemma 7** ([Pip77]). There exists a superconcentrator G with at most 7N vertices, containing N input vertices and N output vertices, such that  $indeg(G) \leq 9$  and  $depth(G) \leq 4 \log N$ .

**Lemma 8.** Let G be an (e, d)-reducible DAG with N nodes with indeg(G) = 2. Then

$$\begin{split} \Pi_{cc}^{\longleftrightarrow,\parallel}(\operatorname{superconc}(G)) &\leq \min_{g \geq d} \left\{ 3eN + 13gN + \frac{(25d+1)N^2}{g} + \frac{2Nd}{g} + 28N \log N + \frac{84N^2 \log N}{g} + 2N \right\}. \end{split}$$

*Proof.* We give a *reversible* pebbling strategy for the superconcentrator overlay graph  $G' = \operatorname{superconc}(G)$ :

**Reversible Pebbling Strategy for**  $G' = \operatorname{superconc}(G)$ :

- 1. Pebble all the input nodes input(G') = G using the reversible pebbling strategy from Blocki et al. [BHL22].
- 2. Efficiently pebble interior(G') using the property of superconcentrator, i.e., superconc(G) with N input/output nodes has depth at most 4 log N. At the end of Step 2, remove pebbles by running a reversible monotonic pebbling sequence to the precondition for each light phase.
- 3. Pebble all nodes in  $\mathsf{output}(G')$  by alternating between light and balloon phases.
  - Light Phase: Walk pebble across the interval I<sub>i</sub> = [o<sub>(i-1)g+1</sub>, o<sub>ig</sub>] in O(g) steps.
     Precondition: pebbles on parents(o<sub>(i-1)g+1</sub>) ∪ (parents(I<sub>i</sub>) \ I<sub>i</sub>) ∪ S<sub>≤o<sub>(i-1)g</sub></sub>
     Postcondition: pebbles on {o<sub>ig</sub>} ∪ S
  - Balloon Phase: Recover all the missing pebbles in  $input(G') \cup interior(G')$  for the upcoming light phase.
    - Precondition: publies on  $\{o_{iq+1}\} \cup S$
    - Midcondition: pebbles on  $\{o_{ig+1}\} \cup input(G') \cup interior(G')$
    - Postcondition: publes on  $parents(o_{ig+1}) \cup (parents(I_{i+1}) \setminus I_{i+1}) \cup S$

Analysis. We will examine the cumulative pebbling complexity of  $G' = \operatorname{superconc}(G)$  for each step above.

1. We need to pebble all the input nodes input(G') = G using the reversible pebbling strategy from Blocki et al. [BHL22], which will be upper bounded by

$$\varPi_{cc}^{\Longleftrightarrow,\parallel}(G) \leq \min_{g \geq d} \left\{ 2N\left(\frac{2Nd}{g} + e + 3g\right) + N + \frac{2Nd}{g} \right\},$$

followed by [BHL22, Theorem 4]. We remark that the difference here is that while [BHL22, Theorem 4] denotes the reversible pebbling cost to pebble the last node of G only, we need to pebble all nodes in G. However, we observe that we can recover pebbles on all nodes by running one extra balloon phase concurrently and such cost is already contained in  $4N^2d/g+N+2Nd/g$ . Hence, we have the same upper bound with  $\Pi_{cc}^{\leftrightarrow,\parallel}(G)$ .

2. When we start with having pebbles on all nodes in input(G') = G, since superconc(G) has depth at most  $4 \log N$ , we can pebble all nodes in interior(G') with CC at most  $7N \cdot 4 \log N = 28N \log N$ . Next, we would need to remove pebbles by running a reversible monotonic pebbling sequence to the precondition for each light phase. However, we can observe that the CC of this procedure

is exactly the same as the CC of pebbling rounds starting from the precondition of each light phase to  $\mathsf{input}(G') \cup \mathsf{interior}(G')$ . This is contained in running one extra balloon phase (from midcondition to postcondition), which is going to be at most  $(d + 4 \log N)7N \cdot N/g$  by the analysis of Step 3 below.

3. In this step, we would like to walk a pebble across the output nodes from  $o_1$  to  $o_N$ . To save cost during this step, we should alternate light phases and balloon phases repeatedly N/g times in total as we split the output nodes into intervals  $I_i = [o_{(i-1)g+1}, o_{ig}]$  of size g each. Let S be a (e, d)-depth-reducing set for G. In each light phase, to walk a pebble across the interval  $I_i$ , we would need to keep pebbles on S and parents $(I_i) \setminus I_i$ . Since each node in  $I_i$  has at most 7 parents and we keep one pebble in  $I_i$  (the current node) for each step, the maximum number of pebbles to keep would be |S| + 7g + 1 + N/g = e + 7g + 1 + N/g for each step. So far, the maximum pebbling cost to reach the last node in  $I_i$  is (e + 7g + 1)g + N. After placing a pebble on the last node  $o_{ig}$  in  $I_i$ , we would need to discard unnecessary pebbles and prepare for the next light phase as well by running a balloon phase. Since S is a (e, d)-depth-reducing set, we have that depth $(G' \setminus (S \cup \text{output}(G'))) \leq d + 4 \log N$  (see Figure 2). Hence, for each balloon phase, we have reversible pebbling cost at most  $(d + 4 \log N)7N$ . Since we need to run balloon phase twice in each block, the total reversible pebbling cost for Step 3 will be at most  $[(e + 7g + 1)g + N + 2(d + 4 \log N)7N] \frac{N}{g}$ .

Taken together, we have

$$\begin{split} \Pi_{cc}^{\leftrightarrow \rightarrow, \parallel}(G') &\leq \min_{g \geq d} \left\{ 2N \left( \frac{2Nd}{g} + e + 3g \right) + N + \frac{2Nd}{g} + 28N \log N \\ &+ \left[ (e + 7g + 1)g + N + 3(d + 4\log N)7N \right] \frac{N}{g} \right\} \\ &\leq \min_{g \geq d} \left\{ 3eN + 13gN + \frac{(25d + 1)N^2}{g} + \frac{2Nd}{g} + 28N \log N \\ &+ \frac{84N^2 \log N}{g} + 2N \right\}, \end{split}$$

as desired.

**Reminder of Theorem 11.** Given a DAG G with constant indegree, it is Unique Games hard to approximate  $\Pi_{cc}^{\longleftrightarrow,\parallel}(G)$  within any constant factor.

*Proof.* Let  $k \geq 2$  be an integer that we shall later fix and  $\varepsilon > 0$  be a constant that we will later fix as well. Given a DAG G with N nodes, we know that it is Unique Games hard to distinguish between two cases where (1) G is  $(e_1, d_1)$ -reducible for  $e_1 = \frac{1}{k}N^{\frac{1}{1+2\varepsilon}}$  and  $d_1 = kN^{\frac{2\varepsilon}{1+2\varepsilon}}$ , and (2) G is  $(e_2, d_2)$ -depth robust for  $e_2 = (1 - \varepsilon)N^{\frac{1}{1+2\varepsilon}}$  and  $d_2 = 0.9N^{\frac{1+\varepsilon}{1+2\varepsilon}}$  [BLZ20]. If G is  $(e_1, d_1)$ -reducible, then by Lemma 8, for  $e_1 = \frac{1}{k}N^{\frac{1}{1+2\varepsilon}}$ , and  $g = e_1$ , we have

$$\begin{split} \Pi_{cc}^{\longleftrightarrow,\parallel}(\mathsf{superconc}(G)) &\leq \min_{g \geq d} \left\{ 3e_1N + 13gN + \frac{(25d_1 + 1)N^2}{g} + \frac{2Nd_1}{g} + 28N\log N + \frac{84N^2\log N}{g} + 2N \right\} \end{split}$$

Fig. 2: A reversible pebbling strategy for a superconcentrator overlay  $G' = \operatorname{superconc}(G)$ . By definition, we have  $\operatorname{input}(G') = G$ , and all the output nodes  $o_1, \ldots, o_N$  are overlayed by a line graph. We note that each input node has outdegree 6 that is connected to the interior of the superconcentrator, and each output node has indegree at most 7 (six from the interior and one from the prior output node) due to the superconcentrator construction by Pippenger [Pip77]. Here, orange nodes in the input nodes denote the depth-reducing set S of  $G = \operatorname{input}(G')$ . Then since we have that the depth of the superconcentrator is at most  $4 \log N$  and the graph G is (e, d)-depth reducible, we observe that  $\operatorname{depth}(G' \setminus (S \cup \operatorname{output}(G'))) \leq d + 4 \log N$ , which is illustrated by a green path above.

$$\leq 16e_1N + \underbrace{\frac{(25d_1+1)N^2}{e_1} + \frac{2Nd_1}{e_1} + 28N\log N + \frac{84N^2\log N}{e_1} + 2N}_{\ll e_1N}$$
  
$$\leq 17e_1N = \frac{17}{k}N^{\frac{2+2\varepsilon}{1+2\varepsilon}}.$$

On the other hand, if G is  $(e_2, d_2)$ -depth robust, then we have

$$\varPi_{cc}^{\longleftrightarrow,\parallel}(\mathsf{superconc}(G)) \geq \min\left\{\frac{e_2N}{8}, \frac{d_2N}{8}\right\}$$

by [BHK<sup>+</sup>19, Theorem 9]. We remark that since  $\Pi_{cc}^{\leftrightarrow,\parallel}(G) \geq \Pi_{cc}^{\parallel}(G)$  for any DAG G, the same lower bound for the superconcentrator overlay carries over to the reversible setting. In particular, since  $e_2 \ll d_2$ , we have

$$\varPi_{cc}^{\Longleftrightarrow,\parallel}(\operatorname{superconc}(G)) \geq \frac{e_2N}{8} = \frac{1-\varepsilon}{8}N^{\frac{2+2\varepsilon}{1+2\varepsilon}}$$

Let c > 1 be any constant. Setting  $\varepsilon = 0.1$  and  $k = \lceil \frac{1360}{9}c^2 \rceil$ , we get that if G is  $(e_1, d_1)$ -reducible, then  $\Pi_{cc}^{\longleftrightarrow,\parallel}(\operatorname{superconc}(G)) \leq \frac{9}{80c^2}N^{\frac{2+2\varepsilon}{1+2\varepsilon}}$  but if G is  $(e_2, d_2)$ -depth robust, then  $\Pi_{cc}^{\longleftrightarrow,\parallel}(\operatorname{superconc}(G)) \geq \frac{9}{80}N^{\frac{2+2\varepsilon}{1+2\varepsilon}}$ . Hence, it is Unique Games hard to approximate  $\Pi_{cc}^{\longleftrightarrow,\parallel}(G)$  with a factor of c.  $\Box$ 

# **B** Pebbling Composition

Bennett [Ben89] gave the following reversible pebbling strategy, whose analysis was improved by Li and Vitányi [LV96]. For a line graph on nodes  $[2^k - 1]$ , Bennett define the intervals  $I_j$  and nodes

 $i_j$  such that  $I_0 = \langle \rangle$  and

$$I_k = \langle I_{k-1}, i_{k-1}, \dots, I_0, i_0 \rangle.$$

Intuitively, the nodes in the recursive list  $I_k$  partitions  $[2^k - 1]$ , and the nodes appear from least to greatest. The interval  $I_1$  contains 1 node and the interval  $I_k$  contains twice the nodes of  $I_{k-1}$ , with one additional node  $i_{k-1}$ . That is, N(k) = 2N(k-1) + 1. Blocki, Holman, and Lee [BHL22] improved this pebbling by lowering the time cost at the expense of space. For a tunable parameter c, they pebble the line graph with  $N(c,k) = \Theta\left((c+1)^k\right)$ , by letting  $I_j^c = \left\langle I_j^{(1)}, i_j^{(1)}, \ldots, I_j^{(c)}, i_j^{(c)} \right\rangle$ , where each  $I_i^{(\ell)}$  is a copy of  $I_j$ . Finally,

$$I'_{k} = \left\langle I'_{k-1}, i'_{k-1}, \dots, I'_{0}, i'_{0} \right\rangle$$

where each  $i'_{j}$  is a single node, and the elements of [N(c, k)] occur in increasing order.

The pebbling  $P_c^k$  on the line graph  $\mathcal{L}_{N(c,k)}$  is defined as follows:

- (1) For  $j = k 1, \dots, 1$ : (a) Pebble  $I_j^{(1)}$  via  $P_1^j$ .

  - (b) Place a pebble on  $i_{k-1}^{(1)}$ .
  - (c) For  $\ell = 2, \dots, c$ : i. Unpebble  $I_{k-1}^{\ell-1}$  by reversing  $P_1^j$ . ii. Pebble  $I^{\ell}$  via  $P_1^j$ . iii. Place a pebble on  $i_i^{\ell}$ .

The end state of this pebbling has a pebble on node N(c, k), and we can run it in reverse to remove all pebbles. Choosing  $k = \sqrt{\log N}$  and  $c = 2^k$  leads to Theorem 5.

Theorem 5 (Reversible Line Graph Pebbling [BHL22]). There exist a family of sequential pebblings  $L_N$  and a family of parallel reversible pebblings  $L_N^{\parallel}$  for line graphs  $\mathcal{L}_N$  such that

$$\begin{array}{l} (1) \ \Pi_t\left(L_N\right) = \mathcal{O}\left(N^{1+\frac{1}{\sqrt{\log N}}}\right), \Pi_s\left(L_N\right) = \mathcal{O}\left(N^{\frac{1}{\sqrt{\log N}}}\sqrt{\log N}\right), \Pi_{st}\left(L_N\right), \Pi_{cc}\left(L_N\right) = \mathcal{O}\left(N^{1+\frac{2}{\sqrt{\log N}}}\sqrt{\log N}\right), \\ and \ \operatorname{toggle}(L_N) = \mathcal{O}\left(N^{\frac{1}{\sqrt{\log N}}}\right), and \\ (2) \ \Pi_t\left(L_N^{\parallel}\right) = \mathcal{O}\left(N\right), \ \Pi_s\left(L_N^{\parallel}\right) = \mathcal{O}\left(N^{\frac{2}{\sqrt{\log N}}}\right), \ \Pi_{st}\left(L_N^{\parallel}\right), \Pi_{cc}\left(L_N^{\parallel}\right) = \mathcal{O}\left(N^{1+\frac{2}{\sqrt{\log N}}}\right), and \\ \operatorname{toggle}(L_N^{\parallel}) = \mathcal{O}\left(N^{\frac{1}{\sqrt{\log N}}}\right). \end{array}$$

*Proof.* Let  $k = \sqrt{\log N}$  and  $c = 2^k$ . We'll prove the claims unproven in [BHL22]:

- (Time Complexity)  $\Pi_t \left( L_N^{\parallel} \right) = O(N)$ : [BHL22] show that  $\Pi_t \left( L_N^{\parallel} \right) = O\left( (c+2)^k \right) =$  $O\left((c+2)^k\right) = O(N).$
- (Toggle Number) Notice that if we pebble or unpebble any node at most t times in  $I'_i$ , then we pebble or unpebble any node in  $I'_{j+1}$  at most 2t times. The nodes in  $I'_0$  are pebbled once and unpebbled once, so  $\mathsf{toggle}(L_N) \leq 2^{k+1}$ .

**Theorem 4** (Reversible Composition Pebbling). Let  $P = (P_1, \ldots, P_t)$  be a (possibly irreversible) pebbling for a DAG G, and  $L = (L_1, \ldots, L_{t'})$  be a reversible pebbling for  $\mathcal{L}_N$ . Then the composition  $L \circ P$  is a legal reversible pebbling of G satisfying  $\Pi_{st}(Q) \leq \Pi_s(P) \cdot \Pi_{st}(L)$ .

*Proof.* Consider the transition between two configurations  $Q_i$  and  $Q_{i+1}$ :

- (Property 1, Empty Start) This follows from the fact that L and P start with out any pebbles on the graph.
- (Property 2, Placing Pebbles) We have

$$\mathsf{parents}(Q_{i+1} \setminus Q_i, G) = \mathsf{parents}\left(\bigcup_{j \in L_{i+1}} P_j \setminus \bigcup_{k \in L_i} P_k, G\right) \tag{1}$$

$$\subseteq \mathsf{parents}\left(\bigcup_{j\in L_{i+1}\setminus L_i} P_j\setminus P_{j-1}, G\right) \tag{2}$$

$$\subseteq \bigcup_{j \in L_{i+1} \setminus L_i} \operatorname{parents} \left( P_j \setminus P_{j-1}, G \right)$$
(3)

$$\subseteq \bigcup_{j \in L_{i+1} \setminus L_i} P_{j-1} \tag{4}$$

$$= \bigcup_{k \in \mathsf{parents}(L_{i+1} \setminus L_i, \mathcal{L}_{t'})} P_k \tag{5}$$

$$\subseteq \bigcup_{k \in L_i} P_k \tag{6}$$

$$=Q_i \tag{7}$$

Eq. (21) follows by the reversibility of  $\mathcal{L}_{t'}$ .

- (Property 3, No Deletion) We have

parents 
$$(Q_i \setminus Q_{i+1}, G) = \text{parents} \left( \bigcup_{j \in L_i} P_j \setminus \bigcup_{k \in L_{i+1}} P_k, G \right)$$
 (8)

$$= \operatorname{parents}\left(\bigcup_{j \in L_i \setminus L_{i+1}} P_j \setminus \bigcup_{k \in L_{i+1}} P_k, G\right)$$
(9)

$$\subseteq \mathsf{parents}\left(\bigcup_{j\in L_i\setminus L_{i+1}} P_j\setminus P_{j-1}, G\right) \tag{10}$$

$$= \bigcup_{j \in L_i \setminus L_{i+1}} \operatorname{parents} \left( P_j \setminus P_{j-1}, G \right)$$
(11)

$$\subseteq \bigcup_{j \in L_i \setminus L_{i+1}} P_{j-1} \tag{12}$$

$$= \bigcup_{k \in \mathsf{parents}(L_i \setminus L_{i+1}, \mathcal{L}_{t'})} P_k \tag{13}$$

$$\subseteq \bigcup_{k \in L_i} P_k \tag{14}$$

$$=Q_i \tag{15}$$

In Eq. (9) we see that for any  $i \in L_i$ , if *i* is also in  $L_{i+1}$ , then  $P_j \setminus \bigcup_{k \in L_{i+1}} P_k = \emptyset$ . Eq. (10) follows from the fact that *L* is reversible, so if *j* was deleted on step i + 1, then the parents of *j* (which is just j - 1) must be kept around on step i + 1. Eq. (12) follows since *P* is a legal pebbling. Since  $\mathcal{L}_{t'}$  is a line graph,  $\mathsf{parents}(\{j\}, \mathcal{L}_{t'}) = \{j - 1\}$ . Finally, Eq. (14) follows from the no deletion property of *L*.

- (Property 4, Reversibility) We have

$$\mathsf{parents}(Q_{i+1} \setminus Q_i, G) = \mathsf{parents}\left(\bigcup_{j \in L_{i+1}} P_j \setminus \bigcup_{k \in L_i} P_k, G\right)$$
(16)

$$\subseteq \mathsf{parents}\left(\bigcup_{j\in L_{i+1}\setminus L_i} P_j \setminus P_{j-1}, G\right) \tag{17}$$

$$\subseteq \bigcup_{j \in L_{i+1} \setminus L_i} \operatorname{parents} \left( P_j \setminus P_{j-1}, G \right)$$
(18)

$$\subseteq \bigcup_{i \in L_{i+1} \setminus L_i} P_{j-1} \tag{19}$$

$$= \bigcup_{k \in \mathsf{parents}(L_{i+1} \setminus L_i, \mathcal{L}_{t'})} P_k \tag{20}$$

$$\subseteq \bigcup_{k \in L_{i+1}} P_k \tag{21}$$

$$=Q_{i+1}.$$
(22)

Here, each step follows for the same reasoning as before, except Eq. (21) follows by the reversibility of  $\mathcal{L}_{t'}$ . Likewise, we have

$$\mathsf{parents}\left(Q_i \setminus Q_{i+1}, G\right) \subseteq \bigcup_{k \in \mathsf{parents}\left(L_i \setminus L_{i+1}\right), \mathcal{L}_{t'}} P_k \tag{23}$$

$$\subseteq \bigcup_{k \in L_i} P_k \tag{24}$$

$$=Q_i,$$
 (25)

where Eq. (24) comes from Eq. (13), and Eq. (25) follows from the reversibility of L. (Denote  $\mathbf{F}_{\mathbf{r}}$  Channel )  $\mathbf{C}_{\mathbf{r}}$  (13),  $\mathbf{C}_{\mathbf{r}}$  (25) follows from the reversibility of L.

- (Property 5, Cleanup) Since  $L_{t'} = \{t\}, Q_{t'} = P_t = \operatorname{sinks}(G)$ .

Now we examine the space-time cost of Q. We have

$$\Pi_s(Q) \le \Pi_s(P) \cdot \Pi_s(L)$$

since Q has publies on at most  $\Pi_s(L)$  publing configurations of P, each of which have space at most  $\Pi_s(P)$ . Since  $\Pi_t(Q) = \Pi_t(L)$ , we have

$$\Pi_{st}(Q) = \Pi_s(P) \cdot \Pi_s(L) \cdot \Pi_t(L).$$

**Lemma 5.** Let G be an f-reducible DAG of depth on N nodes then if  $f(d) = \widetilde{\mathcal{O}}\left(\frac{N}{d^b}\right)$  for some constant  $0 < b \leq 2/3$  and let  $a = \frac{1-2b+\sqrt{1+4b^2}}{2}$ . Then for any constant  $\varepsilon > 0$ ,  $\Pi_{cc}^{\leftrightarrow,\parallel}(G) \leq \mathcal{O}\left(\delta N^{1+a+\epsilon}\right)$ .

Proof. Let  $d_0 = \operatorname{depth}(G)$ . Alwen et al. [ABP17] show that such a graph is  $(e_i, d_i)$  reducible for  $e_i = N^{a_i + \varepsilon/3}$  with depth-reducing sets  $S_i$  of size  $e_i$  and  $d_i \leq N^{\frac{1-a_i}{b}}$  for each i > 0. They also observe that  $d_{i+1}N \leq e_{i+1}d_i/2$  for all i > 1, and for any  $\varepsilon$ , there exists a constant k such that  $d_k \leq N^{\varepsilon/3}$ . Let

$$C_{i} = \max_{|T'| \le \delta e_{1}} \Pi_{cc}^{\longleftrightarrow,\parallel} \left( G - S_{i}, T', 2d_{1} \right)$$

We can now apply Theorem 8 recursively. Then we have

$$\begin{aligned} \Pi_{cc}^{\leftrightarrow,\parallel}(G, \{N\}, 4d_0) &\leq 4k(\delta+2)N^{1+a+\varepsilon/2} + 4d_0 + N^{a+\varepsilon/3}C_i \\ &\leq 4k(\delta+2)N^{1+a+\varepsilon/2} + 4d_0 + N^{a+\varepsilon/3}\left(2Nd_k\right) \\ &\leq 4k(\delta+2)N^{1+a+\varepsilon/2} + 4d_0 + N^{a+\varepsilon/3}\left(N^{1+\varepsilon/3}\right) \\ &= O\left(\delta N^{1+a+\varepsilon}\right). \end{aligned}$$

**Corollary 2.** If  $P = (P_1, \ldots, P_t)$  is a sequential pebbling of a DAG G and L is a reversible sequential pebbling of  $\mathcal{L}_t$ , then  $L \circ P$  is a reversible sequential pebbling of G.

*Proof.* Let  $Q = L \circ P$ . We have

$$\begin{aligned} |Q_{i+1} \setminus Q_i| &= \left| \bigcup_{j \in L_{i+1}} P_j \setminus \bigcup_{k \in L_i} P_k \right| \\ &= \left| \bigcup_{j \in L_{i+1} \setminus L_i} P_j \setminus \bigcup_{k \in L_i} P_k \right| \\ &\leq \left| \bigcup_{j \in L_{i+1} \setminus L_i} P_j \setminus P_{j-1} \right| \\ &\leq 1, \end{aligned}$$

since  $|L_{i+1} \setminus L_i| \leq 1$ .

**Lemma 2.** Define functions h, f, and g such that for any  $0 < c < \sqrt{2}$ ,  $h(N) = 2^{c\sqrt{\log N}}$ ,  $f(N) = N \cdot h(N)$ , and  $g(N) = 2f\left(\frac{N}{h(N)}\right) + f\left(N - \frac{N}{h(N)}\right)$ . There exists  $N_0 \ge 1$  such that  $f(N) \le g(N)$  for all  $N \ge N_0$ .

Proof of Lemma 2. Let  $h(N) = 2^{c\sqrt{\log N}}$ , so  $f(N) = N \cdot h(N)$  and g(N) = 2f(N/h(N)) + f(N/h(N)). It suffices to show

$$\lim_{N \to \infty} g(N) - f(N)$$

$$= \lim_{N \to \infty} N\left(h\left(N - \frac{N}{h(N)}\right) - h(N)\right) + \frac{N}{h(N)}\left(2h\left(\frac{N}{h(N)}\right) - h\left(N - \frac{N}{h(N)}\right)\right)$$

$$= \infty.$$

In particular, we show that h(N) - h(N - N/h(N)) = o(1) and  $2h(N/h(N)) - h(N - N/h(N)) = \Omega(1)$  for all  $0 < c < \sqrt{2}$ . First, we have

$$\lim_{N \to \infty} \sqrt{\log N} - \sqrt{\log N/h(N)} = \lim_{N \to \infty} \sqrt{\log N} - \sqrt{\log N} - c\sqrt{\log N}$$

$$= \lim_{x \to \infty} \sqrt{x} - \sqrt{x - c\sqrt{x}}$$
$$= \lim_{x \to \infty} \frac{c\sqrt{x}}{\sqrt{x} + \sqrt{x - c\sqrt{x}}}$$
$$= \frac{c}{2} \qquad \text{since } c = O(1).$$

Thus,  $h(N/h(N))/h(N) \ge 2^{-\frac{c^2}{2}-o(1)}$  for N sufficiently large. This means that  $\frac{N}{h(N)}(2h(N/h(N)) - h(N)) \ge N(2^{1-c^2/2-o(1)} - 1)$ , which is positive when  $c < \sqrt{2}$ . Next, We have

$$\lim_{N \to \infty} \sqrt{\log N} - \sqrt{\log(N - N/h(N))} = \lim_{N \to \infty} \sqrt{\log N} - \sqrt{\log N - \log\left(\frac{1}{1 - 1/h(N)}\right)}$$
$$= \sqrt{\log N} - \sqrt{\log N - 0},$$
$$= 0$$

meaning  $h(N - N/h(N))/h(N) \le 2^{-o(1)}$ . Thus

$$\lim_{N \to \infty} g(N) - f(N) = \lim_{N \to \infty} N(2^{1 - c^2/2 - o(1)} - o(1))$$
  
=  $\infty$  if  $0 < c < \sqrt{2}$ .

#### C Reversible Recursive Pebbling Attack

**Lemma 3.** For any  $(e_1, d_1)$ -depth reducible DAG G = (V = [N], E) of depth  $d_0$ , target set  $T' \subseteq [N]$ , and family of pebblings B(G', T', t') for all DAGs G' = (V', E'), target sets  $T' \subseteq V'$ , and  $t' \geq 2 \cdot \operatorname{depth}(G')$ , the pebbling

$$P = \mathsf{RRGenPeb}(G, d_0, \{(e_1, d_1, S_1)\}, B)$$

is a legal parallel reversible pebbling of G, where  $S_1$  is a depth-reducing set of size  $e_1$ .

Proof. Since  $g \ge 2d_1$ , each balloon phase is contained in the corresponding light phase. Next, since LightReq<sup>c</sup> is a reversible pebbling sequence and BalloonReq<sup>c</sup> is a reversible pebbling sequence, their union is as well. Now we will consider the transitions between phases. We have that BalloonReq<sup>c</sup><sub>2g</sub> = parents $(I_{c+1})\setminus I_{c+1}$  and LightReq<sup>c</sup><sub>2g</sub> =  $S_{\le cg}$ . Then there is a legal move from LightReq<sup>c</sup><sub>2g</sub>  $\cup$ BalloonReq<sup>c</sup><sub>2g</sub> to LightReq<sup>c</sup><sub>1</sub>  $\cup$  BalloonReq<sup>c</sup><sub>1</sub> =  $S_{\le cg+1} \cup \{cg+1\}$ . Thus, every step in P is reversible. Since the first half of each light phase pebbles exactly one set  $D_j$  per step and the second half takes exactly as many steps as the first half, it follows that  $\Pi_t(P) \le 4d_0$ . By the definition of LightReq, it follows that  $P_{|P|} = T$ . So, P is a legal reversible pebbling.

**Lemma 4.** For any  $(e_1, d_1)$ -depth reducible DAG G = (V = [N], E) of depth  $d_0$ , target set  $T' \subseteq [N]$ , and family of pebblings B(G', T', t') for all DAGs G' = (V', E'), target sets  $T' \subseteq V'$ , and  $t' \geq 2 \cdot \operatorname{depth}(G')$ ,

$$\begin{split} \Pi_{cc} \left( \mathsf{RRGenPeb}(G, d_0, \{(e_1, d_1, S_1)\}, B) \right) \\ &\leq 4d_0(\delta + 2)e_1 + 4d_0|T| + \frac{2e_1}{N} \cdot \max_{|T'| \leq \delta e_1} \Pi_{cc} \left( B \left( G - S, T', 2d_1 \right) \right) + \frac{2e_1}{N} \left( \frac{1}{N} - \frac{1}{N} \right) \left( \frac{1}{N} \right) \left( \frac{1}{N} -$$

where  $S_1$  is a depth-reducing set of size  $e_1$ .

*Proof.* During the  $c^{th}$  light phase, we have pebbles on at most S, T, parents $(I_c)$ , and  $I_c$ , so

$$\Pi_s(\mathsf{LightReq}) \leq e_1 + (\delta+1)g\frac{N}{d_0} + |T| \leq (\delta+2)e_1 + |T|$$

Thus, the contribution of all of the light phases to the CC of P is at most  $4d_0(\delta + 2)e_1 + 4d_0|T|$ . Next, the contribution to the CC of P of the balloon phases is at most

$$\frac{2d_0}{g} \cdot \max_{|T'| \le (\delta e_1)} \Pi_{cc} \left( B(G-S,T,2d_1) \right) \le \frac{2e_1}{N} \cdot \max_{|T'| \le \delta e_1} \Pi_{cc} \left( B\left(G-S,T',2d_1\right) \right) \le \frac{2e_1}{N} \cdot \max_{|T'| \le \delta e_1} \Pi_{cc} \left( B\left(G-S,T',2d_1\right) \right) \le \frac{2e_1}{N} \cdot \max_{|T'| \le \delta e_1} \Pi_{cc} \left( B\left(G-S,T',2d_1\right) \right) \le \frac{2e_1}{N} \cdot \max_{|T'| \le \delta e_1} \Pi_{cc} \left( B\left(G-S,T',2d_1\right) \right) \le \frac{2e_1}{N} \cdot \max_{|T'| \le \delta e_1} \Pi_{cc} \left( B\left(G-S,T',2d_1\right) \right) \le \frac{2e_1}{N} \cdot \max_{|T'| \le \delta e_1} \Pi_{cc} \left( B\left(G-S,T',2d_1\right) \right) \le \frac{2e_1}{N} \cdot \max_{|T'| \le \delta e_1} \Pi_{cc} \left( B\left(G-S,T',2d_1\right) \right) \le \frac{2e_1}{N} \cdot \max_{|T'| \le \delta e_1} \Pi_{cc} \left( B\left(G-S,T',2d_1\right) \right) \le \frac{2e_1}{N} \cdot \max_{|T'| \le \delta e_1} \Pi_{cc} \left( B\left(G-S,T',2d_1\right) \right)$$

Putting it all together we get

$$\Pi_{cc}(P) \le 4d_0(\delta+2)e_1 + 4d_0|T| + \frac{2e_1}{N} \cdot \max_{|T'| \le \delta e_1} \Pi_{cc} \left( B \left( G - S, T', 2d_1 \right) \right)$$

for  $1 \leq i \leq d_0$ .

## D Depth Robustness and Reversible CC

**Reminder of Theorem 10.** Let G = (V = [N], E) be a DAG such that  $(i, i + 1) \in E$  for all i < N and the graph  $G_{\mathsf{Trunc},d}$  is (e, d)-depth robust. Then  $\widetilde{\Pi}_{cc}^{\leftrightarrow,\parallel}(G) \ge e(2d - 1)$ .

Proof of Theorem 10. Let  $P_1, \ldots, P_t$  be a relaxed reversible pebbling of G. As before for each  $i \in [2d-1]$  we let  $B_i = P_i \cup P_{i+2d-1} \cup P_{i+2(2d-1)} \cup \ldots \cup P_{i+m(2d-1)}$  where m = m(i) is the largest integer such that  $i + m(2d-1) \leq t$ . As before we note that  $\sum_i |B_i| \leq \sum_j |P_j| = \widetilde{\Pi}_{cc}^{\leftrightarrow,\parallel}(G)$ . It follows that there exists some  $B \coloneqq B_i$  with  $|B| \leq \frac{\widetilde{\Pi}_{cc}^{\leftrightarrow,\parallel}(G)}{2d-1}$ .

Now we will show there is no path of length d in  $G_{\mathsf{Trunc},d} - B$ . Suppose, for contradiction, that there exists a node  $v \in [N - d] \setminus B$  such that  $\mathsf{depth}(v, G_{\mathsf{Trunc},d} - B) \ge d$ . Let p(v) be the first step in which node v is pebbled. Then we observe the following claims:

Claim 1.  $p(v) \leq t - d$ .

Proof of Claim 1. Since node  $N \in P_t$  which implies  $N - d \in P_{t-d}$  (otherwise it would not have been able to place a pebble on node N on round t), which is the last node in  $G_{\mathsf{Trunc},d}$ . Hence, v must have been pebbled some round on/before  $P_{t-d}$ .

Claim 2. p(v) > i + m(2d - 1).

Proof of Claim 2. Suppose not. Then there exists some j with  $j+1 \leq m$  such that i+j(2d-1) < p(v) < i + (j+1)(2d-1) (here,  $p(v) \neq i + j(2d-1)$  and  $p(v) \neq i + (j+1)(2d-1)$  since  $v \notin P_{i+j(2d-1)} \cup P_{i+(j+1)(2d-1)}$ ). Since depth $(v, G_{\mathsf{Trunc},d} - B) \geq d$ , it would take at least d steps to place a pebble on node v starting from  $P_{i+j(2d-1)}$  and then take at least d steps to remove this pebble before  $P_{i+(j+1)(2d-1)}$ . This is a contradiction since there are fewer than 2d intermediate rounds between  $P_{i+j(2d-1)}$  and  $P_{i+(j+1)(2d-1)}$ . Hence, we can conclude that p(v) > i + m(2d-1).

Hence, we have  $i + m(2d - 1) < p(v) \le t - d$ . Now by definition of m, we observe that

$$p(v) - (i + m(2d - 1)) \le t - d - (i + m(2d - 1))$$
  
=  $[t - (i + m(2d - 1))] - d$   
<  $(2d - 1) - d = d - 1$ ,

since *m* was the largest integer such that  $i + m(2d-1) \leq t$  which implies t < i + (m+1)(2d-1). This implies that there are less than d-1 rounds between  $P_{i+m(2d-1)}$  and  $P_{p(v)}$ . However, at time  $P_{i+m(2d-1)}$ , there is an unpebbled path of length  $\geq d$  ending at *v*, which means that it is impossible to place a pebble on *v* at time  $P_{p(v)}$ . Contradiction! (as we defined p(v) to be the first step in which node *v* is pebbled.) This contradiction was caused due to the assumption  $depth(v, G_{Trunc,d} - B) \geq d$ . Hence, we can conclude that there is no path of length *d* in  $G_{Trunc,d} - B$ , which implies that  $G_{Trunc,d}$  is (|B|, d)-reducible. Since  $G_{Trunc,d}$  is (e, d)-depth robust, we have  $|B| \geq e$ . Combining with  $|B| \leq \frac{\widetilde{\Pi}_{cc}^{\leftrightarrow,\parallel}(G)}{2d-1}$ , we can conclude that  $\widetilde{\Pi}_{cc}^{\leftrightarrow,\parallel}(G) \geq e(2d-1)$ .

Remark 1. We can make an improvement on the lower bound of the relaxed parallel reversible cumulative pebbling cost of DRSample by applying Theorem 10. Recall that DRSample [ABH17] is the first practical construction of a data-independent MHF, which is a graph G = (V = [N], E)that has the following edge distribution:  $E = \{(i, i + 1) : i \in [N - 1]\} \cup \{(r(v), v) : i \in [3, N]\},$ where r(v) is picked according to the following random process: (1) randomly select a bucket index  $i \leq \log v$ , and (2) randomly sample r(v) from the bucket  $B_i(v) = \{u : 2^{i-1} < v - u \leq 2^i\}.$ 

Let  $G^{\mathsf{DRS}} = (V^{\mathsf{DRS}} = [N], E^{\mathsf{DRS}})$  be a randomly sampled graph according to the DRS ample edge distribution. Then we know that (whp)  $G^{\mathsf{DRS}}$  is  $(c_1 N / \log N, c_2 N)$ -depth robust for some constant  $c_1, c_2 > 0$ , which implies that

$$\widetilde{\Pi}_{cc}^{\longleftrightarrow,\parallel}(G^{\mathsf{DRS}}) \ge \Pi_{cc}^{\parallel}(G^{\mathsf{DRS}}) \ge \frac{c_1 c_2 N^2}{\log N},$$

by the previous lower bound [ABP17].

Now we observe that, due to the way that DRSample's edge distribution is defined,  $G_{\text{Trunc},d}^{\text{DRS}}$  can simply be viewed as a randomly sampled DRSample graph with N - d nodes. Thus, (whp)  $G_{\text{Trunc},d}^{\text{DRS}}$  is  $(c_1(N-d)/\log(N-d), c_2(N-d))$ -depth robust. To apply Theorem 10, we would need the condition  $d = c_2(N-d)$ , which can be solved by setting  $d = c_2N/(1+c_2)$ . Then we have that  $G_{\text{Trunc},\frac{c_2N}{1+c_2}}^{\text{DRS}}$  is  $\left(\frac{c_1N}{(1+c_2)\log(N/(1+c_2))}, \frac{c_2N}{1+c_2}\right)$ -depth robust. Then by Theorem 10, we have

$$\begin{split} \widetilde{H}_{cc}^{\leftrightarrow,\parallel}(G^{\mathsf{DRS}}) &\geq \frac{c_1 N}{(1+c_2) \log(N/(1+c_2))} \left(\frac{2c_2 N}{1+c_2} - 1\right) \\ &\geq \frac{c_1 N}{(1+c_2) \log N} \left(\frac{2c_2 N}{1+c_2} - 1\right) \\ &= \frac{\alpha}{(1+c_2)^2} \cdot \frac{c_1 c_2 N^2}{\log N}, \end{split}$$

where  $\alpha = 2 - \frac{1+c_2}{c_2N}$ . We can observe that as long as we have  $\frac{\alpha}{(1+c_2)^2} > 1$ , this is an improvement from the classical lower bound which immediately carries over to the reversible case. Since we have  $c_2 = 0.03$  [ABP17], we can see that as long as  $N > 1.03/(0.03 \times (2 - 1.03^2)) \simeq 35.8$  we achieve an

improvement. In particular, if  $N \geq 1.03/(0.03 \times (2-t \cdot 1.03^2))$  then we can achieve an improvement by multiplicative factor of t, e.g., if  $N = 10^7$  then we can expect an improvement by multiplicative factor of t up to  $t \leq \left(2 - \frac{1.03}{0.03N}\right) \cdot 1.03^{-2} \approx 1.885$ . As  $N \to \infty$ , we have  $t \to 2/1.03^2 \approx 1.88519$ .
